Brief Contents

1 Nurse's Role in Care of the Child: Hospital, Community, and Home *1*

2 Family-Centered Care and Cultural Considerations 17

3 Genetic and Genomic Influences *45*

4 Growth and Development *66*

5 Pediatric Assessment *98*

6 Introduction to Health Promotion and Maintenance *144*

7 Health Promotion and Maintenance for the Newborn and Infant *154*

8 Health Promotion and Maintenance for the Toddler and Preschooler *166*

9 Health Promotion and Maintenance for the School-Age Child and Adolescent *182*

10 Nursing Considerations for the Child in the Community *207*

11 Nursing Considerations for the Hospitalized Child *222*

12 The Child With a Chronic Condition *246*

13 The Child With a Life-Threatening Condition and End-of-Life Care *260*

14 Infant, Child, and Adolescent Nutrition *281*

15 Pain Assessment and Management in Children *310*

16 Immunizations and Communicable Diseases *333*

17 Social and Environmental Influences on the Child *367*

18 Alterations in Fluid, Electrolyte, and Acid–Base Balance *404*

19 Alterations in Eye, Ear, Nose, and Throat Function *440*

20 Alterations in Respiratory Function *474*

21 Alterations in Cardiovascular Function *518*

22 Alterations in Immune Function *563*

23 Alterations in Hematologic Function *589*

24 The Child With Cancer *610*

25 Alterations in Gastrointestinal Function *655*

26 Alterations in Genitourinary Function *701*

27 Alterations in Neurologic Function *739*

28 Alterations in Mental Health and Cognitive Function *790*

29 Alterations in Musculoskeletal Function *821*

30 Alterations in Endocrine Function *861*

31 Alterations in Skin Integrity *900*

Appendix A Physical Growth Charts *942*

Appendix B Blood Pressure Tables *952*

Appendix C Dietary Reference Intakes *954*

Appendix D Selected Pediatric Laboratory Values *956*

Appendix E Diagnostic Tests and Procedures *959*

Appendix F Body Surface Area Nomogram *964*

Appendix G Conversions and Equivalents *965*

Glossary *966*

Index *978*

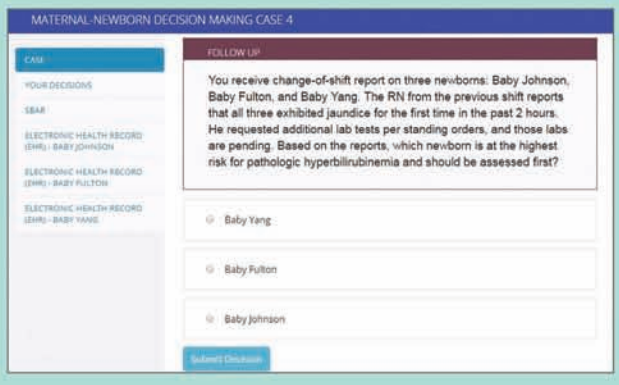
Help your students learn to **Think Like a Nurse** with **new digital learning resources** in Maternal and Pediatric Nursing!

MyNursingLab®

MyNursingLab's personalized learning path helps students master and retain course information more quickly so they can focus on higher-level decision-making skills.

NEW! Clinical Decision-Making Cases in MyNursingLab provide opportunities for students to practice analyzing information and making important decisions at key moments in patient care scenarios.

Learn more at mynursinglab.com



NEW! Maternity & Pediatric Nursing Reference App

The Maternity & Pediatric Nursing Reference App provides a collection of handy tools and additional content, previously only available in text format, for quick reference in the clinical setting. Students can now easily access this vital content in a useful mobile format wherever and whenever they need it! Now available for free on both the Apple App Store and Google Play.

Dedication

We dedicate this book to:

- Our families who are ever supportive and understanding about our passion for children and writing,
- Our mentors, colleagues, and students who inspire us to apply our knowledge and challenge our thinking,
- The children, adolescents, and families with whom we work and who foster our philosophy of pediatric nursing.

About the Authors

JANE W. BALL graduated from the Johns Hopkins Hospital School of Nursing and subsequently received a BS from the Johns Hopkins University. She began her nursing career working in the pediatric surgical inpatient, emergency department, and outpatient clinic of the Johns Hopkins Medical Center, first as a staff nurse and then as a pediatric nurse practitioner. After recognizing a need to focus on the health of children, she returned to school and obtained both a master's degree of public health and a doctorate of public health degree from the Johns Hopkins University Bloomberg School of Public Health with a focus on maternal and child health. After graduation, Dr. Ball became the chief of child health services for the Commonwealth of Pennsylvania Department of Health. In this capacity she oversaw the state-funded well-child clinics and explored ways to improve education for the state's community health nurses. After relocating to Texas, she joined the faculty at the University of Texas at Arlington School of Nursing to teach community pediatrics to registered nurses returning to school for a BSN. During this time Dr. Ball became involved in writing her first textbook, *Mosby's Guide to Physical Examination*, which is currently in its eighth edition. After relocating to the Washington, DC, area, she worked at Children's National Medical Center on a number of federally funded projects. The first project in 1986, teaching instructors of emergency medical technicians from all states about the special care children need during an emergency, revealed the shortcomings of the emergency medical services system for children. This exposure was a career-changing event. A textbook titled *Pediatric Emergencies: A Manual for Prehospital Providers* was subsequently developed. A second project led to the development of a pediatric emergency education program for nurses in emergency departments to promote improved care for children. Both of these programs served as a foundation for other pediatric emergency education developed and sponsored by national organizations. For 15 years Dr. Ball managed the federally funded Emergency Medical Services for Children's National Resource Center. As executive director, she provided and directed the provision of consultation and resource development for state health agencies, health professionals, families, and advocates about successful methods to improve the healthcare system so that children get optimal emergency care in all healthcare settings. After leaving that position, she continues to be engaged in many projects with a focus on the emergency care system. She is a consultant to the American College of Surgeons Committee on Trauma, supporting state trauma system development. She recently completed a federally funded project to study whether the implementation of a statewide pediatric emergency department recognition program improved pediatric emergency care. In 2010, Dr. Ball received the Distinguished Alumna Award from the Johns Hopkins University.

RUTH C. MCGILLIS BINDLER received her BSN from Cornell University—New York Hospital School of Nursing. She worked in oncology nursing at Memorial-Sloan Kettering Cancer Center in New York, and then as a public health nurse in Dane County, Wisconsin. Thus began her commitment to work with children as she visited children and their families at home and served as a school nurse. Due to this interest in child healthcare needs, she earned her MS in child development from the University of Wisconsin. A move to Washington State was accompanied by a new job as a faculty member at the Intercollegiate Center for Nursing Education in Spokane. Dr. Bindler was fortunate to be involved for over 38 years in the growth of this nursing education consortium, which is a combination of public and private universities and colleges and is now the Washington State University (WSU) College of Nursing. She obtained a PhD in human nutrition at WSU, where she taught theory and clinical courses in child health nursing, cultural diversity and health, graduate research, pharmacology, and assessment, and served as lead faculty for child health nursing. Dr. Bindler was the first director of the PhD in Nursing program at WSU and most recently served as Associate Dean for Graduate Programs, which include Master of Nursing, Post-Masters certificates, PhD, and Doctor of Nursing Practice (DNP) programs. She recently retired and serves the college and profession as a professor emeritus, continuing work with graduate students and research. Her first professional book, *Pediatric Medications*, was published in 1981, and she has continued to publish articles and books in the areas of pediatric medications and pediatric health. Research foci have been childhood obesity, type 2 diabetes, metabolic syndrome, and cardiometabolic risk factors in children. Ethnic diversity and interprofessional collaboration have been additional themes in her work. Dr. Bindler believes that her role as a faculty member and administrator enabled her to learn continually, foster the development of students in nursing, lead and mentor junior faculty into the teaching role, and participate fully in the profession of nursing. In addition to teaching, research, publication, and leadership, she enhances her life by professional and community service and by activities with her family.

KAY J. COWEN received her BSN from East Carolina University in Greenville, North Carolina, and began her career as a staff nurse on the pediatric unit of North Carolina Baptist Hospital in Winston-Salem. She developed a special interest in the psychosocial needs of hospitalized children and preparing them for hospitalization. This led to the focus of her master's thesis at the University of North Carolina at Greensboro (UNCG), where she received a master of science in nursing education degree with a focus in maternal child nursing.

Mrs. Cowen began her teaching career in 1984 at UNCG, where she continues today as clinical professor in the Parent Child Department. Her primary responsibilities include coordinating the pediatric nursing course, teaching classroom content, and supervising a clinical group of students. Mrs. Cowen shared her passion for the psychosocial care of children and the needs of their families through her first experience as an author in the chapter "Hospital Care for Children" in Jackson and Saunders' *Child Health Nursing: A Comprehensive Approach to the Care of Children and Their Families* published in 1993.

In the classroom, Mrs. Cowen realized that students learn through a variety of teaching strategies and became especially interested in the strategy of gaming. She led a research study to evaluate the effectiveness of gaming in the classroom and subsequently continues to incorporate gaming in her teaching. In the clinical setting, Mrs. Cowen teaches her students the skills needed to care for patients and the importance of family-centered care, focusing not only on the physical needs of the child but also on the psychosocial needs of the child and family. During her teaching career, Mrs. Cowen has continued to work part time as a staff nurse, first on the pediatric unit of Moses Cone Hospital in Greensboro and then at Brenner Children's Hospital in Winston-Salem. In 2006, she became the part-time pediatric nurse educator in Brenner's Family Resource Center. Through Mrs. Cowen's expertise, she is able to extend her love of teaching to children and families, and through her role as an author, she is able to extend her dedication to pediatric nursing and nursing education.

MICHELE R. SHAW received her BSN from Pacific Lutheran University in Tacoma, Washington. She began her career as a nurse at a long-term care facility and then as a home healthcare nurse in Spokane, Washington. While making home visits, she became interested in the nursing care needs of children and families. She realized the importance of educating the family about their child's condition and to include family members while planning and carrying out the nursing care plan. This interest in family nursing led her into the area of maternal-child nursing, where she served as a postpartum nurse for nearly 18 years. Her experience with providing nursing care to families in various settings has highlighted her belief in the need of a family-centered approach in order to provide optimal nursing care.
Dr. Shaw began her teaching career as a teaching assistant in 2001 at the Washington State University (WSU) College of Nursing, where she continues today as an associate professor. It was during those early years as a teaching assistant that she began to realize her passion for educating nursing students. This interest led to her completing a master's degree in nursing with an emphasis on education at WSU. Knowing that she wanted to continue working in nursing academia, Dr. Shaw went on to receive her PhD in nursing from the University of Arizona in Tucson. She has taught theory, seminar, and clinical courses in maternal-child nursing, family health, evidence-based practice, ethical decision making, physical assessment, and professional practice. Dr. Shaw recently assisted in the development of the Bachelor of Science-to-PhD in Nursing program at WSU. This fast-track program will enable students with an earned bachelor's degree to complete a PhD in nursing in four years.

Dr. Shaw enjoys working with undergraduate and graduate students and encourages active participation in research. Her research interests include children with asthma and their families, childbearing women and their families, and substance use among youth and childbearing women. She is particularly interested in children's and families' unique perspectives, and thus much of her research uses qualitative approaches. She continues to publish articles in the areas of pediatric asthma and substance use among childbearing women. Dr. Shaw believes her active role in nursing academia and research allows her to stay current in various pedagogical approaches to enhance nursing students' learning experiences, as well as continuous learning about evidence-based interventions to provide nursing care to children and families.

Thank You!

We are forever grateful to nurse geneticist Linda D. Ward, PhD, APRN, the author of this book's genetics chapter, Chapter 3, "Genetic and Genomic Influences." We appreciate her expertise in genetic and genomic science, her superb writing skills, and her willingness to contribute such an essential chapter to our text. We are also thankful to Brenda Senger, RN, PhD, for contributing the content on mitochondrial diseases in Chapter 30.

We are grateful to all the nurses, both clinicians and educators, who reviewed the manuscript of this text. Their insights, suggestions, and eye for detail helped us prepare a more relevant, useful, and current book, reflective of the present time and of the essential components of learning in the field of child health nursing.

Preface

Health care and healthcare delivery systems are changing dramatically. The Affordable Care Act, a focus on interprofessional collaboration, an emphasis on patient safety, and evidence-based practice will contribute to ongoing challenges and evolution in health care in the coming years. Pediatric nurses must respond to and integrate these changes into their practice. In addition, pediatric nursing presents its own unique challenges for practitioners of health care. Student nurses must learn what helps them to provide safe, effective, and excellent care today, while integrating new knowledge and skills needed as nursing practice continues to develop and respond to healthcare needs. Students must learn how to think and apply information as new knowledge becomes available. "As the student uses knowledge in situations of practice, new understanding is gained as well as knowing how, when, and why it is relevant in particular situations. . . . We call this teaching for a sense of salience."*

Faculty are responsible for selecting patient care assignments that assist the student in applying knowledge in the clinical setting, as well as utilizing various pedagogies to assist the student in focusing on the patient experience. We have integrated concepts from the Carnegie Report that foster clinical expertise by offering a variety of critical thinking and clinical reasoning questions, patient care scenarios, and research and evidence-based practice features. Information technology plays a major role in both health care and teaching, and therefore features in this text encourage the student to use and analyze content available through information technology.

Preparation for Nursing Excellence

The goal of this seventh edition of *Principles of Pediatric Nursing* is to provide core pediatric nursing knowledge that prepares students for excellence in nursing and to offer the tools of scholarship and critical thinking needed to apply this learning in the future. Students must learn to question, evaluate the research evidence available, apply pertinent information in clinical settings, and constantly adapt to growing knowledge and an evolving healthcare system.

This text reflects a multitude of approaches to learning that can be helpful to all students. We acknowledge that many students learn pediatric nursing in a very short time period. Therefore, the approaches in this text are designed to assist students to assess the child's needs, take into account population-based practice, and make care decisions based on the standards of pediatric nursing practice.

Realities of Pediatric Nursing

Pediatric nursing occurs in many acute care and community healthcare settings, such as hospitals, homes, schools, and health centers. Procedures may be performed in short-stay units, and long-term care is often provided at home for children with complex health conditions. Families are often the providers of care as well as the case managers for these children. Technologic advances are resulting in earlier diagnoses and new therapies; these technologic approaches are integrated whenever pertinent throughout the text.

Pediatric nursing care is provided within the context of a rapidly changing society. An examination of the major morbidities and mortalities of childhood guided the revision of material and topics throughout the text. Specific chapters focus on the family, health promotion across the life span, pediatric nutrition, and care for children with chronic conditions. Chapter 2 addresses cultural influences on health care and provides guidance for students caring for children in our growing intercultural society. Chapter 3, on genetics and genomics, is intended to help students recognize the impact of such knowledge on pediatric nursing and apply these concepts when working with families. Current social and environmental challenges for children have guided the further development of Chapter 17, which covers societal and environmental influences on child health.

Many graduating nurses practice in acute care facilities; this text continues to emphasize the information necessary to prepare students for working in hospitals. In addition, the information provided here will enable graduates to assume positions in ambulatory care facilities, home health nursing, schools, and a variety of other settings. Effective communication methods, principles of working with families, and knowledge of pathophysiologic, psychologic, developmental, and environmental factors found in these chapters can all be applied in a wide variety of settings. The importance of interprofessional care is recognized; therefore, collaboration and communication with various health professionals is emphasized.

Another major evolution involves access to information and reliance on the Internet. Nurses must learn to obtain information and then analyze and judge the quality of information they find. Increasingly, nurses need experience with information technology and management. Nurses must also advise children and family members to use the Internet wisely to help them in making healthcare choices. This text will assist the student in making practice decisions based on scholarship and evidence-based research.

Organization and Integrated Themes

We have organized *Principles of Pediatric Nursing: Caring for Children*, Seventh Edition, to present important information on growth and development, family-centered care, culture, genetics, physical assessment, health promotion, nutrition, health issues in today's world, and children's responses to illness and injury. This information is needed to care for children in the many healthcare settings where pediatric nursing care is provided. Following the foundational chapters, this book is

*Benner, P., Sutphen, M., Leonard, V., & Day, L. (2010). *Educating nurses: A call for radical transformation* (p. 94). San Francisco, CA: Jossey-Bass.

organized by body systems to facilitate the student's ability to locate information, focus studying, and prepare for clinical experiences with children and families. The organizational framework also eliminates redundancy, so that the student uses time efficiently. **Learning Outcomes** begin the chapter, and **Chapter Highlights** end the chapter.

The **Bindler-Ball Child Healthcare Model** is used to illustrate the important core value that all children need health promotion and health maintenance interventions, no matter where they seek health care or what health conditions they may be experiencing.

The nursing process is used as the framework for nursing care. **Nursing Management** is the major heading, with subheadings of **Nursing Assessment and Diagnosis, Planning and Implementation,** and **Evaluation**. When it is appropriate to focus on care in a specific setting, Hospital-Based Care, Discharge Planning, and Community Care are separated into sections. We feature nursing care plans throughout the text to help students approach care from the nursing process perspective. Some have an acute care hospitalization focus, whereas others have a community-based focus. **Nursing Care Plans** include nursing diagnoses, goals, interventions, and rationales.

Several major concepts are integrated throughout the text to encourage the student to think creatively and critically about nursing care. These major themes are interwoven throughout the text through the many features and supplements, including:

- *Nursing care* is the critical and central core of this text. Nursing assessment and management are emphasized in all sections of the book, with examples of nurses providing care in a number of different settings. Nurses apply a variety of guidelines related to the profession and to health conditions. The new feature, **Professionalism in Practice**, relates guidelines important to nursing care.
- *Collaborative care* descriptions of the diagnostic and therapeutic care for various health conditions reflect the interprofessional team role of nurses with other healthcare professionals (e.g., physicians, physical therapists, mental health counselors, pharmacists, and others) as described in *The Essentials of Baccalaureate Education for Professional Nursing Practice* (American Association of Colleges of Nursing, 2008).
- *Clinical reasoning and problem-solving principles* are integrated in the organization, pedagogy, and writing style. Examples include the evidence-based practice features, clinical reasoning boxes, the end-of-chapter **Clinical Reasoning in Action** feature, and art captions. Students practice clinical reasoning and critical thinking in their everyday lives, but they need help to apply these concepts to the practice of nursing. This text and the accompanying learning materials help students understand how their normal curiosity and problem-solving ability can be applied to pediatric nursing.
- *Communication* is one of the most important skills that students need to learn. Effective communication with children is challenging because they communicate differently, according to their developmental levels. Family members have communication needs in addition to those of their children. Effective communication with a variety of healthcare providers is essential for effective care. This book integrates communication skills by applied examples that help the student communicate effectively with children, their families, and other health professionals.
- *Patient safety* is emphasized in nursing management sections and in the **Safety Alert!** boxes.
- *Family and patient education* about health care is an integral part of the pediatric nurse's responsibilities. Because hospitalizations are often brief, leaving families increasingly responsible for caring for recuperating children at home, information about healthcare needs and procedures has become even more important. The **Families Want to Know** feature describes teaching strategies and content for various patient conditions.
- *Developing cultural competence* is critical for all nurses in the increasingly diverse community of today's world. Students have met people from different ethnic and cultural groups, but they need help to understand, respect, and integrate differing beliefs, practices, and healthcare needs when providing care.
- *Growth and development considerations and physical assessment* are central to the effective practice of pediatric nursing. A separate chapter is devoted to each area (Chapters 4 and 5, respectively). In addition, both topics are integrated where appropriate in narrative, growth and development boxes, figures, and captions.
- *Health promotion* is an important focus of nursing care for children with acute and chronic health conditions. Four chapters focus on health promotion. One provides an overview of concepts related to health promotion; the other three address health promotion principles for children of different ages. In addition, a **Health Promotion** feature helps illustrate opportunities for maintaining and improving the health of children with certain health conditions.
- *Community care* is an increasing part of nursing responsibilities. To assist students in transferring knowledge to caring for children in community settings, information is provided in the nursing management sections of chapters. In addition, an entire chapter is devoted to nursing care in the community and directly addresses the nurse's roles in several community settings.

These themes and others are interwoven in the narrative of most chapters and are reflected in the art as well as in the supplements that students can use to augment their learning.

Resources for Student Success

- **Online Resources** are available at www.pearsonhighered.com/nursingresources and aim to further enhance the student's learning experience, build on knowledge gained from this textbook, prepare students for the NCLEX-RN® examination, and foster clinical reasoning.
- The ***Clinical Skills Manual for Maternity and Pediatric Nursing***, ISBN 0134257006, is a useful resource to assist students in successful planning and performance of essential nursing skills. This manual helps translate theoretic concepts into performance while caring for health clients in a variety of settings.
- **NEW! Pearson's *Maternity and Pediatric Nursing Reference App***, now available for both iPhone and Android devices, provides a collection of handy tools and additional content for students and professionals looking for a quick reference in maternity or pediatrics nursing. The pediatric content provided in the **Guidance for Children and Families** section includes insight

into the issues related to health maintenance, development, and family that may present from birth to adolescence.

- **MyNursingLab for Pediatric Nursing** is designed to engage students with pediatric content while offering data-driven guidance that helps them better absorb course material and understand difficult concepts. The Pearson eText version of *Principles of Pediatric Nursing*, Seventh Edition, is available with MyNursingLab for Pediatric Nursing.

Resources for Faculty Success

Pearson is pleased to offer a complete suite of resources to support teaching and learning, including:

- **TestGen Test Bank**
- **Lecture Note PowerPoints**
- **Classroom Response System PowerPoints**
- **Instructor's Resource Manual**

Acknowledgments

It is both exciting and challenging to have the opportunity to write a textbook and to keep it updated with each revision. It is inspiring to observe the evolution of pediatric nursing practice and to encourage nursing students to share the excitement and enthusiasm we feel for working with children and their families. Although each edition carries its own unique set of challenges and circumstances, it continues to be a privilege to contribute to the education of the new generation of student nurses.

This seventh edition integrates new features and digital approaches developed in collaboration with Pearson Nursing. Erin Rafferty, content producer at Pearson, has been responsive and receptive, as well as an effective collaborator with us in this new edition. We are grateful for the support of our portfolio manager at Pearson, Katrin Beacom. The vice president and publisher, Julie Alexander, enthusiastically supported this venture and has supported us in decisions regarding changes, updates, and features for the text.

For this edition, we have been blessed to have Mary Cook as a development editor. Mary challenged us creatively, ensured consistency, and kept us on track. She has been supportive, innovative, and composed during the long months of hard work.

We are grateful to the families and many healthcare facilities that have permitted us to capture the images used in photographs throughout the book. George Dodson provided us with much of the photography to help illustrate current nursing concepts.

We also gratefully acknowledge the contributions of Linda Ward, a nurse leader who authored Chapter 3, "Genetic and Genomic Influences," and Brenda Senger, who contributed the mitochondrial disease content in Chapter 30.

Our thanks also go to Mary Siener, art director, for guiding all aspects of the design for this edition. At SPi Global, it has been a pleasure to work with Patty Donovan, who coordinated production.

A special thank you goes to Katie m. Berggren, who gave permission to use her painting *A Day In May* for the cover of this edition. This work and others can be viewed at www.Km-Berggren.com.

Finally, our families once again have supported us tirelessly through the revision process. They sacrificed by allowing us to work on the book when we could have been with them. Yet, they show others the book with pride. We could not have accomplished this without their love and patience.

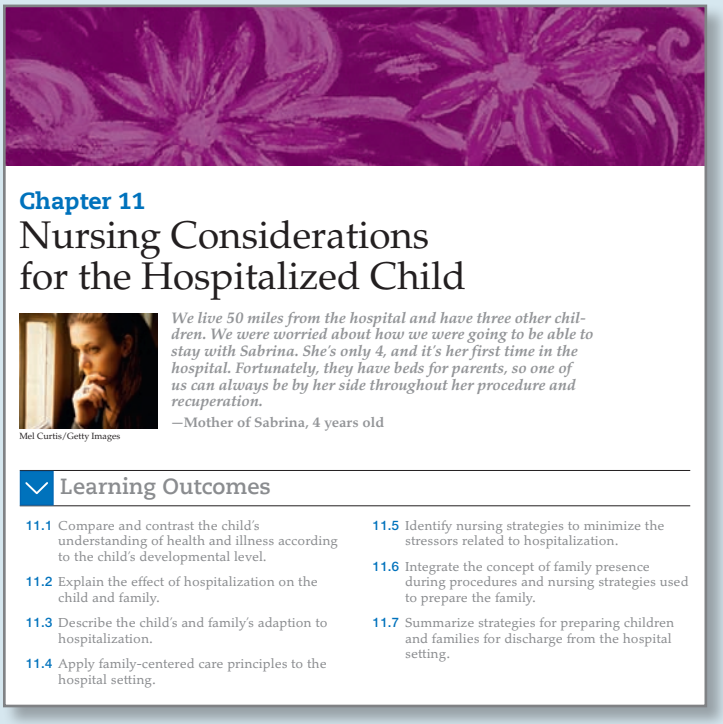
Features to Help You Use This Textbook Successfully

Instructors and students alike value the in-text learning aids that we include in our textbooks. The following guide will help you use the features and resources from *Principles of Pediatric Nursing*, Seventh Edition, to be successful in the classroom, in the clinical setting, on the NCLEX-RN® examination, and in nursing practice.

Each chapter begins with **Learning Outcomes** and a chapter-opening **Quote**. These personal stories illustrate the diversity of cultures, parental concerns, and family situations that nurses will encounter throughout the course of their careers. A **Focus On** section appears at the beginning of each systems chapter as a reference to use while reading the chapter. Each Focus On section includes the following:

- **Anatomy and Physiology** provides a quick review of the body system.
- **Pediatric Differences** will help you recognize physiologic and mental differences in children at various ages.
- **Diagnostic Tests and Laboratory Procedures** offer information related to the specific body system to assist in clinical application.
- **Assessment Guides** assist with diagnoses by incorporating physical assessment and normal findings, alterations and possible causes, and guidelines for nursing interventions.



Chapter 11

Nursing Considerations for the Hospitalized Child

Mel Curtis/Getty Images

We live 50 miles from the hospital and have three other children. We were worried about how we were going to be able to stay with Sabrina. She's only 4, and it's her first time in the hospital. Fortunately, they have beds for parents, so one of us can always be by her side throughout her procedure and recuperation.

—Mother of Sabrina, 4 years old

Learning Outcomes

11.1 Compare and contrast the child's understanding of health and illness according to the child's developmental level.

11.2 Explain the effect of hospitalization on the child and family.

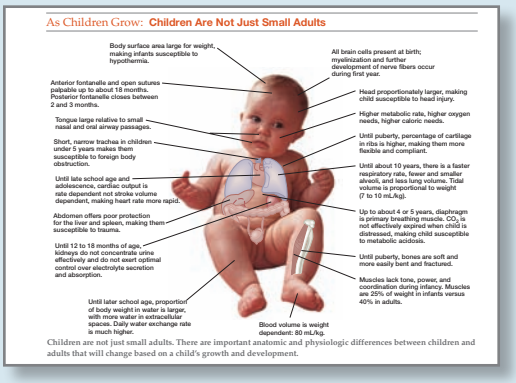
11.3 Describe the child's and family's adaption to hospitalization.

11.4 Apply family-centered care principles to the hospital setting.

11.5 Identify nursing strategies to minimize the stressors related to hospitalization.

11.6 Integrate the concept of family presence during procedures and nursing strategies used to prepare the family.

11.7 Summarize strategies for preparing children and families for discharge from the hospital setting.



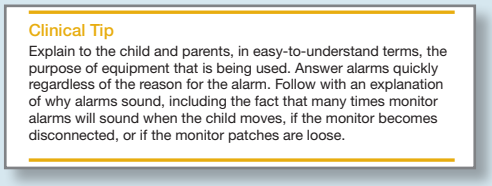
Children are not just small adults. There are important anatomic and physiologic differences between children and adults that will change based on a child's growth and development.

As Children Grow boxes illustrate the anatomic and physiologic differences between children and adults. These features illustrate how the child progresses through developmental stages and the important ways in which a child's development influences healthcare needs.

Clinical Reasoning Health Promotion

The pediatric nurse should apply concepts of health promotion and maintenance in all healthcare settings. If the child is seen in an emergency room for treatment of a fracture, what questions should the nurse ask about immunization status and safety issues? If the nurse sees a child with a chronic disorder of cerebral palsy in the outpatient clinic at an orthopedic hospital, what health promotion and health maintenance services should be integrated?

Clinical Reasoning boxes provide brief case scenarios that ask students to determine the appropriate response.

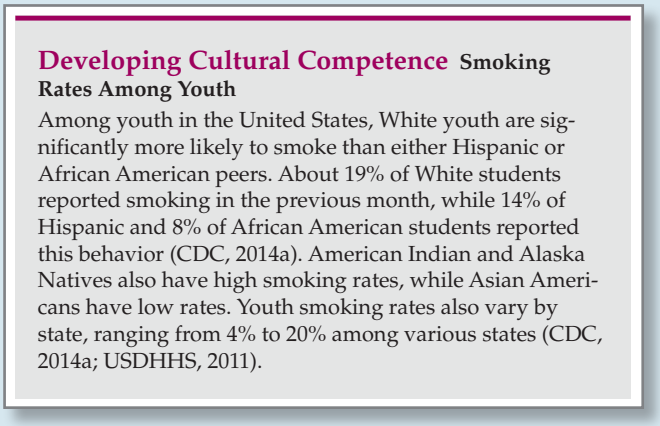


Clinical Tip

Explain to the child and parents, in easy-to-understand terms, the purpose of equipment that is being used. Answer alarms quickly regardless of the reason for the alarm. Follow with an explanation of why alarms sound, including the fact that many times monitor alarms will sound when the child moves, if the monitor becomes disconnected, or if the monitor patches are loose.

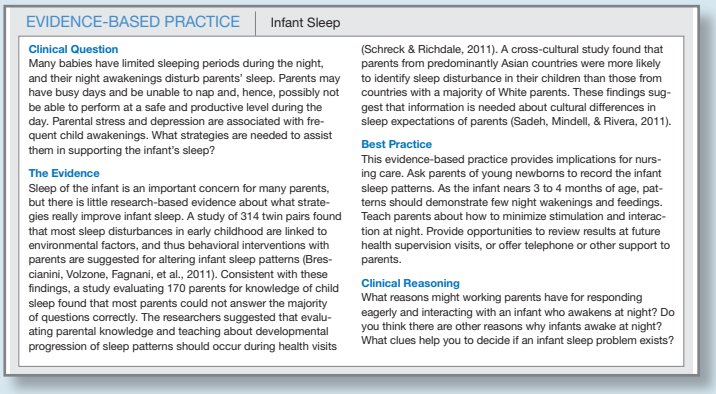
Clinical Tip features offer hands-on suggestions and clinical advice. These are placed at locations in the text that will help students apply them. They include topics such as legal and ethical considerations, nursing alerts, and home and community care considerations.

Developing Cultural Competence boxes highlight specific cultural issues and their application to nursing care.



Developing Cultural Competence Smoking Rates Among Youth

Among youth in the United States, White youth are significantly more likely to smoke than either Hispanic or African American peers. About 19% of White students reported smoking in the previous month, while 14% of Hispanic and 8% of African American students reported this behavior (CDC, 2014a). American Indian and Alaska Natives also have high smoking rates, while Asian Americans have low rates. Youth smoking rates also vary by state, ranging from 4% to 20% among various states (CDC, 2014a; USDHHS, 2011).



EVIDENCE-BASED PRACTICE | Infant Sleep

Clinical Question

Many babies have limited sleeping periods during the night, and their night awakenings disturb parents' sleep. Parents may have busy days and be unable to nap and, hence, possibly not be able to perform at a safe and productive level during the day. Parental stress and depression are associated with frequent child awakenings. What strategies are needed to assist them in supporting the infant's sleep?

The Evidence

Sleep of the infant is an important concern for many parents, but there is little research-based evidence about what strategies really improve infant sleep. A study of 314 twin pairs found that most sleep disturbances in early childhood are linked to environmental factors, and thus behavioral interventions with parents are suggested for altering infant sleep patterns (Brescianini, Volzone, Fagnani, et al., 2011). Consistent with these findings, a study evaluating 170 parents for knowledge of child sleep found that most parents could not answer the majority of questions correctly. The researchers suggested that evaluating parental knowledge and teaching about developmental progression of sleep patterns should occur during health visits (Schreck & Richdale, 2011). A cross-cultural study found that parents from predominantly Asian countries were more likely to identify sleep disturbance in their children than those from countries with a majority of White parents. These findings suggest that information is needed about cultural differences in sleep expectations of parents (Sadeh, Mindell, & Rivera, 2011).

Best Practice

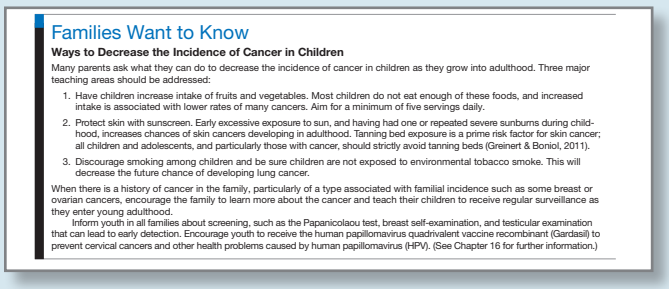
This evidence-based practice provides implications for nursing care. Ask parents of young newborns to record the infant sleep patterns. As the infant nears 3 to 4 months of age, patterns should demonstrate few night wakenings and feedings. Teach parents about how to minimize stimulation and interaction at night. Provide opportunities to review results at future health supervision visits, or offer telephone or other support to parents.

Clinical Reasoning

What reasons might working parents have for responding eagerly and interacting with an infant who awakens at night? Do you think there are other reasons why infants awake at night? What clues help you to decide if an infant sleep problem exists?

Evidence-Based Practice boxes present recent nursing research, discuss implications, and challenge students to incorporate this information into nursing practice through nursing actions.

Families Want to Know features present special healthcare issues or problems and the related key teaching points to address with the family.



Families Want to Know

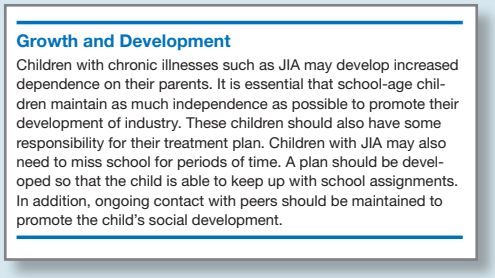
Ways to Decrease the Incidence of Cancer in Children

Many parents ask what they can do to decrease the incidence of cancer in children as they grow into adulthood. Three major teaching areas should be addressed:

1. Have children increase intake of fruits and vegetables. Most children do not eat enough of these foods, and increased intake is associated with lower rates of many cancers. Aim for a minimum of five servings daily.
2. Protect skin with sunscreen. Early excessive exposure to sun, and having had one or repeated severe sunburns during childhood, increases chances of skin cancers developing in adulthood. Tanning bed exposure is a prime risk factor for skin cancer; all children and adolescents, and particularly those with cancer, should strictly avoid tanning beds (Greinert & Boniol, 2011).
3. Discourage smoking among children and be sure children are not exposed to environmental tobacco smoke. This will decrease the future chance of developing lung cancer.

When there is a history of cancer in the family, particularly of a type associated with familial incidence such as some breast or ovarian cancers, encourage the family to learn more about the cancer and teach their children to receive regular surveillance as they enter young adulthood.

Inform youth in all families about screening, such as the Papanicolaou test, breast self-examination, and testicular examination that can lead to early detection. Encourage youth to receive the human papillomavirus quadrivalent vaccine recombinant (Gardasil) to prevent cervical cancers and other health problems caused by human papillomavirus (HPV). (See Chapter 16 for further information.)



Growth and Development

Children with chronic illnesses such as JIA may develop increased dependence on their parents. It is essential that school-age children maintain as much independence as possible to promote their development of industry. These children should also have some responsibility for their treatment plan. Children with JIA may also need to miss school for periods of time. A plan should be developed so that the child is able to keep up with school assignments. In addition, ongoing contact with peers should be maintained to promote the child's social development.

Growth and Development boxes provide information about the different responses of children at various ages to health conditions.

Healthy People 2020

(MICH-30.1) Increase the proportion of children who have access to a medical home

- While 57.5% of children under age 18 years had an established medical home in 2007, the objective of 63.3% of children with such access is the present goal (U.S. Department of Health and Human Services, 2011).

Healthy People 2020 goals are cited throughout the text to acquaint students with national public health efforts and to assist them in making connections between care of individual families and broad-based community health care and public policy. The coding in front of each objective identifies the specific chapter—for example, "Maternal, Infant, and Child Health" (MICH); "Adolescent Health" (AH); and "Injury and Violence Prevention" (IVP)—and number for the initiative. See the *Healthy People 2020* website to find the chapter abbreviations for all objectives listed in our text.

A feature titled **Health Promotion** summarizes the needs of children with specific chronic conditions, such as asthma or diabetes. These overviews teach students that children with chronic conditions, like all children, have health maintenance and promotion needs that require prevention and education to maximize potential.

Health Promotion **The Child With Bronchopulmonary Dysplasia**

Health Supervision

- Assess blood pressure to detect abnormal findings associated with pulmonary hypertension.
- Coordinate vision screening by an ophthalmologist every 2 to 3 months during the first year of life. Myopia and strabismus are common in children who were born prematurely.
- Coordinate pulmonary function tests annually or as needed for clinical condition.
- Perform hearing and other screening tests as recommended for age.

Growth and Developmental Surveillance

- Assess growth and plot measurements on a growth chart corrected for gestational age. Even if length and weight are lower than normal, monitor for continued growth following the growth curves.
- Perform a developmental assessment, correcting for gestational age.

Nutrition

- Review caloric intake. Ensure that increased calories are provided to support growth. Assess feeding difficulties related to oral motor function associated with long-term enteral feeding. Refer to a nutritionist as necessary.

Physical Activity

- Organize care to provide rest periods during the day.
- Give parents ideas for promoting the infant's motor development, such as reaching for and moving toward toys and objects of interest.

Family Interactions

- Identify ways to coordinate nighttime care to reduce child and family sleep disturbances.
- Provide discipline appropriate for developmental age.

Disease Prevention Strategies

- Reduce exposure to infections. Encourage selection of a childcare provider who cares for a small number of children, if one is used. If possible, avoid the use of childcare centers during respiratory syncytial virus (RSV) season.
- Immunize the child with the routine vaccine schedule based on chronologic age.
- Administer the 23-valent pneumococcal vaccine at 2 years of age.
- Provide monthly injections of palivizumab throughout the RSV season.

Condition-Specific Guidance

- Develop an emergency care plan for times when the infant's condition rapidly worsens.

Medications Used for Infective Endocarditis: Prophylaxis for Dental and Invasive Respiratory Procedures

ANTIBIOTIC RECOMMENDATIONS	NURSING MANAGEMENT
Amoxicillin for oral use Ampicillin for IM or IV use If allergic to penicillin: Cephalexin Clindamycin Azithromycin Clarithromycin	• Give 1 large dose 30–60 min before procedures, or up to 2 hr after the procedure if preprocedure dose is missed. • Teach parents and the child to keep at least 1 dose in the home for dental visits or emergencies. • Have parents inform each healthcare provider of the child's need for prophylaxis.

A., Shrestha, N. K., & Menon, V. (2013). Contemporary drug treatment of infective endocarditis. *American Journal of Cardiovascular Drugs, 13*, 251–258; Park, M. K. (2014). *Pediatric cardiology for practitioners* (6th ed., p. 349). Philadelphia: Elsevier Saunders.

A **Medications Used to Treat** feature in tabular format provides an overview of the types of medications that can be used for a specific condition and nursing considerations associated with their use.

Nursing Care Plan: The Child With a Visual Impairment Secondary to Retinopathy of Prematurity

1. Nursing Diagnosis: *Communication, Readiness for Enhanced,* related to altered reception, transmission, and integration resulting of visual images (NANDA-I © 2014)

GOAL: The child will receive adequate sensory input.

INTERVENTION	RATIONALE
• Provide kinesthetic, tactile, and auditory stimulation during play and in daily care (e.g., talking and playing). Provide music while bathing an infant, using bells and other noises on each side of infant. Verbally describe to a child all actions being carried out by adult.	• Because visual sensory input is not present, the child needs input from all other senses to compensate and provide adequate sensory stimulation.

EXPECTED OUTCOME: Child will demonstrate minimal signs of sensory deprivation.

2. Nursing Diagnosis: *Injury, Risk for,* related to impaired vision (NANDA-I © 2014)

GOAL: The child will be protected from safety hazards that can lead to injury.

INTERVENTION	RATIONALE
• Evaluate environment for potential safety hazards based on age of child and degree of impairment. Be particularly alert to objects that give visual cues to their dangers (e.g., stairs, stoves, fireplaces, candles). Eliminate safety hazards and protect the child from exposure. Take the child on a tour of new rooms, explaining safety hazards (e.g., schools, hotel room, hospital room).	• The child may be at risk for injury related both to developmental stage and to inability to visualize hazards.

EXPECTED OUTCOME: Child will experience no injuries.

3. Nursing Diagnosis: *Development: Delayed, Risk for,* related to impaired vision (NANDA-I © 2014)

GOAL: The child has experiences necessary to foster normal growth and development.

INTERVENTION	RATIONALE
• Help parents plan early, regular social activities with other children.	• The child with a visual impairment benefits developmentally from contact with other children.
• Provide opportunities and encourage self-feeding activities.	• To obtain adequate nutrients, the child needs to feel comfortable feeding self.
• Provide an environment rich in sensory input.	• Sensory input is needed for normal development to occur.
• Assess growth and development during regular examinations to identify the child's strengths and needs.	• Regular examinations aid in early identification of growth problems or developmental delays, so that appropriate interventions can be planned.

EXPECTED OUTCOME: Child will demonstrate normal growth and development milestones.

4. Nursing Diagnosis: *Family Processes, Interrupted,* related to child's prolonged disability from sensory impairment (NANDA-I © 2014)

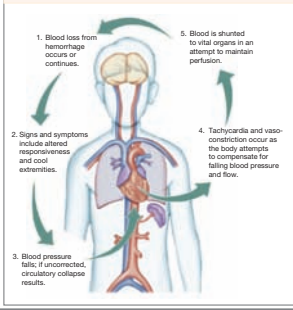
GOAL: The family will identify methods for coping with their child with a visual impairment.

INTERVENTION	RATIONALE
• Provide explanation of visual impairment as appropriate.	• The parents may feel guilt about the child's visual impairment, which can be allayed by knowledge of the cause.
• Refer parents to organizations, early intervention programs, and other parents of children with visual impairments.	• The parents will receive needed information and support from others.
• Assist parents to plan for meeting the developmental, educational, and safety needs of their child with a visual impairment. Offer resources for changing home environment to assist child.	• The child may require an enhanced environment in order to foster developmental progress.

EXPECTED OUTCOME: Family will successfully cope with the experience of having a child with a visual impairment.

Nursing Care Plans are also provided. They address health conditions and illustrate the conceptual approach that nurses need in caring for children, including assessment, NANDA nursing diagnoses, goals, plans, and interventions.

Pathophysiology Illustrated: **Hypovolemic Shock**



If hemorrhage reduces the circulating blood volume, the body compensates by increasing the heart rate and constricting the peripheral blood vessels. This allows the remaining blood to be circulated to the vital organs. When blood loss exceeds 20% to 25%, the child's body can no longer compensate; blood pressure falls, and circulatory collapse is imminent.

Pathophysiology Illustrated boxes feature unique drawings that illustrate conditions on a cellular or organ level, and may also portray the step-by-step process of a disease. These images visually explain the pathophysiology of certain conditions to increase students' understanding of the condition and its treatment.

Professionalism in Practice Accommodations for Children With JIA

Section 504 of the Rehabilitation Act of 1973 and the Individuals with Disabilities Education Act (IDEA) protect children with disabilities from discrimination. A formal plan such as an individualized education plan (IEP) should be developed for the child with arthritis that outlines accommodations and modifications that are needed at school (Solomon, 2014). The school nurse can work with the family and school administration to determine the plan. Accommodations at school may include providing a set of books for the home so that the child is not required to carry the books home daily. Additional time may be required for the child to move from class to class. The school nurse can refer parents and children to the Arthritis Foundation and the American Juvenile Arthritis Organization for further information and support. The adolescent should also be referred for vocational counseling and offered support for transition to adult services.

Professionalism in Practice boxes focus on important topics related to contemporary nursing practice issues, including legal and ethical considerations. This feature reflects a commitment to quality improvement in all aspects of care.

SAFETY ALERT!

If you feel a mass during palpation of a child's abdomen, stop palpating immediately and report the finding to the child's primary healthcare provider. Never palpate the liver or abdomen of a child with Wilms tumor as this could cause a piece of the tumor to dislodge. Place a sign on the child's bed and in the chart alerting healthcare providers not to palpate the abdomen.

The **SAFETY ALERT!** features present essential information that calls attention to issues that could place a patient or a nurse at risk and provide guidance on maintaining a safe environment for all patients and healthcare providers.

Each chapter ends with **Chapter Highlights** that outline the main points of the chapter and a list of **References** from which students can locate additional resources. In addition, the **Clinical Reasoning in Action** features at the end of each chapter propose a real-life scenario and a series of clinical reasoning questions so that you can apply to the clinical setting what you learned in class.

Where relevant, SKILLS found in the companion book, *Clinical Skills Manual for Maternity and Pediatric Nursing*, Fifth Edition, are cited.

Chapter Highlights

- The hypothalamic-pituitary axis produces several releasing and inhibiting hormones that regulate the function of many endocrine glands.
- Puberty is the process of sexual maturation that occurs when the gonads secrete increased amounts of the sex hormones estrogen and testosterone, resulting in the development of primary and secondary sexual characteristics.
- Children with hypopituitarism have short stature as a result of growth hormone deficiency. Treatment with growth hormone early in life enables these children to potentially attain genetically appropriate heights.
- An excessive secretion of growth hormone or hyperpituitarism may cause children to have tall stature, growing up to 7 or 8 feet in height if no intervention is provided before the epiphyseal plates close.
- Diabetes insipidus is a disorder of the posterior pituitary gland and is defined as an inability of the kidneys to concentrate urine.
- Syndrome of inappropriate antidiuretic hormone (SIADH) results from an excessive amount of serum antidiuretic hormone (ADH), leading to water intoxication and hyponatremia.
- Precocious puberty is defined as the appearance of any secondary sexual characteristics before 8 years in girls and 9 years in boys. If no treatment is provided, the hormones will stimulate closure of the epiphyseal plates and the child will have short stature as an adult.
- Untreated or ineffectively treated congenital hypothyroidism results in impaired growth and intellectual disability.
- Signs of hyperthyroidism include an enlarged, nontender thyroid gland (goiter), prominent or bulging eyes , eyelid lag, tachycardia, nervousness, increased appetite with weight loss, emotional lability, moodiness, heat intolerance, hypertension, hyperactivity, irregular menses, insomnia, tremor, and muscle weakness.
- During infancy, most cases of endogenous Cushing disease are due to a functioning adrenocortical tumor. The most common cause of endogenous Cushing syndrome in children older than 7 years of age is Cushing disease, in which a pituitary tumor (adenoma) secretes excess ACTH.
- Congenital adrenal hyperplasia has two forms, salt-losing or non–salt-losing with virilization. The salt-losing form accounts for 75% of cases and is caused by aldosterone deficiency and overproduction of androgen. The non–salt-losing form accounts for the other 25% of cases.
- Congenital adrenal hyperplasia is the most common cause of pseudohermaphroditism (ambiguous genitalia) in newborn girls.
- Adrenal insufficiency, also known as *Addison disease*, is a rare disorder in childhood characterized by a deficiency of glucocorticoids (cortisone) and mineralocorticoids (aldosterone). Symptoms include weakness, fatigue, weight loss, and gastrointestinal symptoms such as nausea, vomiting, diarrhea, constipation, and abdominal pain. Other symptoms include hyperpigmentation, hypotension, dizziness, joint pain, salt cravings, and hypoglycemia.
- Pheochromocytoma is a tumor that arises from the adrenal gland and causes an excessive release of catecholamines. Clinical manifestations include hypertension, palpitations sweating, anxiety, tremors, and headache.
- Diabetes mellitus type 1 is the most common metabolic disease in children and one of the most common chronic diseases in school-age children. It is a disorder of carbohydrate, protein, and fat metabolism.
- Treatment of the child with diabetic ketoacidosis includes intravenous fluids and electrolytes for dehydration and acidosis. Insulin is given by continuous infusion pump to decrease the serum glucose level at a slow but steady rate to prevent the development of cerebral edema.
- Common causes of hypoglycemia in children with type 1 diabetes include an error in insulin dosage, inadequate calories because of missed meals, or exercise without a corresponding increase in caloric intake.
- Type 2 diabetes mellitus is a condition that results from insulin resistance. Children most commonly affected are obese, and many have family members with the same type of diabetes.
- Secondary amenorrhea is the cessation of spontaneous menstrual periods for at least 120 days and occurs 6 months or 3 cycles after menarche.

Chapter 1
Nurse's Role in Care of the Child: Hospital, Community, and Home

Manny takes medication for seizures, and he is in the health clinic because he had a seizure last week. I will help the parents learn more about seizures, how they are treated, and what they should do when Manny has a seizure.

—Nurse caring for Manny, 3 years old

Learning Outcomes

1.1 Describe the continuum of pediatric health care.

1.2 Compare the roles of nurses in child health care.

1.3 Analyze the current societal influences on pediatric health care and nursing practice.

1.4 Report the most common causes of child mortality by age group and reasons for hospitalization.

1.5 Contrast the policies for obtaining informed consent of minors to policies for adults.

1.6 Examine three unique pediatric legal and ethical issues in pediatric nursing practice.

Pediatric Healthcare Overview

Nurses provide care to healthy children as well as to those with illnesses, injuries, and chronic conditions such as seizures, in a wide variety of settings. They contribute to the health and welfare of children as they monitor their growth and development, and help them adapt to and manage their health conditions. Fortunately, most children are healthy, experiencing only occasional short-term health problems, and nurses have the opportunity to help children and families prevent disease and promote a healthy lifestyle. However, children with special healthcare needs require frequent contact with the healthcare system to achieve and maintain their optimal level of health.

Pediatric health care occurs along a continuum that reflects not only the various settings of care but also the complexity and range of care needed by individual children and their families. For example, all children need health promotion and health maintenance services, but some children will need care for chronic conditions, acute illnesses and injuries, and even end-of-life care. See Figure 1–1 for the model of pediatric health care on which this text is based.

The range of healthcare settings in which pediatric nurses work includes the following:

- The hospital, including pediatric wards, intensive care units, newborn nursery, emergency department, radiology, and specialty clinics
- Physician offices, clinics, and healthcare centers
- The child's home
- Rehabilitation centers and residential treatment centers
- Schools, childcare centers, and camps
- The community

Without a doubt, nurses play a significant role in the provision of health care for children. Their responsibilities vary in the

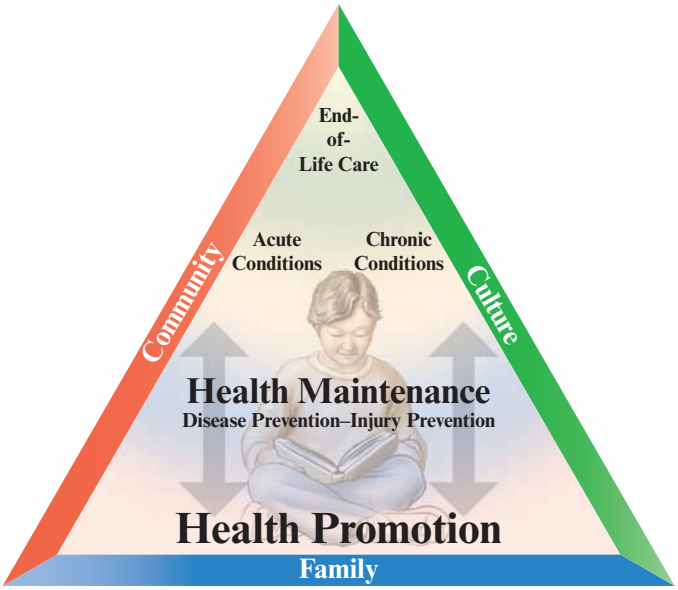

Figure 1–1 **The Bindler-Ball Continuum of Pediatric Health Care for Children and Their Families. The outer bars represent the family, cultural, and community influence on the care that the child receives, either through the services sought by the family or the services provided in the community. Cultural influences include the family's values and beliefs, and the cultural competence of the nurse in caring for a child and family.**

The inner categories represent the range of health care needed by children. All children need health promotion and health maintenance services, represented by the base of the triangle. Notice the arrows representing the upward and downward movement between the levels of care as the child's condition changes.

Children may be healthy with episodic acute illnesses and injuries. Some children develop a chronic condition for which specialized health care is needed. A child's chronic condition may be well controlled, but acute episodes (such as with asthma) or other illnesses and injuries may occur, thus prompting additional health promotion and health maintenance services. Some children develop a life-threatening illness and ultimately need end-of-life care. A healthy child may also experience a catastrophic injury leading to death, thereby requiring supportive end-of-life care for the family.

SOURCE: Bindler, R. C., & Ball, J. W. (2007). The Binder-Ball healthcare model: A new paradigm for health promotion. *Pediatric Nursing, 22*(2).

different clinical settings as they collaborate with other healthcare providers, such as physicians, social workers, pharmacists, optometrists, psychologists, dentists, nutritionists, speech therapists, and physical and occupational therapists.

Assessment, nursing care interventions, and client education are universal roles for nurses regardless of the setting in which they work. This chapter defines the various roles for the nursing care of children and reviews concepts important to pediatric nursing.

Role of the Nurse in Pediatrics

Pediatric nursing, using a family-centered care approach, focuses on promoting the health of children of newborn age through young adulthood; protecting them from illness and injury; recognizing the differences in presentation of diseases between children and adults; adapting nursing care to the age, development, social factors, and health status of the child; assisting and educating the family to care for their child's health condition needs; and advocating for the care of children and their families in all healthcare settings and the community. The nursing roles in caring for children and their families include direct care, client education, advocacy, and case management. Pediatric nurses collaborate with other healthcare professionals as a team member while performing each of these nursing roles.

Nurses who specialize in pediatrics apply foundational knowledge learned during their nursing education, such as the nursing process, anatomy and physiology, physical assessment, healthcare condition recognition and management, and the full range of nursing skills. Pediatric nurses then add additional competencies related to the care of children and their families, such as the following:

- Interacting effectively with children of different ages and their families
- Modifying physical assessment techniques for the age and development of the child
- Identifying strategies to reduce the child's pain and stress
- Accurately calculating medication dosages and volume for administration
- Considering the child's developmental status for client safety and injury prevention activities
- Adapting nursing procedures to the developmental age of the child

Several nursing organizations have collaborated to develop standards of practice for pediatric nurses.

Professionalism in Practice Standards for Pediatric Nursing Practice

The American Nurses Association, the National Association of Pediatric Nurse Practitioners, and the Society of Pediatric Nurses jointly developed *Pediatric Nursing: Scope and Standards of Practice* (2015). These standards describe the expectations for professional performance during care to children and their families. Practicing nurses have an obligation to maintain competence, update their knowledge of new research and practice changes, and practice in an ethical manner when assessing, planning, and evaluating the care provided to children and their families. Collaboration with the family and other healthcare professionals as well as advocating for the child and family are additional expectations when providing nursing care.

Direct Nursing Care

The nursing process provides the framework for delivery of direct pediatric nursing care. The nurse assesses the child, identifies the health concerns, and lists the nursing diagnoses describing the responses of the child and family to those health concerns in the nursing care plan. The nurse then implements

and evaluates nursing care. This care is designed to meet the physical and emotional needs of the child and family. It is tailored to the child's developmental stage, giving the child additional responsibility for self-care with increasing age. Planned care is offered in a sensitive manner, compatible with the cultural beliefs of the child and family in collaboration with the family, using family-centered care principles (see Chapter 2).

Nurses play an important role in minimizing the psychologic and physical distress experienced by children and their families. Providing support to children as well as their families is one component of direct nursing care. This often involves listening to their concerns, being present during stressful or emotional experiences, and implementing strategies to help children and family members cope (see Chapter 2). Nurses can also help families by suggesting ways to support their children in all healthcare settings, including the home.

Patient Education

The education of children and their families improves treatment results. In pediatric nursing, patient education may be challenging, because nurses work with children at various levels of understanding. Rather than giving simple facts, the goal of client education is to help the child and parents or guardians make informed choices about health and healthy behaviors.

As patient educators, nurses help children adapt to the hospital setting and prepare them for procedures (Figure 1–2). Most hospitals encourage a parent to stay with the child and to provide much of the direct and supportive care. Nurses teach parents to watch for important signs and responses to therapies, to increase the child's comfort, and even to provide advanced care. Taking an active role prepares the parent to assume total responsibility for care after the child leaves the hospital.

Planning and preparation, as well as an understanding of the child's developmental level, are needed to effectively educate children and parents. An assessment of the knowledge the child and family have about health conditions or health practices, their past experiences, and their attitudes and beliefs is a starting point for education. The nurse needs to think about strategies and resources available to help the child and family learn about the current health condition. See *Developing Cultural Competence: Adapting the Reading Level of Patient Education Materials*. Education can be evaluated during future visits of children receiving ongoing health promotion and health maintenance care and of those with a chronic condition that requires home management.

Figure 1–2 **Explaining procedures can reduce this adolescent's and family's fears and anxieties about what to expect as well as teach procedures and proper home care.**

Developing Cultural Competence Adapting the Reading Level of Patient Education Materials

Understanding written information in patient care instructions, education materials, and even prescription labels is important to promote **adherence** (the extent to which a client or parent follows recommended care for the health problem). Among U.S. adults, 20% read at a fifth-grade level or below; however, this rate varies by cultural group with higher rates of poor literacy among Latinos, Blacks, and Asians (Pontius, 2013). This means that many parents have difficulty using and understanding health information. Healthcare materials must be provided in the appropriate language and at the appropriate reading level (e.g., sixth-grade reading level for low literacy individuals) (Pontius, 2014). Printed materials to educate children and families about a health condition might be readily available, but they may be written at a reading level that is too high. Even though printed material may be available in the primary language of the client and family, do not assume that the family has reading skills in that language.

When developing patient education materials with a lower reading level:

- Use short familiar words with one or two syllables in short sentences.
- Substitute simple language that defines a medical term rather than using the term.
- Use pictures or graphics to give instructions when possible.
- Use active voice rather than passive voice.
- Use the term *must* to express a requirement.
- Divide the content into small sections and use headers.
- Use lists and tables to simplify content.
- Use a computer program to evaluate the reading level of the materials you develop.

Patient Advocacy

Advocacy—acting to safeguard and advance the interests of another—is directed at enabling the child and family to adjust to the changes in the child's health in their own way. To be an effective advocate, the nurse must be aware of the needs of the child and family, the family's resources, and the healthcare services available in the community. The nurse can then assist the family and the child to make informed choices about these services and to act in the child's best interests.

As advocates, nurses often serve on committees to ensure that the policies and resources of healthcare agencies meet the psychosocial needs of children and their families. The nurse must also protect the child and family by taking appropriate actions related to any incidents of incompetent, unethical, or illegal practices by any member of the healthcare team.

Case Management

What happens when a child has significant health problems? Can one nurse handle it all? When a child has a significant chronic health condition, healthcare professionals (physicians, nurses, social workers, physical and occupational therapists, and other specialists) often create an interdisciplinary plan to meet the child's medical, nursing, developmental, educational, and psychosocial needs. Because nurses spend time with the child and family while providing nursing care, they often know about the family's wishes and resources. As a member of the interprofessional team, the nurse can serve as the family's advocate to ensure that the care plan considers the family's wishes and contains appropriate services. A nurse may become the child's case manager, coordinating the implementation of the interdisciplinary care plan. Sometimes the parent or a social worker becomes the case manager.

Case management is a process that involves the assessment, planning, facilitation, and delivery of healthcare services, including healthcare options by the interprofessional team to promote quality and cost effectiveness of care (Woodward & Rice, 2015). This practice promotes **continuity of care**, the process of facilitating a client's care between and among healthcare providers and settings based on health needs and available resources. The nurse case manager has control over the use of healthcare resources that are considered appropriate for the child's condition and links the child and family to these services. Case management may be used for care of the patient when hospitalized and for long-term care of chronic conditions.

Discharge planning is a form of case management. Good discharge planning promotes a smooth, rapid, and safe transition into the community and improves the results of treatment begun in the hospital. To be a discharge planner, the nurse needs to know about community medical resources, home care agencies qualified to care for children, educational interventions, and services reimbursed by the child's health plan or other financial resources.

Research

Clinical research helps develop, refine, and expand knowledge that advances the science of pediatric nursing care and improves the nursing care provided to children (Christian, 2012). Research can focus on evaluating innovations in care to determine if practice is improved. Pediatric nurses read and analyze new research findings and apply those findings to practice. Such findings may potentially advance healthcare outcomes, improve comfort, or even reduce the cost of care. This research may also be used in developing specific healthcare facility evidence-based clinical practice guidelines. For example, pediatric nurses may identify issues in client care processes that involve clinical practice, education, ethical issues, and specific needs of particular populations of children.

Nursing Process in Pediatric Care

Clinical Reasoning

Clinical reasoning is the analytical process used when assessing client cues and information, synthesizing that information and applying it to understand a child's or family's problem or concern, and then using the nursing process to plan and evaluate the child's care. **Critical thinking** is an individualized, creative thinking or reasoning process that nurses use to solve problems. Both of these reasoning skills are essential for nurses. For example, the child's condition can change during a hospitalization, requiring nurses to recognize subtle cues that need attention to prevent the child's deterioration.

The nursing process involves clinical reasoning and critical thinking when planning nursing care for infants, children, and adolescents. Consider how the five steps of the nursing process relate to children:

- *Assessment* involves collecting client and family data and performing physical examinations in all healthcare settings. The nurse analyzes and synthesizes data to make a judgment about the child's problems.
- *Nursing diagnoses* describe the health promotion and health patterns that nurses can identify and manage by developing a plan for specific nursing actions. The North American Nursing Diagnosis Association (NANDA) has established the standard language for these nursing diagnoses. Each nursing diagnosis has defining characteristics, related factors or risk factors, nursing intervention classifications (NIC), and nursing outcome classifications (NOC).
- *Nursing care plans* are based on the identification of desired outcomes or goals that will improve the child's or family's healthy or dysfunctional health patterns. The nurse creates a nursing care plan in collaboration with the child and family or customizes standard care plans for specific diagnoses that may be used in all healthcare settings. Standard care plans are customized based on data collected from the child's assessment and an evaluation of the child's response to care. The family (and the child, when old enough) and the nurse should agree with the care plan goals.
- *Implementation* is performing the interventions or specific action steps outlined in the nursing care plan.
- *Evaluation* is the use of specific objective and subjective measures (often called *outcome measures* or *outcome criteria*) to measure the progress of the child and family in reaching the goals defined in the nursing care plan. As the child's condition improves and goals are attained, the nursing care plan is modified with new goals and nursing actions based on data from ongoing assessments.

Evidence-Based Practice

Evidence-based practice (EBP) is a problem-solving approach that integrates the best research evidence with a healthcare professional's clinical expertise and the client's values or preferences (Ritt, 2013). It provides a bridge between research and practice by using a systematic search for the most relevant evidence related to a clinical question or problem, followed by a critical review of that evidence to help answer it. Evidence-based practice is one strategy to keep nursing practice current and to promote positive outcomes for children and their families. It has become an important strategy used by healthcare institutions to improve client safety and quality of care. Use of EBP requires the nurse to be a lifelong learner.

Several steps are involved in the EBP (Lockwood, Aromataris, & Munn, 2014):

1. Ask and clearly describe the specific clinical question.
2. Collect the most relevant and best evidence from well-designed studies.
3. Critically review, synthesize, and analyze the evidence for quality and application to the clinical question and population served.

4. Integrate the evidence with your clinical experience and the client's preferences and values, often providing the development of a practice guideline for nursing practice.
5. Evaluate the nursing practice change resulting from the EBP process for its impact on quality of care.

Nurses often collaborate with an interprofessional team to investigate EBP clinical questions to develop a **clinical practice guideline**, a consensus of evidence-based and expert opinion statements about the care for a specific diagnosis used to assist the interprofessional team of healthcare providers to make decisions about the appropriate care of a child who has that condition (Keiffer, 2015). Some practice guidelines are developed by government agencies and national professional organizations. These guidelines encourage practice changes that improve quality and encourage more cost-effective care. Practice guidelines are tools that promote uniformity in care so that client outcomes and healthcare professional performance can be measured. One example is the pediatric asthma guidelines developed by the National Asthma Education Program.

Practice guidelines help promote **collaborative practice**, a comprehensive model of health care that uses an interprofessional team of health professionals to provide high-quality, cost-effective care. Other examples of practice guidelines include the care of a child with type 1 diabetes and traumatic brain injury.

Settings for Pediatric Nursing Care

Pediatric nurses function in a variety of settings within the hospital. Acute care may be provided in the emergency department, observation or short-stay unit, postanesthesia unit, intensive care unit, general pediatric inpatient unit, and various outpatient clinics. In rehabilitation centers, nurses provide inpatient and ambulatory care to help restore children to an optimal state and plan for discharge management of chronic conditions. Pediatric nurses working with children and families on a general pediatric hospital unit promote health improvement in the following ways:

- Gathering data and assessing the health of children and their families
- Providing ordered medical therapies
- Delivering nursing care in a manner that preserves as many of the child's and family's normal routines as possible while maintaining the family unit
- Working with the family and healthcare team to develop an individualized healthcare plan and a discharge plan, or to implement a clinical practice guideline

The hospital stay is part of a care continuum that allows children to complete therapy at home, at school, or in other community settings. Pediatric nurses assist families in transitioning from the acute hospital setting to the home or other facility, such as a rehabilitation center or long-term care facility. Managing the child's transition from acute care to another setting involves discharge planning that integrates interdisciplinary care plans and collaboration with a broad range of healthcare professionals. The nurse may assist the family of a child with significant health problems to prepare for the child's return home and to develop an emergency care plan in case the child has an unexpected healthcare crisis. See Chapter 11 for more information on caring for children in the hospital setting.

Pediatric nurses also work in several community healthcare settings such as physician offices, health centers, specialty care clinics, home health agencies, and schools. See Chapter 10 for more information about nursing care in community settings.

Contemporary Climate for Pediatric Nursing Care

In 2014, more than 73.6 million children under the age of 18 years lived in the United States. They accounted for 23.1% of the population (U.S. Census Bureau, Population Division, 2015). (See Figure 1–3 for a distribution of the population by age group.) The racial and ethnic diversity of children under 18 years of age in the United States continues to increase and is currently estimated as follows (Federal Interagency Forum on Child and Family Statistics, 2014):

- White, non-Hispanic: 52.4%
- Black, non-Hispanic: 13.8%
- Hispanic: 24.1%
- Asian: 4.6%
- All other races: 5.1%

Culturally Sensitive Care

The U.S. population has a varied mix of cultural groups, with ever-increasing diversity. In 2012, approximately 47.6% of all children under age 18 years were from families of minority populations. By the year 2050, it is expected that the proportion of children who are of Hispanic origin will increase to 36%, equaling the proportion of non-Hispanic White children (Federal Interagency Forum on Child and Family Statistics, 2013). Diversity also exists among the non-Hispanic White population, representing many cultural groups who have immigrated from European and former Soviet bloc countries. See Chapter 2 for more information on cultures.

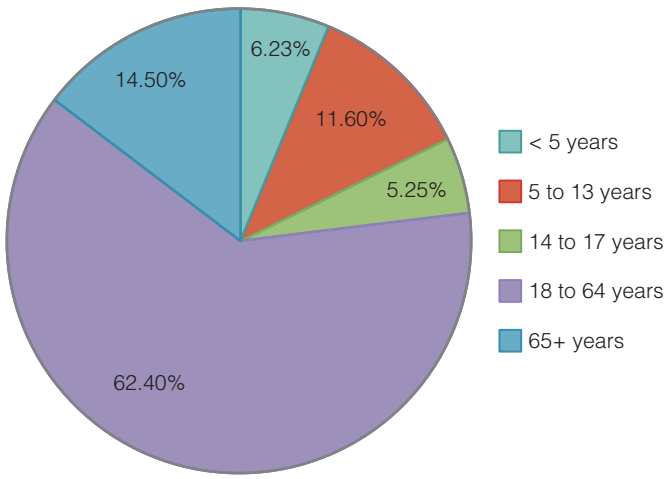

Figure 1–3 The population of children under age 18 years was estimated in 2014 to account for 23.1% of the population in the United States. Note the comparison of the pediatric population size with other population age groups.

SOURCE: Data from U.S. Census Bureau, Population Division. (2015). *Annual estimates of the resident population for selected age groups by sex for the United States, states, counties, and Puerto Rico Commonwealth and municipios: April 1, 2010, to July 1, 2014.* Retrieved from http://factfinder.census.gov

Figure 1–4 **Many facilities now encourage family visitation for children with health problems that require long-term hospitalization. Extended family visits enable parents to learn about the child's care, and provide siblings with opportunities to interact with the hospitalized child.**

Family-Centered Care

Recognizing the family as the constant influence and support in a child's life is the foundation for developing a trusting relationship with families. The family is the principal caregiver and support for the child, and the family is important in helping the child recover from an illness or injury (Figure 1–4). The effort to address and meet the emotional, social, and developmental needs of children and families seeking health care in all settings is a concept known as **family-centered care**. Families are often considered partners in care, learning about children's conditions and participating in decisions regarding their care. Thus, families gain greater confidence and competence in caring for their children who have healthcare problems.The key elements of family-centered care are described in Chapter 2.

TABLE 1–1 Five Leading Causes of Infant Mortality, 2013

CAUSE OF INFANT MORTALITY	RATE PER 1000 LIVE BIRTHS
Congenital malformations	121.0
Low birth weight	106.9
Maternal complications	40.6
Sudden infant death syndrome	39.7
Unintentional injuries	29.6

Source: Adapted from Kochanek, K. D., Murphy, S. L., Xu, J., & Arias, E. (2014). Mortality in the United States, 2013. *NCHS Data Brief, No. 178*. Retrieved from http://www.cdc.gov/nchs/data/databriefs/db178.pdf

Pediatric Health Statistics

Mortality

Children have different healthcare problems than adults, and the problems may be related to stage of development or other factors. The **infant mortality** (death in infants under 12 months of age) rate was 5.96 deaths per 1000 live births in the United States in 2013 (Kochanek, Murphy, Xu, et al., 2014). See Table 1–1 for the leading causes of infant mortality in 2013. The mortality rate for non-Hispanic Black infants is more than twice the rate of non-Hispanic Whites (U.S. Department of Health and Human Services, 2013). The leading causes of infant mortality vary according to the age of the infant. For example, the leading causes of death in the neonatal period (birth to 28 days of age) are short gestation, low birth weight, and congenital malformations. The leading causes of mortality in the postneonatal period (between 1 and 12 months of age) are sudden infant death syndrome, congenital malformations, and unintentional injuries (U.S. Department of Health and Human Services, 2013).

The most common cause of death for children between 1 and 19 years of age is unintentional injury. Congenital malformations, cancer, and diseases of the heart are among the most common medical causes of death in children and adolescents. Figure 1–5

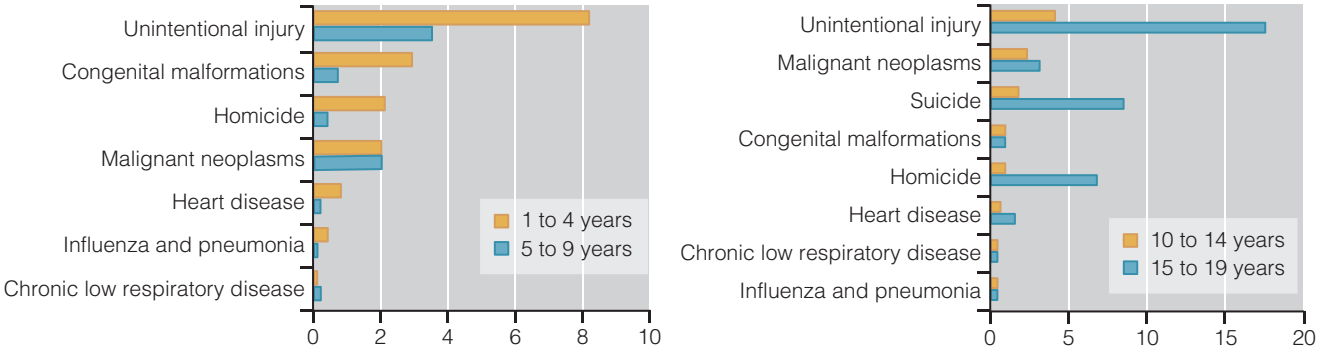

Figure 1–5 **Age-specific death rates per 100,000 children for the leading causes of mortality in the United States in 2013. *A*, Leading causes of death and death rates for children between 1 and 9 years of age. *B*, Leading causes of death and death rates for children between 10 and 19 years of age. The leading cause of death in children in all age groups was unintentional injury. Why do you think that is? Which type of unintentional injury has the highest rate of death? Drowning? Fires and burns? Motor vehicle crashes? What about intentional injury? See Table 1–2 for the answers.**

SOURCE: Data from Centers for Disease Control and Prevention, National Center for Health Statistics. (2015a). *Health data interactive*. Retrieved from www.cdc.gov/nchs/hdi.htm

shows the age-specific mortality rates for the leading causes of death by age group.

Healthy People 2020

(MICH-3) Reduce the rate of child deaths

Injury accounted for an alarming percentage of deaths to children and youth in 2013: children 1 to 4 years—40.7%, children 5 to 9 years—35.9%, youth 10 to 14 years—45.1%, and adolescents 15 to 19 years—71.7% (Centers for Disease Control and Prevention, National Center for Health Statistics, 2015b). Although unintentional injury is the leading cause of death for children and youth, intentional injury (homicide and suicide) is among the top five major causes of death for our nation's children. The major causes of unintentional injury mortality in childhood include motor vehicle (passengers and pedestrians), drowning, fires and burns, suffocation, and poisoning. Table 1–2 illustrates the leading causes of injury deaths by age group. Many injury prevention programs have been implemented by state health departments, healthcare facilities, and national organizations to reduce the number of children who die unnecessarily.

The U.S. government set objectives to improve the health of children and young adults in the 21st century in the report titled *Healthy People 2020.* These national health objectives focus on reducing the incidence of death and disability from the major causes of death shown in Figure 1–5 and Tables 1–1 and 1–2. *Healthy People 2020*'s overarching goals are listed in Box 1–1. Often federal funding in grants is linked to the development of programs aimed at reducing the number of deaths from these factors in specific high-risk groups. Throughout this text, *Healthy People 2020* objectives related to health promotion and specific conditions are identified in specially designed "speed bumps." The coding in front of each objective identifies the specific topic area and objective number for the *Healthy People 2020* initiative. Pediatric nurses focus directly on many of these topic areas, including the following:

- Maternal, infant, and child health (MICH)
- Adolescent health (AH)
- Injury and violence prevention (IVP)
- Nutrition and weight status (NWS)
- Educational and community-based programs (ECBP)
- Vision (V)
- Substance abuse (SA)
- Tobacco use (TU)
- Environmental health (EH)
- Physical activity (PA)
- Immunization and infectious diseases (IID)
- Respiratory diseases (RD)
- Disability and health (DH)

Box 1–1 *Healthy People 2020* Overarching Goals

Goal 1: Attain high-quality, longer lives free of disease, disability, injury, and premature death.
Goal 2: Achieve health equity, eliminate disparities, and improve the health of all groups.
Goal 3: Create social and physical environments that promote good health for all.
Goal 4: Promote quality of life, healthy development, and healthy behaviors across all life stages.

Morbidity

Morbidity is an illness or injury that limits activity, requires medical attention or hospitalization, or results in a chronic condition. Morbidity varies according to the age of the child. In 2011, children under 18 years of age accounted for more than 5.6 million hospitalizations, and the number of hospitalizations in this age group had decreased 26% since 1997. Infants less than 1 year of age accounted for 4.2 million of these hospitalizations. Most of these hospitalizations were related to live birth, but other leading causes of hospitalization included acute bronchitis, hemolytic jaundice, pneumonia, and short gestation/low birth weight (Pfuntner, Wier, & Stocks, 2013). Figure 1–6 illustrates the five leading causes of hospitalization of children 1 through 17 years of age in 2011. Diseases of the respiratory system account for the greatest number of hospitalizations when pneumonia and asthma hospitalizations are combined. Hospitalizations for mood disorders have increased 68% since 1997. What do you think could account for the increase in hospitalizations for mood disorders? See Chapter 17.

TABLE 1–2 Five Leading Causes of Injury Death by Age Group, 2013*

	RANKING				
AGE GROUP	FIRST	SECOND	THIRD	FOURTH	FIFTH
Under 1 year	Suffocation	Homicide, unspecified cause	Homicide, specified cause	Motor vehicle	Undetermined suffocation
1 to 4 years	Drowning	Motor vehicle	Suffocation	Homicide	Fire, burns
5 to 9 years	Motor vehicle	Drowning	Fire, burns	Homicide, firearms	Suffocation
10 to 14 years	Motor vehicle	Suicide, suffocation	Suicide, firearms	Homicide, firearms	Drowning
15 to 19 years	Motor vehicle	Homicide, firearms	Suicide, suffocation	Suicide, firearms	Poisoning

*Darker shading indicates unintentional injuries.

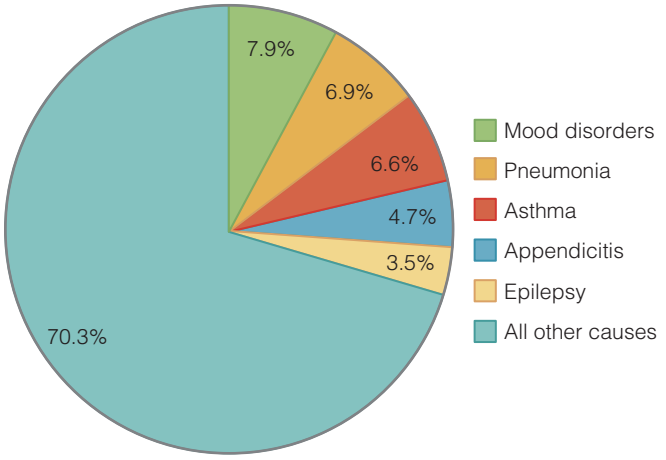

Figure 1–6 **The five leading causes of hospitalization for children 1 to 17 years of age in the United States in 2011 are presented as a percentage of all causes of hospitalization in this age group.**

SOURCE: Data from Pfuntner, A., Wier, L. M., & Stocks, C. (2013). Most frequent conditions in U.S. hospitals, 2011. *H-CUP Statistical Brief, No. 162*. Retrieved from http://www.hcup-us.ahrq.gov/reports/statbriefs/sb162.pdf

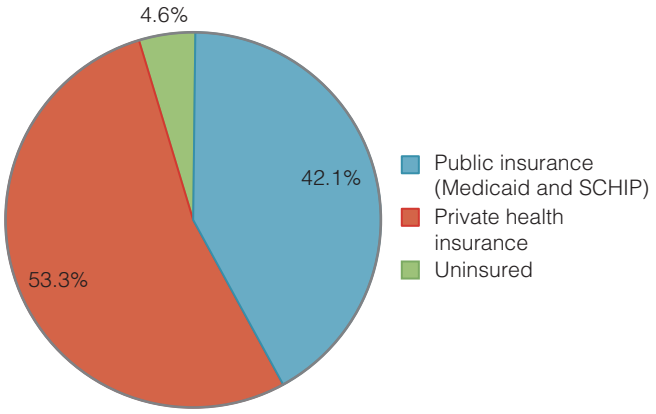

Figure 1–7 **In the United States, how is health care of children through age 18 years paid for? These data from 2014 show that U.S. taxes support 42.1% of the costs. What can you do to help? Something as simple as counseling parents about injury prevention and providing immunizations while a child is under care for other problems can prevent potential health problems. Part of good nursing care is supporting the well-being of the child in addition to caring for the presenting problem.**

Healthcare Issues

Healthcare Financing

Cost and access to health care are important policy issues. Congress created the Children's Health Insurance Program (CHIP) in 1997 to serve uninsured children up to age 19 years. This program was reauthorized in 2009 to provide health insurance for children when their family's income is too high to qualify for Medicaid but inadequate to pay for private insurance coverage. Medicaid and the State Children's Health Insurance Program (SCHIP) provide health coverage to more than 31 million children, including half of all low-income children in the United States (Centers for Medicare and Medicaid Services, 2014a). See Figure 1–7 for the distribution of children's health insurance status.

Clinical Tip

The federal poverty rate is used to determine eligibility for many health and welfare services. The rate is a sliding scale based on the number of persons in the family, and it is updated annually. For example, in 2013, the Affordable Care Act specified that 133% of the federal poverty level ($31,321.50 for a family of four) be used as the eligibility criteria for Medicaid. Eligibility for CHIP begins at 200% of the federal poverty level, but some states set a higher level for eligibility (Centers for Medicare and Medicaid Services, 2014b).

The Patient Protection and Affordable Care Act (ACA) bridges a portion of the gap for children whose family income is too low for private health insurance but too high to qualify for Medicaid and SCHIP. It ends preexisting condition exclusions for children, eliminates annual limits on insurance coverage, and keeps young adults covered for a longer period on their parents' health insurance policy (U.S. Department of Health and Human Services, 2015). Pediatric healthcare professionals continue to have concerns regarding the need to have pediatric service requirements similar to the essential services required by Medicaid and SCHIP, especially if the SCHIP program is not reauthorized. Services for children with special healthcare needs and rehabilitation included in large-group private health plans may potentially be threatened if these health payers modify benefits to fit the ACA requirements (Fry-Bowers, 2015).

Despite the availability of SCHIP, many eligible children are not enrolled. The expectation is that when parents contact their state Affordable Care Act Health Insurance Marketplace, qualifications for Medicaid or SCHIP will be identified and parents will be directed to enroll their children in those programs. Nurses can play an important role in encouraging families to investigate their eligibility for the program. Obtain current guidelines in your state about eligibility requirements and coverage benefits.

Healthcare Technology

Research and technology have enabled many children with congenital anomalies and low birth weights to survive, with and without chronic conditions. Technologic advances have led to the development of portable medical equipment for home care that children use to support physiologic functions. For example, approximately 9 million U.S. children have special healthcare needs requiring complex care or specialized equipment (e.g., ventilators, feeding tubes, intravenous or central lines and their associated pumps, cardiorespiratory monitors, peritoneal dialysis, and pacemakers) (Baker & Cormier, 2013). The number of children assisted by technology continues to increase as scientific and technologic advances grow. However, this technology also adds burdens to the family, such as stresses on family functioning, preparation for power outages, and higher costs for health care. Some families have regained control over their lives by creating intensive care units in their homes (Figure 1–8). See Chapter 12 for more information on children with special healthcare needs.

Figure 1–8 **It is often desirable from a family and cost perspective to provide health care in the home, and technologic advances have made this possible. But is it less costly to provide care in the home for a child with technology assistance? Are the parents' out-of-pocket expenses for medical supplies considered? What about a parent's need to discontinue employment to care for the child? What is the emotional strain on families who care for their child 24 hours a day, 7 days a week? What support is needed by these families to continue providing this level of care at home? See Chapters 10 and 12 for answers.**

Figure 1–9 **An important client safety action is to verify the identity of the child prior to performing any procedure or administering medication. The nurse needs two forms of identification. In this case the child's identification bracelet is compared to the name and birth date on the laboratory test form, and the parent also confirms the child's identity.**

Legal Concepts and Responsibilities

Regulation of Nursing Practice

Nurses are accountable for their professional actions, and each state regulates nursing practice with a nurse practice act. A state's nurse practice act defines the legal roles and responsibilities of nurses. As professionals, nurses set standards for education and practice that conform to state regulations. Standards for nursing education are modified as the science of nursing progresses.

Accountability and Risk Management

ACCOUNTABILITY

The family entrusts the child's care to the healthcare team. Family members expect this team to provide good medical and nursing care and to avoid mistakes that cause harm. The Quality and Safety Education for Nurses (QSEN) project, established in 2005, is designed "to meet the challenge of preparing future nurses who will have the knowledge, skills and attitudes (KSAs) necessary to continuously improve the quality and safety of the healthcare systems within which they work" (QSEN, 2014). The project focuses on competencies in six areas: patient-centered care, teamwork and collaboration, evidence-based practice, quality improvement, safety, and informatics.

PATIENT SAFETY

Patient safety is defined as the freedom from unintentional injury caused by medical care; it includes freedom from harm by death-related or adverse drug events, misidentification of the patient, and healthcare-associated infections (AAP, 2011b). Correct client identification is essential prior to all procedures and medication administration. See Figure 1–9. Some aspects of pediatric care increase the risk for medical error, such as medication dosages that must be calculated for the child's weight and liquid medications that require an additional calculation for volume per dose. The young child's immature physiology may also affect the ability to metabolize and excrete certain medications.

Clinical Tip

Parents play an important role in their child's safety as a partner with the child's healthcare team. Recognize their role and encourage parents to collaborate with healthcare professionals to keep their child safe in the clinical setting. Encourage them to ask questions and to persist until they understand and agree with the proposed outcome of care. Parents also help prevent injuries to their child in the clinical setting, and they may identify potential deficiencies or errors in care, such as failure to perform hand hygiene.

Many medical errors within hospitals are "systems errors," such as medication prescription and dispensing errors, rather than being the error of a single individual. (See *Evidence-Based Practice: Medication Errors*.) The Joint Commission has National Patient Safety Goals (NPSG) that focus on correct identification of patients, improved staff communication, safe medication administration, infection control, safe use of alarms, identifying patients at risk for suicide, and preventing mistakes in surgery (The Joint Commission, 2014).

Reasons for the higher rate of medication error in children may include the following:

- Medication dosage is based on weight or body surface area, often making dosage calculations more complex. This means the optimal dose is based on mg/kg and divided by number of doses to be given a day. When suspensions or liquid preparations are used, dosage calculation increases

EVIDENCE-BASED PRACTICE | Medication Errors

Clinical Question

Medication error is a significant problem in pediatric nursing because children are at higher risk for serious adverse effects. What characteristics of medication errors involving nurses need more attention by hospital patient safety programs?

The Evidence

A large children's hospital used anonymous reporting of adverse medication events to evaluate medication errors and to identify prevention strategies; however, underreporting by RNs was suspected. When RNs were surveyed to identify situations in which they would not file a safety event or near miss (an error intercepted before it reached the client) report, responses included not enough time and not being aware of a need to report near miss events. The RNs were then educated to recognize events that should be reported and tips to decrease the time needed to report events. Next, they were given data about trends in reported medication errors and near-miss events (e.g., incorrect intravenous fluid use, the need for better storage supply bin labeling, and separation of similarly named fluids). Efforts resulted in an increased event reporting, but nurses still reported inadequate time to submit reports (Hession-Laband & Mantell, 2011).

A prospective study was conducted in three tertiary pediatric hospitals in Canada to review anonymously reported pediatric medication administration errors by nurses working on 18 medical/surgical and critical care units. A total of 372 occurrences of potential errors (34.1%) and actual errors (65.9%) were reported over a 3-month period. The majority occurred on medical/surgical units (74%) compared to critical care units (26%). Three primary factors contributed to medication errors: workload, distraction, and ineffective communication (Sears, O'Brien-Pallas, Stevens, et al., 2013).

A meta-analysis of 63 research studies was conducted and aimed at reducing medication errors in children under age 19 years cared for in the hospital and ambulatory settings. Studies focused on preventable events that could lead to inappropriate medication use or potential harm as well as events that caused harm. The events were associated with prescribing, administering, and dispensing medications. Studies that included voluntary reporting of medication errors or near-miss events were excluded, as it was believed underreporting would exist. Problems identified in studies that affect their usefulness included lack of uniformity in definitions of medication error causes, as well as variations in data collection methods and how outcomes were reported. Although medication error reductions were reported, these problems prevented the identification of good evidence regarding medication error interventions that healthcare facilities should implement (Rinke, Bundy, Velasquez, et al., 2014).

Best Practice

Nurses need to learn about the system problems that contribute to medication error, so they can help identify strategies to reduce the risk for error, such as ways to reduce distraction during medication preparation and administration. New hospital systems are being implemented to reduce medication error, and strategies to successfully encourage reporting of actual and potential medication errors continue to be needed. Increased reporting by nurses, physicians, and pharmacists would help identify additional factors contributing to medication errors in different units and the effectiveness of new strategies to reduce errors.

Clinical Reasoning

Identify the medication error reduction policies and strategies for the inpatient pediatric unit. What medication safety practices have resulted from a review of error reports? Identify two potential strategies to improve medication safety in this setting.

in complexity. Then both the correct dose and the amount of liquid preparation (mg/mL) for that dose must be calculated. Some medications are in concentrations that require dilution, further complicating the accurate medication dosage calculation.

- A misplaced decimal when calculating a medication dosage may result in a harmful overdose or ineffective dose. Children with a critical illness or injury do not have the reserves to deal with a medication overdose.
- Off-label medications (not approved for use in children by the U.S. Food and Drug Administration) are sometimes prescribed, so the appropriate pediatric dose and adverse effects are unknown.
- Young children cannot communicate well regarding the adverse effects of medication.

RISK MANAGEMENT

Healthcare facilities are challenged to promote optimal patient care and to reduce liability by implementing strategies to reduce medical errors in all child patients. **Risk management** is a process established by a healthcare institution to identify, evaluate, and reduce the risk of injury to patients, staff, and visitors, and thus reduce the institution's liability. This involves the study of causes of medical errors and near-miss errors within a healthcare facility and implementing system changes to prevent future errors similar to those studied. Box 1–2 explains several strategies that have been developed to reduce medication errors in children.

Quality improvement is the continuous study of systems, services, and processes of care, and using that information to improve healthcare processes, services, and patient outcomes. Nurses participate in the development of institutional policies and standards of nursing practice. Hospitals and home health agencies encourage the development of diagnosis-specific nursing care plans and interdisciplinary clinical practice guidelines that serve as minimal standards of care for the facility.

During the development of standards of care for the facility, indicators of effective care by pediatric nurses and other providers are identified. These indicators may measure either the process of care, the facility's systems, or the expected outcome of care for a specific patient condition. Client records are regularly reviewed to identify deviations from the facility standards or clinical practice guidelines. When deviations from expected processes and outcomes are identified, opportunities to improve the system or processes of care provision are explored with all

Box 1–2 System Strategies to Reduce Pediatric Medication Errors

- Use the child's weight in kilograms in all healthcare settings as the standard weight for prescriptions.
- Look for the child's weight and age, the calculated dose, and mg/kg dose on every prescription. Unit dose dispensing systems should be used. The administration rate for all IV medications should be specified.
- Do not use a zero after a whole number (e.g., 5.0 could be misread as 50) because an error with a 10-fold dosage increase could occur. Use a leading zero before a decimal point when the dose is less than a whole unit to ensure that the decimal is seen (e.g., 0.5 rather than .5).
- Do not store medications with similar sounding names close together. Look at labels for capital letters that a pharmacy may use to help distinguish between medications with similar sounding names (e.g., DOBUTamine and DOPamine).
- Expect prescriptions to be typed or written legibly with printed letters. Milliliter rather than teaspoon volume measurement should be used. Electronic prescription systems supported by the American Academy of Pediatrics may improve legibility, require all needed prescribing information, and actually calculate the correct dosage for the prescriber (American Academy of Pediatrics, 2013).
- Follow all guidelines for patient identification before administering the medication, even if bar coding is used.

care providers. Recommendations for the revision of institutional standards to further improve care by nurses and other health providers in the institution often result.

Policy and procedure manuals should be current and have evidence incorporated to provide guidance on nursing procedures, use of technology, patient education, and evaluation of interventions to promote client safety. Nurses often participate as committee members in the development and revision of these policy and procedure manuals.

Documentation of nursing care is an essential part of risk management and quality improvement. If a patient record is subpoenaed, documented care is considered the only care provided, regardless of the quality of undocumented care. The patient assessment, the nursing care plan, and the child's responses to medical therapies and nursing care, including the regularly scheduled evaluation of the client's progress toward nursing goals, must all be documented accurately and sequentially. Nurses must also report any untoward incidents that could inhibit the client's recovery.

Clinical Tip

The patient's record is a legal document that is admissible evidence in court. Information in the patient's record must be written in objective terms or appropriately recorded in the electronic medical record. When recording a client's response to therapy, the nurse must include physiologic responses and exact quotes. The date, time, and nurse's signature and title are required.

Legal and Ethical Issues in Pediatric Care

Marvin, a 15-year-old boy with acute nonlymphocytic leukemia, has relapsed after a second remission with an acute onset of fever, joint pain, and petechiae (Figure 1–10). A hematopoietic stem cell (bone marrow) transplant is one of his therapeutic options. Although Marvin has agreed to a transplant if a suitable donor is found, he does not want to be resuscitated and placed on life support equipment if he has a cardiac arrest. Marvin has experienced all the burdens of therapy up to this point. He has talked extensively with the hospital chaplain and social worker and feels comfortable with his decision. His parents want an all-out effort to sustain his life until a donor is located.

Marvin's case illustrates the legal and ethical dilemmas in caring for older children and adolescents, especially since he has the ability to understand and make reasonable decisions. At what age can children make an informed decision about whether to accept or refuse treatment? What happens when the parents and child have conflicting opinions about treatment? How are ethical decisions resolved?

Informed Consent

Informed consent is a formal authorization by the child's parent or guardian allowing an invasive procedure to be performed or for participation in research. Information that must be provided to obtain informed consent includes the following:

- An explanation of the child's diagnosis
- A description of the proposed treatment or research; possible outcome, benefits, and significant risks associated with the proposed treatment or research
- Alternative treatments and their potential outcome, benefits, and significant risks
- Answers to questions
- Informing a parent or guardian about the right to refuse treatment or research participation on behalf of the child

Figure 1–10 Marvin, a 15-year-old boy with acute nonlymphocytic leukemia, has definite opinions about his treatment. His parents have a difficult time accepting his opinions when they differ from their own. At what age can children make an informed decision about whether to accept or refuse treatment?

The physician is legally responsible for obtaining informed consent. In the case of research, the investigative researcher may formally designate a person to obtain informed consent. The nurse should verify that informed consent has been obtained prior to any procedure or research participation, alert physicians to the need for informed consent, serve as a witness for informed consent, and respond to questions asked by parents and children.

Consent must be given voluntarily and prior to the procedure or research. Parents, as the legal custodians of minor children, are customarily requested to give informed consent on behalf of a child. Both children and parents must understand that they have the right to refuse treatment at any time.

When parents are divorced and have joint custody, in most cases either may give informed consent. When parents are divorced and one parent has custody, some states limit the parental rights to give informed consent to the parent with custody. Obtain information about your state law regarding custody and who can provide informed consent for healthcare procedures and treatments.

Clinical Tip

Obtain legal advice for complex family issues related to guardianship, divorced parents disagreeing over care, or a caregiver who is not the legal guardian. Each agency should have designated legal experts or consultants for provision of such legal advice.

Many children live in homes with a parent and other adult (stepparent, cohabiting unmarried adult, or grandparent) who does not have legal authority to sign consent. Proxy consent can be granted in writing by the parent to another adult so that children can obtain health care when needed. In an emergency, treatment to preserve life or limb does not require consent, if it cannot be immediately obtained. After examining the child and determining that an emergency condition does not exist, nonurgent treatment should not be provided until the parent or guardian with legal authority can be reached (even if by telephone) (AAP, 2011a).

Child Participation in Healthcare Decisions

Older children and adolescents often have the cognitive capacity to participate in or make medical decisions, but their rights to make most medical decisions are controlled by state law. Adolescents under the age of majority, as defined by state law, are considered minor children, and parental consent is required for medical treatment in the majority of states. Adolescents can legally give informed consent in the following special circumstances:

- **Emancipated minors** (economically self-supporting adolescents under 18 years of age [e.g., married, pregnant, enlisted, or incarcerated] not subject to parental control) and minor parents of a child patient can legally give informed consent.
- **Mature minors** (adolescents between 14 and 18 years able to understand treatment risks) may give independent consent to receive or refuse treatment for limited conditions by federal law, such as testing and treating sexually transmitted infections, contraception services, substance abuse, and mental health care. However, mature minors do not have authority to consent for general medical treatment in most states (Coleman & Rosoff, 2013).

Despite these limitations in informed consent, children and adolescents should have an opportunity to participate in treatment decisions with their parents as reasoning skills develop. **Assent** is the voluntary agreement to accept treatment or to participate in a research project. To give assent, the child needs a basic understanding of what will be done and what is required for participation. The child must also know that he or she can say no (dissent). Parents may wish to actively involve the child in listening to the informed consent information and permit them to express agreement or disagreement with treatment. Nurses can help parents recognize when the child is ready to participate in care decisions and help answer questions the child has about the condition and treatment. The parents, however, make final decisions regarding the treatment or research participation. The child's dissent to participate in research should be respected.

Growth and Development Consent Considerations

By 7 to 8 years of age, a child is usually able to understand concrete explanations about assent for research participation. Generally, by age 11 years, a child's abstract reasoning and logic are advanced. By age 14 years, an adolescent can usually weigh options and make decisions regarding consent as capably as an adult.

Child's Rights Versus Parents' Rights

Parents or guardians have the authority to make choices about their child's health care except in the following cases:

- The parents' choice of treatment does not permit lifesaving treatment for the child. See *Developing Cultural Competence* for information about religious beliefs and emergency treatment.
- There is a potential conflict of interest between the child and parents, such as with suspected child abuse or neglect.
- The child and parents do not agree on major treatment options.

Developing Cultural Competence Religious Beliefs

Jehovah's Witnesses oppose transfusions of blood products for themselves and their children because they believe transfusions are equivalent to the oral intake of blood, which is morally and spiritually wrong according to their interpretation of the Bible (Leviticus 17:13–14). A Jehovah's Witness who receives a transfusion believes he or she has committed a sin and may have forfeited everlasting life. Most healthcare facilities have policies to address the care of these children. Every effort is made to avoid the use of blood products with alternative therapies, except when a blood product will be lifesaving. Then a judicial order is sought.

Healthcare providers involve adolescents in decision making about major treatment interventions in an effort to promote agreement about the treatment plan. In some cases, adolescents and parents or guardians disagree about a major treatment intervention (e.g., bone marrow transplant, heart transplant). Healthcare providers may try negotiation and compromise as a

first step to help adolescents and parents reach agreement about interventions so that the adolescent's voice and opinion are considered. Medical consultation may be sought to identify other treatment options that might be acceptable to both the adolescent and parents. The facility's ethics committee (often composed of healthcare professionals, clergy, consumer representatives, and an ethics expert) usually becomes involved to help resolve the issue. If agreement cannot be reached, the adolescent may need to seek designation as an emancipated minor or ultimately follow the parents' decision regarding treatment.

CONFIDENTIALITY

The Health Insurance Portability and Accountability Act (HIPAA), P.L. 104-191, was enacted by Congress in 1996. One goal of the law is to protect the privacy of citizens by establishing standards for the management of confidential electronic medical information. Healthcare organizations have developed policies to prevent the inappropriate disclosure of protected health information. Patients have the right to determine who can have access to their health information. Sharing protected patient information in the hospital within the hearing of others as well as on social media is a violation of confidentiality. Be aware of policies that hospitals and other health facilities have regarding guidelines for confidentiality with electronic medical records and for the use of social media.

Confidentiality is an agreement between a client and a provider that information discussed during the healthcare encounter will not be shared without the client's permission. Adolescents often do not want their parents informed about sensitive healthcare information. Their concerns about confidentiality may influence whether or not they seek health care. The electronic medical record systems are an additional challenge to adolescent confidentiality, even if seeking care for contraception or a condition such as a sexually transmitted infection. Healthcare systems are developing electronic health record (EHR) systems that can be accessed by parents of adolescents. Guidelines for controlled access to sensitive information are not uniformly built in to those EHR systems so that individual healthcare providers can code some information as private (Daniel, Malvin, Jasik, et al., 2014). The issue of confidentiality for adolescents is further complicated because the parents are responsible for the financial costs of the healthcare services. In some cases parents may get indirect information from health insurance bills. See *Families Want to Know: Adolescents and Confidentiality* for ways to promote confidentiality.

Patient Self-Determination Act

The federal Patient Self-Determination Act directs healthcare institutions to inform hospitalized patients about their rights, which include making **advance directives** (writing a living will or authorizing a durable power of attorney for healthcare decisions on the client's behalf). An adolescent with a serious or life-limiting condition, such as Marvin presented earlier, has a strong and legitimate interest in expressing an opinion about aggressive therapy. The adolescent and parents should be encouraged to talk and reach a joint therapy decision. If the parents and adolescent are unable to agree, the legal issues become complex, as previously described.

Do-not-attempt-resuscitation (or allow natural death) orders have become more common for children with terminal illnesses in which no further aggressive treatments are available or desired. In some cases these children are cared for at home. State health policies and guidelines must be in place for an emergency care provider in the community to honor a written do-not-resuscitate order for a child who has a life-threatening event (Abbott & Stone, 2014). See Chapter 13 for issues related to palliative and end-of-life care.

Ethical Issues

Major advances in medical technology—such as the ability to save the lives of severely impaired newborns, to extend the lives of chronically ill and seriously injured children, to perform genetic testing, and to provide gene therapy—have led to challenges for healthcare professionals and parents to make the best decision for the child's condition. For example, limiting or withdrawing life-sustaining treatment may be appropriate for the child who is severely ill or injured at the end of life to promote comfort, or making a decision not to attempt cardiopulmonary resuscitation (Kodish & Weise, 2016). Healthcare professionals have a moral obligation to deliver care with compassion and respect for the worth and uniqueness of each individual; they must understand and respect religious and cultural differences that impact parental decisions about requesting or refusing a treatment.

Ethics is the philosophic study of morality, and the analysis of moral problems and moral judgments. It is an inquiry into the justification of particular actions. Ethical issues may arise from a **moral dilemma**—a conflict involving individual beliefs, social values, and ethical principles. Each side of the conflict may support different courses of action (e.g., performing or refraining

Families Want to Know

Adolescents and Confidentiality

Adolescents need a safe and confidential environment to discuss healthcare issues so they will seek health care when needed. Ways to promote confidentiality include the following actions:

- Discuss the importance to the adolescent and parents about giving adolescents, and the parents, an opportunity to talk in private with the healthcare provider about their concerns.
  - Adolescents learn how to speak for themselves about their health concerns.
  - This becomes the basis for a trusting relationship with the healthcare professional.
- Explain the limits of confidentiality.
  - Privacy will be maintained unless something dangerous or life threatening regarding the adolescent is revealed.
  - The electronic health record and health insurance billing information may reveal some private information to the parents.
  - Some conditions require mandatory reporting to the health department, such as tuberculosis and the human immunodeficiency virus (HIV).
- Obtain the phone number or other contact information so the adolescent may be contacted to share laboratory test results or to check on response to treatment.
- Make sure clinic literature is small enough to fit discreetly into a purse or wallet.

from performing a therapy). Emotions play a significant role in the development of ethical dilemmas. Parents want to protect the child, and they have their vision of what is good for the child. Healthcare professionals have different values than families because of their culture and life experiences. Differences in values may also exist between members of the healthcare team caring for the child. Regardless, all healthcare professionals want the child to benefit from the care they give.

Nurses may face ethical dilemmas when providing pediatric care. They witness parents struggling to decide among treatment options. Pediatric nurses have a responsibility to become knowledgeable about the moral and legal rights of their patients and families and to protect and support those rights. They must work with parents to form a therapeutic alliance, and attempt to prevent conflicts when the values of the family and healthcare professionals do not match. Pediatric nurses work to find out what is important to the parents in the care of their child. The parents may be able to describe what they wish to avoid having happen to their child, and this could become a starting point for discussion about the child's care with healthcare professionals.

Clinical Tip

No matter what decision parents make about their child's care, they need to be reassured that they are trying to do what they think is best for their child.

Healthcare facilities have an ethics committee to resolve conflicts about treatment decisions between healthcare professionals and the child and family, or to resolve a dispute between healthcare professionals about the care to provide a child. The ethics committee resolves the conflict or dispute by performing an individual case consultation. A healthcare provider or the family can request a consultation.

WITHHOLDING OR WITHDRAWING MEDICAL TREATMENT

Newborn John, at 5 days of age, has a birth weight of 1200 grams, acute respiratory distress, and a severe intraventricular hemorrhage. See Figure 1–11. Consent is being sought by the physician for surgical placement of a ventriculoperitoneal shunt. Regardless of intensive medical care and planned surgical intervention, the newborn is expected to have a severe disability if he survives. The newborn's condition is critical, and it is not certain how well he will respond to surgery.

The Child Abuse and Treatment Act of 1984, also known as the Baby Doe Regulations, defines withholding of medically indicated treatment for a child with a life-threatening condition as medical neglect, except when care is futile (Douglas & Dahnke, 2013). This act was enacted to protect the rights of newborns with severe defects. **Futility** is a situation in which treatments do not provide a clear clinical benefit. Physicians are not obligated to offer interventions that cause extreme pain and suffering when there is no or limited potential benefit.

Parents are participants in the decisions made about care for infants with severe disabilities and children with life-limiting conditions. They are entitled to full information about the risks and benefits of a procedure and the child's long-term prognosis. Parents should have clear information on the seriousness of the child's condition and prognosis, the child's potential quality of life, the degree of pain and suffering, and physician recommendations. Efforts should be made to understand the perspective and values of the parents, especially when their decision does not match the healthcare provider's recommendations. Conflict may arise when parents choose to withdraw therapy or request aggressive therapy when the healthcare providers' recommendations differ. An ethical consultation may be needed to resolve conflicts.

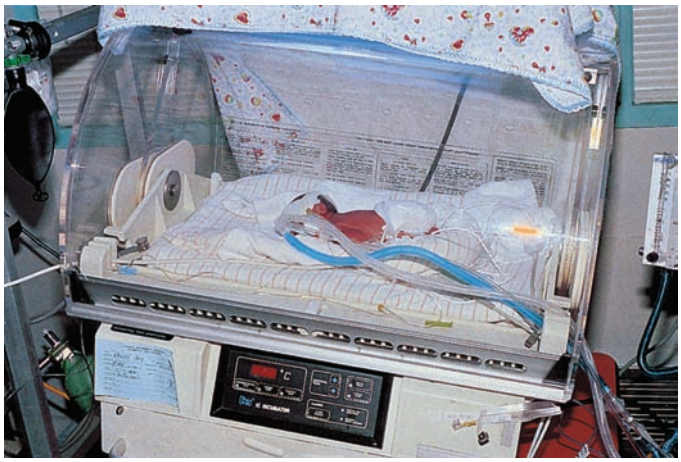

Figure 1–11 **Due to technological advances that sustain life, parents must sometimes face difficult decisions. If a newborn is certain to have severe disabilities, at what point should parents decide to withhold or withdraw treatment?**

SOURCE: Courtesy of Carol Harrigan, RNC, MSN, NNP.

GENETIC TESTING OF CHILDREN

With advances in genetics research, it is now possible to test infants and children for the presence of a genetic condition carrier status. It is also possible to conduct presymptomatic testing for a specific condition, such as Huntington disease or Duchenne muscular dystrophy. Genetic screening of newborns, such as for inborn errors of metabolism, cystic fibrosis, sickle cell anemia, and other conditions, routinely occurs. In this case, the early identification of the genetic condition benefits the infant. A system is in place to confirm the diagnosis, and treatment and follow-up care are available to affected newborns. See Chapter 3 for additional information about ethical issues associated with genetic testing.

ORGAN TRANSPLANTATION ISSUES

The death of a child can benefit several other children through organ transplantation, which has become an accepted therapeutic option for some life-threatening conditions. The limited supply of organs has created numerous ethical issues. Which patients on the waiting list should receive the organs available? Should a patient with multiple congenital anomalies, disabilities, or abnormal chromosomes be eligible for a transplant? Should families be permitted to pay donor families for organs? Should the family's ability to pay for an organ transplant give a child higher priority for an organ? Should a patient receive a second organ transplant, replacing an organ deteriorating because of rejection? Should parents conceive another child, hoping that the new baby is a potential stem-cell donor for a child with an illness? If so, what pressures does this place on both children as they grow older? Each institution performing organ transplants develops guidelines for ethical decision making regarding these and other questions.

The Children's Health Act, P.L.106-310 passed in 2000, directed the development of specific criteria, policies, and procedures to address the specific needs of children regarding priorities for organ allocation. Guidelines for the allocation of hearts, lungs, livers, and kidneys for children have been developed that give preference to children based on factors in addition to time on the waiting list (Workman, Myrick, Meyers, et al., 2013).

Partnering With Families

The topics discussed in this chapter reflect the current challenges children and their families face in the healthcare system—access to health care, specific disease and injury risks, and ethical and legal concerns. A nurse in collaboration with parents and children is essential every step of the way regarding:

- Obtaining informed consent and assent
- Respecting that the parent is an expert with regard to the child's care
- Acknowledging and supporting cultural values in the provision of care
- Preparing parents to assume ongoing complex healthcare responsibilities for their child

Developing relationships with children and families is challenging, exciting, and ultimately gratifying for nurses who choose to specialize in pediatrics.

Chapter Highlights

- Roles of nurses in caring for children include direct patient care, patient education, patient advocacy, case management, and research.
- Nurses care for children in many different settings: the emergency department, radiology, inpatient units, critical care units, postanesthesia units, outpatient clinics, schools, childcare centers, physician offices, community health centers, rehabilitation centers, and the home.
- Family-centered care is a method designed to meet the emotional, social, and developmental needs of children and families needing health care.
- Nurses must identify culturally relevant facts about their clients to provide appropriate and competent care to an increasingly diverse population.
- Unintentional injury is the leading cause of death for children between 1 and 19 years of age.
- The State Children's Health Insurance Program (SCHIP) and the Patient Protection and Affordable Care Act are programs that make health insurance more affordable for families with limited incomes.
- Documentation of nursing care is essential for risk management and quality improvement. Be sure to include the patient assessment, the nursing care plan, the child's responses to medical therapies and nursing care, and a regular evaluation of the child's progress in meeting nursing goals.
- Informed consent is the formal preauthorization for an invasive procedure or participation in research. Parents typically give informed consent for children under 18 years of age unless the child is an emancipated minor (a self-supporting adolescent not subject to parental control).
- Children should be actively involved in decisions about their care as their decision-making abilities develop. Although they cannot provide informed consent to participate in research, children should receive information about a research project and be asked their opinion about participation.
- Because adolescents fear disclosure of confidential information, they may avoid seeking health care. It is important to tell adolescents when confidentiality cannot be maintained, such as when a reportable disease must be reported to a public health agency or when an electronic health record may be reviewed by parents.
- Adolescents with a potentially life-limiting health condition should be encouraged to talk with their parents and to make joint decisions about future care.
- A formalized ethical decision-making process may assist healthcare providers and families in making important decisions about withholding, withdrawing, or limiting a child's therapy.

Clinical Reasoning in Action

Recall 3-year-old Manny, at the beginning of the chapter, who has a seizure disorder. He receives his care in a mobile van sent to his community by the local children's hospital. Manny has a regular source of care because his family income qualifies him for the state's Child Health Insurance Program (CHIP).

1. List at least five competencies nurses need to care for children.
2. Identify at least four different settings in which a child with a seizure disorder could receive health care.
3. List three specific injury prevention messages for a child of Manny's age that should be provided to Manny's parents to reduce his risk for morbidity and mortality.
4. List specific steps the nurse should use in the healthcare setting to ensure that an error is avoided for Manny's prescribed seizure medication and administration by his parents.

Chapter 2
Family-Centered Care and Cultural Considerations

Ryan McVay/Stockbyte/Getty Images

Casey has made a lot of progress since the car accident, but the doctors have told us that the recovery process will take a very long time. I know he will depend on us to take care of him when he is discharged from the hospital.

—Mother of Casey, 16 years old

Learning Outcomes

- **2.1** Describe key concepts of family-centered care.
- **2.2** Compare the characteristics of different types of families.
- **2.3** Contrast four different parenting styles and analyze their impact on child personality development.
- **2.4** Explain the effects of major family changes on children.
- **2.5** List the categories of family strengths that help families develop and cope with stressors.
- **2.6** Summarize the advantages of using a family or cultural assessment tool.
- **2.7** Develop a family-centered nursing care plan for the child and family.
- **2.8** Describe cultural influences on the family's beliefs about health, illness, and treatments.
- **2.9** Discuss nursing interventions for providing culturally sensitive and competent care to the child and family.

Family and Family Roles

The U.S. Census Bureau defines a **family** as two or more individuals who are joined together by marriage, birth, or adoption and live together in the same household (U.S. Census Bureau, 2013). More broadly, however, a family may be a self-identified group of two or more persons joined together by shared resources and emotional closeness, whether or not they are related by blood, marriage, or adoption, or even living in the same household. The family, as defined by its members, is likely to be dynamic, because membership often changes over time. For example, second marriages often integrate children into a newly formed family, and spouses of married children are integrated into an existing family while the newly married couple begins a new family. Family members may live in different cities, states, or even countries. So, there is no *typical* family.

Generally, family members depend on each other for emotional, physical, and economic support. Families are guided by a common set of values or beliefs about the worth and importance of certain ideas and traditions. These values often

bind family members together. These beliefs are greatly influenced by external factors, including cultural background, social norms, education, environmental influences, socioeconomic status, and beliefs held by peers, coworkers, political and community leaders, and other individuals outside the family unit. Because of the influence of these external factors, a family's values may change considerably over the years, or members within a family may hold values that conflict with those of other family members.

Roles of the family include the following:

- Caring, nurturing, and educating children
- Maintaining the continuity of society by transmitting the family's knowledge, customs, values, and beliefs to children
- Receiving and giving love
- Preparing children to become productive members of society
- Meeting the needs of its members
- Serving as a buffer between its members and environmental and societal demands while advocating or addressing the interests and needs of the individual family members

Individual family members take on certain social and gender roles and hold a designated status within the family based on the values and beliefs that bind extended families together. These values and beliefs may evolve from the family's cultural values and practices, social norms, education, and other influences to which parents were exposed during childhood, adolescence, and early adult years. Parental roles, including childrearing practices and beliefs, are usually learned through a socialization process during childhood and adolescence.

Parents have important roles that involve childrearing and the long-term care of children until they reach adulthood. Depending on their other roles in society, parents work to successfully nurture and rear children and to help them meet role expectations. Parents must also meet the needs of the family unit and provide economic support for the family. Children also learn specific roles through a socialization process. Parents set expectations of behavior with discipline and modeling of appropriate behavior.

Ideally the family is a child's source of strength and support, the major constant in the child's life. Families are intimately involved in their children's physical and psychologic well-being, and they play a vital role in the health promotion and health maintenance of their children. By respecting the family's role, strengths, and experiences with the healthcare system, nurses have an opportunity to develop an effective partnership with the child and family as they make healthcare decisions that promote the child's health. This partnership between nurses and families is known as family-centered care.

Family-Centered Care

Family-centered care is a philosophy of health care in which a mutually beneficial partnership develops between families and the nurse, and also other health professionals. In this way the priorities and needs of the family are addressed when the family seeks health care for the child. Each party respects the knowledge, skills, experience, and cultural beliefs that the other brings to the healthcare encounter. This is in contrast to family-focused care, in which the role of the health professional is that of an expert who directs care, tells the family what to do, and intervenes on behalf of the family.

History of Family-Centered Care

Family-centered care became integral to the nursing care of children when it was recognized that families had a significant role in promoting the psychosocial and developmental needs of children in the hospital. When parents were initially allowed to stay with hospitalized children, nurses and other health professionals noticed that children were quieter, happier, and recovering sooner. Research confirmed that children as well as parents had decreased anxiety when the parents were allowed to be present during their child's painful procedures. Allowing parental involvement in the plan of care is beneficial to both the hospitalized child and the family (Committee on Hospital Care & Institute for Patient and Family-Centered Care, 2012).

Nurses have long embraced the family-centered care philosophy. This philosophy is also becoming more widely accepted by other health professionals. Parents are now recognized as partners in their child's care (see Figure 2–1), not as visitors in the healthcare setting, as patient- and family-centered care has become the standard of care in the pediatric setting (Dokken & Buell, 2011). The Society of Pediatric Nurses and the American Nurses Association have developed nursing practice guidelines for family-centered care, as shown in Box 2–1. For additional information related to the hospitalized child, see Chapter 11.

Promoting Family-Centered Care

Collaborating with families in the provision of health care is essential to promote the best outcome when caring for children. Families have important knowledge to share about their child, their child's health condition, and how their child responds to various actions and events. They also need access to information that will make it possible for them to fully participate in planning and decision making. Parents have a role in developing an effective collaborative relationship with nurses and other health professionals. Parents often become experts in their child's health condition and learn to advocate for their child. They also must learn to communicate effectively with the health professionals caring for their child, and in the process develop a trusting relationship.

Figure 2–1 **A health facility policy that permits a parent to be present during a procedure performed on a child is an example of a family-centered care policy. The parent plays an important role in providing security and comfort to this child who is having blood drawn.**

Box 2–1 Concepts of Family-Centered Care

- The family is acknowledged as the constant in the child's life and a partner in the child's health care.
- The family, child, and health professionals work together in the best interest of the child and the family. Over time, the child assumes a partnership role in his or her health care.
- Health professionals listen to and respect the skills and expertise that the family brings to the relationship.
- Trust is a fundamental element of the relationship between the family, child, and health professionals.
- Communication occurs in an open, unbiased manner and is ongoing.
- Families, children, and health professionals make decisions regarding the child's care in a collaborative manner in all healthcare settings and for all types of health care needed (e.g., health promotion, health maintenance, acute care, chronic condition care, and end-of-life care). Negotiation may be involved in collaborative decision making.
- The child is supported to learn about and participate in his or her health care and decision making. The adolescent is supported to assume a partnership role in his or her health care and in the transition to adult health care.
- The racial, ethnic, cultural, and socioeconomic background of the family and child, as well as family traditions, are honored. Health professionals work to integrate these values and the preferences of the family and child when planning and providing health care.
- Family-to-family and peer support are encouraged.
- Healthcare settings develop policies, procedures, practices, and systems that are family friendly and family centered; they support the choices the family and child make regarding care.
- Health information for children and families is available and provided to match the range of cultural and linguistic diversity in the community as well as the health literacy levels.

Clinical Tip

Some healthcare facilities are developing family resource centers to provide consumer information and support (Figure 2–2). In most cases, the resource center is a consumer-oriented health library with staffing, but peer support services may also be coordinated through the center. Families can be supported to access useful information that helps them become informed participants in decision making about their child's care. In addition, the family resource center may serve as a place for family members to read, rest, and reflect (Institute for Patient- and Family-Centered Care, 2013).

Figure 2–2 The family resource center provides an opportunity for family members to obtain more information about their child's illness from the pediatric nurse educator. This nurse uses pictures from a chart to explain a child's illness to the parent.

Beyond the provision of nursing care itself, children and parents can participate in the development of policies and guidelines for family-centered care in all types of healthcare settings. Their experiences while receiving care in the healthcare setting may reveal valuable insights. Taking parents' perspectives into consideration can be critical for staff and hospital administrators in providing quality patient care and achieving successful patient satisfaction. Parents who exhibit leadership qualities can be empowered to serve on advisory boards or councils, representing the family and community perspective.

Parents can also serve a valuable role in family-to-family support networks as mentors to new families entering the healthcare system for a new chronic condition. Some parents may help raise awareness about specific healthcare issues, serve as advocates for public policy issues, and assist with fundraising activities. Guidelines for working with families as advisors and tools for assessing the family-centered policies in various healthcare settings are available from the Institute for Patient- and Family-Centered Care.

It is important to consider how a healthcare setting's written policies, procedures, and literature for families refer to families and what attitudes these materials convey. Words such as *policies, allowed,* and *not permitted* imply that hospital personnel have authority over families in matters concerning their children. Words such as *guidelines, working together,* and *welcome* communicate an openness and appreciation for families in the care of their children.

Family Composition

Families are diverse in structure, roles, and relationships. Various types of families—both those considered traditional and nontraditional—exist in contemporary U.S. society. This section identifies common types of family structures:

- In the *nuclear family,* children live in a household with both biologic parents and no other relatives or persons. One parent may stay home to rear the children while one parent works, but more commonly, both parents are employed by choice or necessity. Two-income families must address

important issues such as childcare arrangements, household chores, and how to ensure quality family time. *Dual-career/dual-earner families* are now considered the norm in modern society.

- The *child-free family* is a growing trend. In some cases, a family is child free by choice; in other cases, a family is child free because of issues related to infertility.
- In an *extended family,* a couple shares household and child-rearing responsibilities with parents, siblings, or other relatives. Families may reside together to share housing expenses and child care. However, in many cases, the child may be residing with the grandparent and one parent because of issues associated with unemployment, parental separation, parental death, or parental substance abuse. Grandparents may raise children due to the inability of parents to care for their own children (see Figure 2–3).
- An *extended kin network family* is a specific form of an extended family in which two nuclear families of primary or unmarried kin live in proximity to each other. The family shares a social support network, chores, goods, and services.
- The *single-parent family* is becoming increasingly common. In some cases, the head of the household is widowed, divorced, abandoned, or separated. In other cases, the head of the household, most often the mother, remains unmarried. Single-parent families often face difficulties because the sole parent may lack social and emotional support, need assistance with childrearing issues, and face financial strain (see Figure 2–4).
- The *single-mother-by-choice family* represents a family composed of an unmarried woman who chooses to conceive or adopt without a life partner (Maggio, 2013). Although these families are included in the single-parent family statistics, they differ significantly in that these women typically are older, college educated, and financially stable and have contemplated pregnancy significantly prior to conceiving (Single Mothers by Choice, 2013).

Figure 2–3 **This child lives with his mother and grandparents following the divorce of his parents. The special attention provided by his grandfather is helping him adapt to the change in his family, and it enables the mother to go to work feeling confident that her son is safely cared for before and after school.**

Figure 2–4 **Single-parent families account for nearly one third of all U.S. families. What types of challenges do single-parent families face?**

SOURCE: © Phase4Photography/Fotolia.

- The *blended or reconstituted nuclear family* includes two parents with biologic children from a previous marriage or relationship who marry or cohabit. This family structure has become increasingly common due to high rates of divorce and remarriage. Potential advantages to the children may include better financial support and a new supportive role model. Stresses can include lack of a clear role for the stepparent, lack of acceptance of the stepparent, financial stresses when two families must be supported by stepparents, and communication problems.
- A *binuclear family* is a postdivorce family in which the biologic children are members of two nuclear households, with coparenting by the father and the mother. The children alternate between the two homes, spending varying amounts of time with each parent in a situation called *coparenting,* usually involving joint custody. **Joint custody** is a legal situation in which both parents have equal responsibility and legal rights, regardless of where the children live. The binuclear family is a model for effective communication. It enables both biologic parents to be involved in a child's upbringing and provides additional support and role models in the form of extended family members.
- A *heterosexual cohabiting family* describes a heterosexual couple who may or may not have children and who live together outside of marriage. This may include never-married individuals as well as divorced or widowed persons. Some individuals choose this model for personal reasons; others do so for financial reasons or to seek companionship.
- *Gay and lesbian families* include those in which two adults of the same gender live together as domestic partners with or without children, and those in which a gay or lesbian single parent rears a child. Children in these families may be from a previous heterosexual union, or be born to or adopted by one or both member(s) of the same-sex couple. A biologic child may be born to one of the partners through artificial insemination or through a surrogate mother. Children who are adopted or born into lesbian and gay families are highly valued, as with heterosexual families (see Figure 2–5). Evidence suggests that children reared by same-sex couples are as well adjusted as those born into heterosexual families and have positive peer relationships (Haney-Caron & Heilbrun, 2014).

Figure 2–5 Children raised in a homosexual family have been found to do as well emotionally, behaviorally, and socially as those born into heterosexual families (Haney-Caron & Heilbrun, 2014). These parents are as dedicated as heterosexual parents to promoting the growth and development of their children.

Clinical Tip

It is important to establish which parent has legal custody, current visitation policies, and other variables (e.g., restraining orders and supervised visitation) when communicating information to parents about their children. Certain legal issues may prohibit the nurse from sharing some information with the noncustodial parent.

Family Functioning

Transition to Parenthood

Choosing to become a parent is a major life change for adults. Many couples experience significant family and cultural pressure to have a baby. Mothers may be eager to have a child but be concerned about fulfilling all the expectations of others (father, the baby, other children, her parents, close friends, and employer). Fathers anticipate increased responsibility and many are concerned about their ability to provide adequate support for the family.

At the time of birth, the parents experience stresses and challenges along with feelings of pride and excitement. Both mothers and fathers make adjustments to their lifestyles to give priority to parenting. The baby is dependent for total care 24 hours a day, and this often results in sleep deprivation, irritability, less personal time, and less time for the couple's relationship. In addition, the family often experiences a change in financial status.

Several factors influence how well the parents adjust to their new role. Social support provided to the mother, especially by the father, is important for the mother's adjustment. Marital happiness during pregnancy is an important adjustment factor for both parents. Infants with significant health conditions or those with difficult temperaments can cause extra stress for the parents and affect their adjustment to the parenting role.

With the birth of the first child, both mothers and fathers have challenges related to renegotiating their employment to accommodate family and childcare time. Fathers are sometimes additionally challenged to develop closeness with the infant and to learn how to care for the infant, especially when they may not have had role models or any childcare experience. Most parents find that caring for infants and children takes more time than anticipated.

Nurses can help new parents through this important transition by listening to the challenges they describe during the infant's first health visits. Encourage fathers and mothers to attend and participate in health promotion visits with the healthcare provider so that positive parenting can be supported. Answer questions and offer ideas to address described problems that the parents may be too tired to solve on their own. Help them recognize that frustrations and feelings they have regarding the challenges of infant care are normal and expected. Encourage both parents to become active in caring for the infant and to gain comfort in that care. Help each parent find activities that she or he enjoys with regard to infant care to encourage interaction and bonding with the infant.

Clinical Tip

Eligible parents of newborns and adopted children are entitled to 12 work-weeks of unpaid leave during a 12-month period initially authorized under the federal Family and Medical Leave Act of 1993. Vacation or sick leave may often be used to pay for time away from work. This act also applies if a child, spouse, or parent of the employee develops a serious health condition. The employee is entitled to return to the previous position or an equivalent position with the same pay, benefits, and other conditions (U.S. Department of Labor, 2012).

Parental Influences on the Child

The qualities of family relationships and of family behaviors are important aspects of family strengths and family functioning. Positive family relationships are characterized by parent–child warmth and supportiveness. Warm parent–child relationships can buffer children from stress and promote positive cognitive and social outcomes. Parents who are warm and place high demands on their children for appropriate behavior have children who tend to be content, self-reliant, self-controlled, and open to learning in school.

Mothers and fathers each contribute to the psychologic, emotional, and social health and development of their children. Both parents provide affection, nurturing, and comfort. They teach children life skills and healthy lifestyles. Although focus is frequently on the role of the mother, research has demonstrated that fathers too are important in the child's development (Bright Futures, 2012).

Family Size

The size of the family influences the amount of attention given to children. In small families, parents often have more time to give attention to the children, to encourage achievement, to meet family expectations, and to support involvement in community activities. Children in larger families are encouraged to be cooperative so that the family group functions well. The child usually receives less personal attention from the parents and must often turn to others in the family for support. Family finances may be more limited in large families. Children may adopt a specialized family role to gain recognition, such as the "responsible one," "the clown," or "the black sheep."

Sibling Relationships

Siblings are the first peers of a child and often have a lifelong relationship lasting up to 70 or more years. Siblings, especially those of the same gender, who are closer in age tend to have a closer relationship because they often share many common experiences through childhood and adolescence. In general, for children who are more widely spaced in age, the parents have greater influence than do the siblings. However, the older sibling may be a strong role model for younger brothers and sisters.

Sibling rivalry exists between children at times in all families, but most children learn to share, compete, and compromise with their siblings. Some sisters and brothers take on roles such as protector, problem solver, friend, and supporter for dealing with issues in the family and in the environment. Some siblings learn to work well together to maintain privacy or to form a coalition for negotiating with the parents. Usually, an older sister or brother helps reinforce rules and roles in the family by prompting and inhibiting certain patterns of behavior in the younger siblings. However, one sibling may test the waters by breaking a previously implicit rule to determine how much flexibility is allowed in certain family rules.

Children develop different personalities because of the need to establish a distinct identity for themselves and to be seen as unique in the family. Siblings may share some experiences, but they are often exposed to different environmental experiences that also help shape their personalities. Few if any personality differences tend to result solely from the birth order of the child. Firstborn children, on average, have slightly higher IQs and greater achievement in school and in their careers, which may be related to the fact that they have all the attention of the parents until the next baby comes along (Craig & Dunn, 2013).

Parenting

The family is an important component in the lives of all children, and it plays an essential role in fostering the development of infants, children, and youth. A significant concept in families is that of parenting. **Parenting** is a leadership role in the family in which children are guided to learn acceptable behaviors, beliefs, morals, and rituals of the family and to become socially responsible contributing members of society. The manner in which children are parented, in combination with their individual personality traits and characteristics, influences their developmental outcomes.

Parents have responsibility for providing stability to children with a nurturing, safe, and structured environment. Every child needs to have physical and emotional space in which to grow and develop. This space enables the child to personally find the relationship balance between closeness and distance, as well as safety and risk. Parents also provide their children with the values, beliefs, rituals, and behaviors learned and transmitted across family generations. See *Developing Cultural Competence: Family Structure and Roles*. To be successful in parenting, parents must have a certain flexibility that enables the family to adapt and adjust to family changes with time and other significant stressors and challenges.

Developing Cultural Competence Family Structure and Roles

A family's structure and roles are largely dependent on cultural influence. For example, culture may determine who has authority (head of household) and is the primary decision maker for other members of the family. Sometimes the decision maker role varies by the type of decisions to be made. For example, in some cultures, such as Hispanic, decisions regarding the health care of children are primarily the responsibility of the female, whereas other decisions are male dominated. Family dominance patterns may be *patriarchal*, as may be seen in Appalachian cultures; *matriarchal*, as may be seen in African American cultures; or more *egalitarian*, as may be seen in European American cultures.

To be successful parents, implement reasonable **limit setting** (established rules or guidelines for behavior) on children's autonomy while they learn values and self-control. At the same time, parents need to foster the child's curiosity, initiative, and sense of competence. Parents use different styles to parent their children. Parental warmth and control are two major factors that are important in the development of children. *Parental warmth* refers to the amount of affection and approval displayed. *Parental control* refers to how restrictive the parents are regarding rules. See Table 2–1 for the characteristics associated with parental warmth and control.

Diana Baumrind identified three parenting styles (*authoritarian, authoritative*, and *permissive*) and described the influences each style has on children. This proposed classification is still useful in identifying parenting behavior (Baumrind, 2012, 2013), as is another parenting style, called *indifferent*, that exists in some families (Craig & Dunn, 2013). Although families generally exhibit one style, they may vary their style for certain situations. Table 2–2 shows characteristics or parenting styles by levels of warmth and control.

TABLE 2–1 Characteristics of Significant Parenting Attributes

PARENTING ATTRIBUTE	PARENTAL WARMTH	PARENTAL CONTROL
High level	Warm, nurturing Express affection and smile at children frequently Limit criticism, punishment Express approval of child	Restrictive control of behavior Survey and enforce compliance with rules Encourage children to fulfill their responsibilities May limit freedom of expression
Low level	Cool, hostile Quick to criticize or punish Ignore children Rarely express affection or approval Rejection may be seen	Permissive, minimally controlling Make fewer demands Fewer restrictions on behavior or expression of emotion Permit freedom in exploring environment

TABLE 2–2 Parenting Styles by Level of Warmth and Control

PARENTING STYLE	WARMTH/CONTROL	BEHAVIOR OF PARENT	CHILD OUTCOMES
Authoritarian	High control Low warmth	Highly controlling, issues commands and expects them to be obeyed Little communication with the child Inflexible rules Permits little independence	May become fearful, withdrawn, and unassertive Girls often passive and dependent during adolescence Boys often rebellious and aggressive
Authoritative	Moderately high control High warmth	Accepts and encourages growing autonomy of the child Open communication with the child Flexible rules	Tends to be best adjusted, self-reliant, self-controlled, and socially competent Higher self-esteem Better school performance
Permissive	Low control High warmth	Few or no restraints Unconditional love Communication flows from child to parent Much freedom and little guidance	May become rebellious, aggressive, socially inept, self-indulgent, or impulsive May be creative, active, and outgoing
Indifferent	Low control Low warmth	No limit setting Lacks affection for the child Focused on stress in own life	May show a high expression of destructive impulses and delinquent behavior

Source: Adapted from Craig, G. J., & Dunn, W. L. (2013). *Understanding human development* (3rd ed., p. 206). Upper Saddle River, NJ: Pearson.

Authoritarian Parents

Authoritarian parents tend to be punitive and adhere to rigid rules, or be more dictatorial. Parents who use this style might say, "Because I'm your parent, that's why," "A rule is a rule," or "Just do what I say." While this style sets firm limits, those limits or rules are not negotiable or open to any discussion. Parents expect family beliefs and principles to be accepted without question. Children have no opportunity to participate in the family decision-making process. Children with authoritarian parents do not develop the skills to examine why a certain behavior is desirable or how their actions might influence others.

Authoritative Parents

Authoritative parents use firm control to set limits, but they establish an atmosphere with open discussion, or are more democratic. Although the limits for behavior are clear and reasonable, the child is encouraged to talk about why certain behaviors occurred and how the situations might be handled differently another time. Parents provide explanations about inappropriate behaviors at the child's level of understanding. Children are allowed to express their opinions and objections, and some flexibility is permitted when appropriate. However, parents make it clear that they are the ultimate authority for decisions. Children with authoritative parents develop a sense of social responsibility because they converse about their responsibilities and approaches.

Permissive Parents

Permissive parents show a great deal of warmth but set few controls or restraints on the child's behavior. Parents are so intent on showing unconditional love that they fail in performing some important parenting functions. Children are allowed to regulate their own behavior. Discipline is inconsistent, and parents may threaten punishment but not follow through. Both extremes result in excessive permissiveness, and the child does not learn socially acceptable limits of behavior. When the parents do not impose any controls on the child, the child ends up controlling the parents.

Indifferent Parents

Indifferent parents display little interest in their children or in their roles as parents. They do not demonstrate affection or approval of the children, nor do they set limits or controls on the children. This may occur because of disinterest, or because their lives are busy and stress filled, leaving little time or energy for their children. Children who experience this style of parenting often have the worst outcomes, such as destructive impulses and delinquent behavior. If the parents are also hostile, the child often develops delinquent behavior (Craig & Dunn, 2013).

Parent Adaptability

Parents who are able to adapt their behavior to meet the needs of children at different developmental stages are also more effective. Parenting styles may change as the child grows older. For example, parents may use negotiation to help the child develop problem-solving skills and learn how to compromise and get along with others. This enables the child to have more self-control and self-responsibility over time. Parents and some children can develop shared goals and jointly participate in decision making, whereas other children require constant negotiation for decision making. See *Families Want to Know: Guidelines for Promoting Acceptable Behavior in Children.*

Assessing Parenting Styles

Nurses can assess parenting styles by asking families how they handle situations that require setting limits. The nurse in all settings is often in a position to discuss parenting styles and to offer suggestions for managing certain types of child behaviors that are frustrating to the family. Keep in mind that no two children are alike, and parents often must vary their parenting styles for different children in the family. For example, children's temperaments are often tied to their behavioral style. (See Chapter 4 for more information on child temperament.) One child may need very clear limits set with discussion and reinforcement, whereas a sibling may immediately respond to the parents' limit setting without a need for discussion. See *Developing Cultural Competence: Cultural Influences on Parenting*.

Families Want to Know

Guidelines for Promoting Acceptable Behavior in Children

- Set realistic expectations and directions for behavior based on the child's age and understanding; consistently enforce the expected directions and behaviors.
- Focus on promoting appropriate and desirable behaviors in the child:
  - Model or suggest appropriate behavior;
  - Review expected behavior for special situations, such as a family party, going to the movies, or other social events;
  - Help the child distinguish between inside and outside voice and behaviors; and
  - Praise or reward the child for using appropriate behaviors.
- As soon as any inappropriate behavior begins, tell the child and offer guidelines for behavior change or provide a distraction.
- When reprimanding the child, focus on the behavior rather than stating that the child is bad. Explain how the behavior is inappropriate; how it makes you, as the parent, and any other person involved feel. Avoid ridicule or accusation that can take the form of shame or criticism. These actions can have an impact on the child's self-esteem if repeated often enough.
- Be alert for situations when the child could potentially misbehave, such as when the child is tired or overexcited. Use a distraction to control or calm the child.
- Help the child gain self-control with friendly reminders (e.g., count to three, as soon as the clothes are on the doll, as soon as you finish the game) regarding the timing for transition to the next event of the day, such as bedtime, putting the toys away, or washing hands before dinner.
- Discuss reasons and social rules for expected behaviors when the child is old enough to understand.

Developing Cultural Competence Cultural Influences on Parenting

Some cultural influences on parenting are associated with chosen lifestyle. For example, living in a predominantly ethnic neighborhood makes it possible to participate in special events that support children in learning about their culture. Parents use the community for social contacts that help reinforce patterns of parenting and establish behavioral expectations of their children. Frequent contact or living with the extended family also helps the children learn family and ethnic traditions, behaviors, and values. Additionally, children may be sent to faith-based schools that foster values important to the family.

Discipline and Limit Setting

Discipline is a method for teaching the rules that govern behavior or conduct. **Punishment** is the action taken to enforce the rules when the child misbehaves. Parenting styles play an important role in the type of discipline and punishment used with children. When clear limits are set and consistently maintained, as with authoritative parenting, punishment may be needed less often. Limit setting and firm control of those limits are important discipline methods used so children learn to what extent they can safely and independently operate within the environment. Firm limits also help children feel secure because they are reassured by consistency and the sense of protection perceived by the limits. Punishment helps children learn that there are consequences for misbehavior, and that other individuals may be affected by that behavior. This helps children develop a sense of responsibility for their behavior.

Clinical Tip

Nurses have an important educational role in helping parents identify an appropriate discipline method and how to take an authoritative role with their children. Encourage and educate parents about the need to be in charge, to set the rules, and to stand by those rules so that children learn how to behave.

Parents use various strategies for the discipline and punishment of children. Factors that affect what type of discipline is used are related to gender of the child, education level and age of the parents, family income, and culture. In addition, the type of misbehavior and the location in which it occurs affects the type of discipline used. Various discipline strategies that are used with children include the following:

- *Reasoning:* Explaining why a behavior or action is inappropriate or describing how limit setting is important. By reasoning, parents can help the child understand why certain behaviors are wrong. Similarly, parents can share personal stories and fables to help children understand social and moral values or to better understand acceptable behavior.
- *Behavior modification:* Giving positive rewards (such as treats or privileges) or reinforcement for good behavior or consistently ignoring inappropriate behavior to minimize the behavior. This encourages children to behave in specified ways.
- *Experiencing consequences:* Allowing the child to learn important lessons associated with misbehavior, such as taking away a toy, using a time-out, withholding privileges, or providing no dessert if the child misses dinner or does not eat nutritious foods (see Figure 2–6).
- *Corporal punishment:* Spanking, slapping, or inflicting pain with a paddle, whip, or other object. This type of punishment is not recommended by the American Academy of Pediatrics and is considered an aversive strategy (AAP, 2015; Theunissen, Vogels, & Reijneveld, 2015).
- *Scolding or yelling:* Using harsh language to verbally reprimand the child. This is not a recommended strategy as this may decrease the child's self-esteem. See Chapters 7 through 9 for age-specific discipline strategies.

Clinical Tip

Time-out is a punishment method of placing the child in a location away from toys and attention as a consequence of misbehavior. The general rule for the length of time-out is 1 minute per year of age (AAP, 2015).

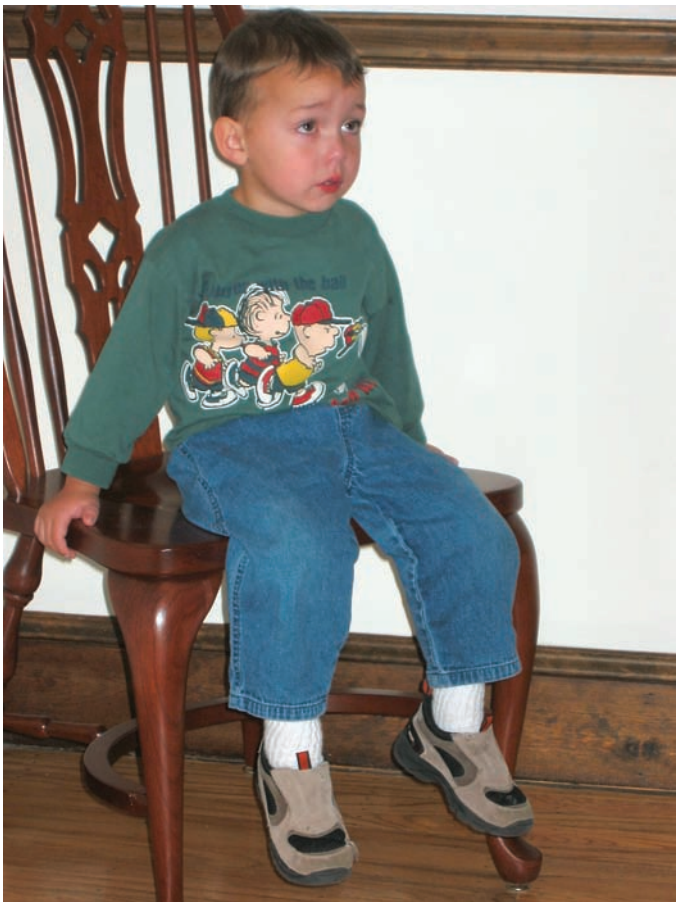

Figure 2–6 **One effective discipline method is to remove the child to an isolated area where no interaction with children and adults can occur and no toys are present. This is used to demonstrate that there is a consequence to misbehavior. For older children, consider the loss of phone, computer, or other privileges.**

Special Family Considerations

Divorce and Its Effects on Children

It is estimated that approximately half of all children in the United States will experience divorce of their parents at some point (Anthony, DiPerna, & Amato, 2014). Children are affected in many ways when the family breaks apart, even if the divorce was preceded by periods of stress and tension in the home. Many children believe they are at fault for the separation and divorce, having said or done something to make the parent leave. When one parent leaves, the children may feel abandoned and divorced by that parent. They may also fear being abandoned by the remaining parent. Children might become engaged in the disputes of parents, and they experience conflicts of loyalty when parents fight for their affection.

In divorces involving a lot of conflict and hostility, the children might experience increased problems with adjustment. When they must make a lot of changes in their lives in addition to the parents' separation (new home, different school), their adjustment is made more difficult because their sense of order is upset. Predictable routines have changed, and children may test limits to see if they still apply. The more changes they must make in the period immediately after the divorce, the more challenging is their adjustment. The disruption associated with divorce is also linked to academic and behavior problems among children (Arkes, 2015). See Table 2–3 for potential effects of divorce on children of different ages.

Sometimes parents are so stressed that their customary parenting styles become inconsistent. They may be unable to provide the warmth, affection, and support that the children need during this time. Battles over custody, child support, property division, and visitation rights all cause more distress for the children.

Nurses can assist families who are experiencing divorce by inquiring about the circumstances and changes that the child is undergoing. Talk with parents about the child's fears of abandonment and concerns, reminding parents that even

TABLE 2–3 Potential Effects of Divorce on Children of Different Ages

AGE	BEHAVIOR*
Preschool	Fear, anxiety, worry Self-blame Sorrow and grief Anger Regression Searching and questioning Temper tantrums Increased crankiness and aggression Loneliness Unhappiness Depression
School age	Worry, anxiety, depression Sadness Insecurity Fantasy Grief Guilt Self-blame Inability to concentrate on schoolwork Lower academic achievement Regression Aggression Confusion Anger Resentment Behavioral problems at school and home Manipulation of parents Withdrawal from friends and activities Fear Loneliness
Adolescence	Panic Fear Depression Guilt Risk taking Fear of loneliness and abandonment Denial Anger Sadness Aggressiveness Skipping or dropping out of school Use of drugs and alcohol Sexual acting out

*This table lists some of the behaviors that could potentially be seen with different age groups and is not all-inclusive. Many other behaviors may be present as well, depending on the individual child.

Families Want to Know

Promoting Relationships With Parents Following Separation and Divorce

Guidelines that may help reduce conflict and foster maintenance of a close relationship between the child and each parent include the following:

- Develop a way to stay in touch with the child even when apart, such as phone calls, text messages, social media, or e-mail.
- Encourage a liberal visitation schedule so that each parent has time to be a normal parent. Overnight stays rather than a few hours at a time allow for more normal interactions.
- When parents have difficulty minimizing conflict in front of the child, transition the child to the other parent after school or child care, or from a friend's home. This keeps the child from feeling responsible for the conflict.

infants and toddlers can sense tensions in the home. Remind parents about the need to keep children out of the middle of confrontations and to maintain limits of acceptable behavior. Encourage parents to avoid saying negative statements about the other parent and encourage them to make every effort to maintain the relationship with the children. Help parents recognize their child(ren)'s needs for love and security during this difficult period.

The quality of the relationship between the divorced parents has an important impact on the future relationships their children have with them as adults. Children do better when both parents remain involved with their children and cooperate with each other after divorce (American Academy of Child and Adolescent Psychiatry, 2011).

Fathers who do not live with their children but live nearby are more likely to have involvement with their children if they have a good relationship with the child's mother, financial resources, and work experience. The relationship between father and child may be improved when the father can interact with the child in a conflict-free environment. See *Families Want to Know: Promoting Relationships With Parents Following Separation and Divorce*.

Stepparenting

When divorced or widowed parents remarry, the child may respond with ambivalence, divided loyalty, anger, or uncertainty. Parents should anticipate how the child and the entire family will respond to changes in lifestyles, routines, and interaction patterns and address them early in the formation of the new family relationship. When a stepparent joins a ready-made family, opportunities for improved emotional and financial support of the child can result, but the development of a new cohesive family requires many adjustments by all family members.

Blending two families often results in the need to identify or negotiate new customs, traditions, rituals, and routines for the family. Children may fear or experience losses such as a close relationship with the noncustodial parent, neighborhood friends (if a move was required), contact with grandparents, and family traditions. Discussions with children about their feelings may help the new family develop plans that ease the transition.

Stepparents must adjust to the habits and personality of the child and then work to gain trust and acceptance. If the child has not accepted the divorce or loss of a biologic parent, the stepparent faces more challenges in developing a trusting, affectionate, and respectful relationship. Sharing in childrearing decisions and responsibilities is an important task for stepparents, but their roles and the role of the joint or noncustodial parent need to be discussed and negotiated.

Stepparents are additional parents, not replacement parents. The stepparent and the child need to adjust to each other. The stepparent should try to establish a position in the child's life that is different from that of the missing biologic parent, rather than competing with the biologic parent. Stepmothers often have more challenges than stepfathers adjusting to their new role. This may be because they spend more time with the children.

In most stepparent families, discipline is a challenge. Family members must agree on standards of behavior, as well as the type of discipline and who carries it out; these guidelines need to be consistently maintained. Discipline by a stepparent is difficult until a bond develops between the stepparent and stepchild. The development of this bond cannot be forced. Time and honest communication are needed to gain the child's trust.

Clinical Tip

Identify the parent who can legally provide consent for medical treatment when there has been a divorce and potentially a remarriage. In some states the noncustodial parent cannot give consent. The stepparent cannot give consent unless the custodial parent grants written permission. Stepparents or other family members may also not know the child's medical history. Identify the legal framework for informed consent with regard to these children so that care is provided in an appropriate and responsible manner.

Contact with the biologic parent often continues through custody arrangements, financial support, and visitation. Children may actually move between two households, adding to the complexity and stressors in their lives. Power conflicts may emerge if the biologic parents do not make efforts to cooperate in parenting decisions. When parents agree to work together for the child's benefit, a parenting coalition between all parents in the two families can reduce the conflicts and tensions that can emerge.

Foster Care

Foster care is the provision of protection and shelter for a child in an approved living situation away from the family of origin. It is legally coordinated by the state's child welfare system. The goal of foster care is to ensure the safety and well-being of vulnerable children. During 2014, 265,000 children entered foster care, and 238,000 exited. As of September 30, 2014, 415,000 children were in foster care (U.S. Department of Health and Human Services, 2015).

Children enter the foster care system for many reasons. The primary reason is child abuse and neglect. Other reasons include parental problems such as abandonment, illness, alcohol/substance abuse, incarceration, and death. Severe behavioral problems in the child can also lead to placement in foster care

(American Academy of Child and Adolescent Psychiatry, 2013). Each state has guidelines regarding qualifications and standards for foster care parents and the process for becoming a foster parent. In an effort to ensure that the child is placed in a safe and nurturing environment, state guidelines that are used when investigating the home often include an interview with the interested adults to check for readiness to be a foster parent, health of all family members, legal background checks, and safety of the residence. Foster parents are also required to have initial training and annual continuing education.

Foster parents may be relatives (kinship care) or unrelated families with whom the child has a strong emotional bond. However, many children needing foster care are placed in extended families because there are fewer suitable nonkinship family foster homes. Kinship placement is frequently viewed as a better alternative, providing a more stable environment for the child. When children are placed with relatives, some sense of continuity and connectedness is maintained for these children (Fusco & Cahalane, 2015). Kinship care is generally perceived as more normative with fewer stigmas attached to it than nonkinship placement. Additionally, children in kinship care have been shown to have better outcomes in relation to safety, stability, and well-being (Font, 2014). Kinship providers are frequently older, in poorer health, have less income, and more likely to be single than nonkinship foster parents (Nesmith, 2015). Also, kinship foster parents receive fewer support services (Soine, 2013).

Foster Parenting

Foster parenting is very demanding, as they must provide for daily needs of children as well as support them emotionally. Foster parents provide transportation to medical and mental health counseling appointments, coordinate visits with birth parents and caseworkers, and advocate for the child in school settings. When the child has complex problems or needs, the challenge of caring for the foster child is even greater. Foster parents do receive some funding to care for the foster child, but it is often inadequate for the child's needs; therefore, the foster parents subsidize the child's care from their own funds. Some foster parents leave the system due to lack of adequate support. When the child must be moved to a different foster family, this may further exacerbate the ongoing stress that the individual child experiences in the foster care system.

Much of the child's adjustment rests with the stability of the family and available resources. Even though foster care is intended to be a temporary short placement—until the child can be returned home or an adoptive home is found—placed children may actually reside with the foster family for a lengthy time, sometimes for years. For children who have come from an environment that has been unstable, abusive, or neglectful, the foster care home can be supportive to the child's health status, development, and academic achievement.

Foster parents caring for children need to provide continuity, consistency, and predictability. It is essential that foster parents provide a nurturing environment for these children and show love and affection toward them. Developmentally appropriate activities are also essential to foster the child's long-term physical and emotional development.

Health Status of Foster Children

Physical health problems, as well as developmental, behavioral, and emotional problems, are common in children in foster care (American Academy of Child and Adolescent Psychiatry, 2013). Efforts to ensure that children receive appropriate health care while in foster care are challenged by various barriers, such as lack of coordination between healthcare providers and social workers.

Every child entering foster care should receive an initial health screening, followed by a more comprehensive health assessment within a month. Findings and recommendations from the health assessment and additional health evaluations should be incorporated into the child's social service case plan. Nurses can play an important role in partnering with foster parents to arrange for and obtain the services needed by the child. Foster parents need to be supported in their efforts to care for these children, helping them to develop self-esteem and resilience.

Transition to Permanent Placement

Although many children are reunited with birth parents, other children cannot be. The Adoption and Safe Families Act of 1997 (P.L. 105-89) led to significant changes in child welfare and was enacted to increase well-being, safety, and permanence. Timelines were shortened for decision making about permanent placement of children, and incentives were established for states to encourage adoption. States were given guidelines regarding when reasonable efforts to reunite children with birth parents are no longer necessary, and when action is required in certain circumstances to terminate parental rights (Phillips & Mann, 2013). Kinship foster care was formally recognized. **Legal guardianship** (a permanent placement option for the child, often with relatives, in which parental rights are not terminated) was established as an alternative to **adoption** (a legal relationship between the child and parents not related by birth in which the adoptive parents assume all legal and financial responsibility for the child). Long-term foster care was eliminated as a permanent placement option in nonkinship care, but it could continue for kinship foster care to promote stability for the involved children (Adoption.com, 2013).

Clinical Tip

The Foster Care Independence Act of 1999 (P.L. 106-169) requires states to provide youth 18 to 21 years of age with services to help them make the transition to self-sufficiency. These services include training and education, financial support, and employment services (U.S. Department of Health and Human Services, 2012).

For those children with kinship foster care, adoption is often not perceived as the best option. Legal guardianship enables the child to retain legal connections with the birth family and relationships with the extended family. The guardian assumes limited financial liability for the child's care. Legal guardianship can be reversed at a future time if the birth parents petition the court.

Adoption

Motivations for adoption of a child vary with the families seeking adoption. In some cases, couples have infertility problems and are unable to have a biologic child. In a family that already has biologic children, the reasons could include the following:

- A desire to provide a home to a child who needs one or to have a larger family without additional biologic children
- Fertility issues requiring invasive medical procedures that are too extensive, expensive, or psychologically overwhelming for a subsequent pregnancy

- Adoption of a foster child with whom the family has established strong bonds
- Adoption by a family relative or stepparent

The supply of healthy infants available for adoption is much smaller than the number of families who want to adopt. Most children in the United States available for adoption are older children, often of minority populations or of mixed races, and those with special healthcare needs. In 2012, the number of children waiting to be adopted was 102,000. This number increased to 108,000 in 2014 (U.S. Department of Health and Human Services, 2015). Because most families choosing to adopt prefer to have an infant, many children have been adopted from foreign nations. Today, adopted children account for approximately 2% of all children in the United States (Jones, Schulte, & Committee on Early Childhood and Council on Foster Care, Adoption, and Kinship Care, 2012).

Legal Aspects of Adoption

Adoption is controlled by individual state law. Most adoptions are arranged through an authorized agency, such as a licensed social service agency. Others are provided by independent agencies in collaboration with physicians, lawyers, nurses, and members of the clergy. State laws require any family who wants to adopt a child to undergo a home study, a process in which parents are interviewed about a large number of topics and issues and are provided education and guidelines to prepare for the adoption. The National Adoption Information Clearinghouse provides information about state adoption laws.

Birth mothers and birth fathers are each required to relinquish legal rights to a child before an adoption can occur. The legal period between the child's birth and when the birth mother relinquishes legal rights varies by state. Efforts are made to ensure that the birth mother is not coerced into relinquishing legal rights to the child immediately after birth. In an open adoption, the birth mother and adoptive parents often have contact with each other prior to the birth and have jointly planned potential future contacts between the child and biologic mother. In some adoptions, birth mothers write a letter to the child that is given to the child at an appropriate age.

Preparation for Adoption

Adopting parents often benefit from preadoption counseling, which may help provide the support and reassurance needed about parenting and the adoptive process, as well as make connections with support groups or other families with adopted children. Preadoptive parents may wonder about their ability to love and parent the child and may have concerns about the responses of relatives, other children, and friends, especially if the child is from a different ethnic or racial group. Children already present in the family need to be reassured that they will not be displaced by the new child. Families need information about the child's understanding of what adoption means and guidance to help inform the child about being adopted.

Responses by Adopted Children

Children vary in their understanding and response to adoption by age (Jones et al., 2012):

- Children under 3 years of age do not recognize a difference between being adopted into a family versus being a biologic child in the family.
- Starting at about 3 years of age, children like to hear about their adoption story and they begin to ask what adoption means. Children adopted at this age may experience the separation from their other family and relatives. They are aware of physical differences between themselves and the adoptive family when they are of a different race or ethnic group. They may be fearful of abandonment by the adoptive family.
- By 5 years of age, adopted children begin to recognize they are different from most of their peers who were not adopted. Some children develop a feeling of responsibility for their biologic parents' decision not to keep them.
- School-age children may fantasize about their biologic family and what their life might have been like if they were not adopted. Their self-esteem may be affected if they think there was a flaw in them that caused their biologic parents to give them up for adoption.
- Adolescents may continue to fantasize about the "ideal" biologic family and try out identities similar to what they know or imagine about their biologic parents. They may also become angry that their own life experience is different from societal norms. Adolescents and young adults may seek information about their biologic family through a reunion registry. See *Families Want to Know: Informing the Child About Adoption*.

Families Want to Know

Informing the Child About Adoption

Most parents have anxiety about when and how to tell the child that he or she was adopted. There is no perfect age to approach this topic, so consider the child's age and developmental stage when sharing information.

- Some authorities believe the child should be told at such a young age that the child will always know that he or she is adopted. This may be especially important when the child is of a different ethnic or racial group or has very different physical characteristics than the parents.
- The terms *adoption*, *adopted*, *birth family*, or *biologic family* should be part of the family's natural conversation (Jones et al., 2012).
- Decide when you and the child are most ready to introduce the topic of adoption—such as when a discussion of babies and where they come from occurs. However, avoid waiting for "just the right moment" because children may wonder what other information has not yet been shared.
- Make sure the child is told *before* a third party is likely to say something. The chances of this happening increase as the child enters school.

- Tell the child in a matter-of-fact manner about the adoption. Let the child know how much he or she was wanted and that some personal qualities of the child made the selection special. Avoid phrases such as "given up" for adoption. A more positive phrase to use is that the biologic family made an adoption plan in the best interest of the child's future.
- Make sure the child understands that his or her place in the family is permanent. The adoptive family's commitment to the child should be repeated frequently.
- Be willing to honestly discuss the child's biologic family and the adoption process so the child feels comfortable asking questions. More discussion about adoption will be needed as the child grows older, especially when the child begins to ask at about 5 to 6 years of age why she or he was not wanted by the biologic parents. Anticipate that the child will grieve about the loss of the birth parents.
- As the child grows older and asks for more information about the birth parents, provide what information is known and try to help the child deal with information that is difficult to hear. Help the child decide what information to share with strangers, friends, and extended family members.
- Recognize that the adolescent may fantasize about the birth parents and want to find them. Listening to the adolescent's concerns and providing support during this challenging time of development is important.

Children who are older when adopted must also make the commitment to the family relationship. They often have a memory of parents and other caregivers, so developing a close relationship with the adoptive parents takes more time. It may also be more challenging for the adoptive parents to develop as strong an emotional bond to the older child as occurs when an infant is adopted. Even when a serious commitment has been made to adopt an older child, adjustment of the family and child may be difficult for everyone. Counseling may be helpful to some families during the transition process.

International Adoptions

International adoption is relatively common in the United States. Often, internationally adopted children need special healthcare services. Nurses work with families that have adopted children from other countries to provide a comprehensive evaluation of the child to detect potential developmental problems and health conditions as soon as the child is brought into the country.

Emotional and psychologic problems may be the result of long-term institutionalization in an orphanage, such as inconsistency in interpersonal development and delayed developmental milestones. The child and family may need counseling and support to help the child adjust to being part of a family. For the child who has been in an orphanage, his or her initial response to the new parents may be crying or turning away. Children need a transition period of several months to adjust to a different daily routine and to bond with the parents. Exposing the child to large numbers of family members or to busy environments may be stressful to the child. The nurse may become involved in providing counseling to the family when it is trying to integrate the adopted child into the family's life and routine (see Figure 2–7). As the child grows, efforts to help the child understand the cultural birth heritage are also important. See Chapter 4 for additional information about international adoption.

Figure 2–7 Adopted children who are of mixed race or a different ethnic group than the parents may cause a few additional challenges for the adoptive parents. Family members may be less supportive of the adoption initially. Because the children may have different physical characteristics, the family may capture more attention than it wishes. The family needs to learn to appreciate the different cultures represented in the newly formed family.

Family Theories

Families must be understood in their own context. It is important, for example, to understand each family's strengths and uniqueness and how the family and its members respond to the complex and often conflicting demands for time and attention.

Family theories are helpful in comprehending family functioning, environment–family interchange, family changes over time, and family response to health and illness. A brief review of family theories provides a context about family functioning that can assist with planning nursing care and developing future partnerships with families and their children.

Each family has structure and functions to help it maintain stability while responding continuously to various stresses and strains within the family and in the family's interactions and functioning within the community. Families develop and modify their responses and functioning over time to adapt or be tolerant of family, community, and environmental changes. Family processes include the behaviors and strategies that help regulate space, time, energy, and other aspects of family functioning to promote family stability, growth, and control.

Family Development Theory

Family development theories use a framework to categorize a family's progression over time according to specific, typical stages in family life. These are predictable stages in the life cycle

TABLE 2–4 Eight-Stage Family Life Cycle

STAGES	CHARACTERISTICS
Stage I	Beginning family, newly married couples*
Stage II	Childbearing family (oldest child is an infant through 30 months of age)
Stage III	Families with preschool children (oldest child is between 2.5 and 6 years of age)
Stage IV	Families with school-age children (oldest child is between 6 and 13 years of age)
Stage V	Families with teenagers (oldest child is between 13 and 20 years of age)
Stage VI	Families launching young adults (all children leave home)
Stage VII	Middle-aged parents (empty nest through retirement)
Stage VIII	Family in retirement and old age (retirement to death of both spouses)

*Keep in mind that this was the norm at the time the model was developed, but today families form through many different types of relationships.

Source: Adapted from Duvall, E. M. (1977). Marriage and family development (5th ed.). Philadelphia, PA: Lippincott; Duvall, E. M., & Miller, B. C. (1985). Marriage and family development (6th ed.). New York, NY: Harper Row; Coehlo, D. P. (2015). Family child health nursing. In J. R. Kaakinen, D. P. Coehlo, R. Steele, A. Tabacco, & S. M. H. Hanson, Family health care nursing: Theory, practice, and research (5th ed., pp. 387–432). Philadelphia, PA: F. A. Davis

of every family, but they follow no rigid pattern. Duvall's (1977) eight stages in the family life cycle of a traditional nuclear family have been used as the foundation for contemporary models of the family life cycle that describe the developmental processes and role expectations for different family types. Table 2–4 lists the eight stages of Duvall's family life cycle to illustrate important developmental transitions that occur at some point in most families.

Other family development models have been developed to address the stages and developmental tasks facing the unattached young adult, the gay and lesbian family, those who divorce, and those who remarry. Textbooks on families and developmental psychology provide further information on this topic.

Nurses can assess families by their developmental stage, how well they are fulfilling the tasks of that stage, and the availability of resources to accomplish developmental tasks. The stages provide a method for anticipating transitions and potential stressors with family role changes that occur at different points along the developmental continuum for different family types. By understanding the family's developmental stage, the nurse can analyze the family growth and health promotion needs and identify developmental transitions and potential stressors. This enables the nurse to identify the types of teaching and anticipatory guidance that might be needed.

Family Systems Theory

Family systems theory focuses on the family as an "organized whole and/or as individuals within family units who form an interactive and interdependent system" (Kaakinen & Hanson, 2015, p. 76). A family is a living social system, consisting of a small group of individuals who are closely interrelated and interdependent while collaborating to attain family functions and goals. In short, the family is more than the sum of its members (Clark, 2015; Kaakinen & Hanson, 2015). In family systems theory, due to the amount of interrelationship and interdependence in the family, any change or stressor experienced by one or more family members affects the entire family and causes disruption. Families are adaptable and can change interactions and behaviors associated with the disruption in response to positive feedback.

From a systems perspective, the family may or may not exchange materials, energy, and information with its physical, social, and cultural environments. An *open family* seeks information and resources and actively interacts with the community to solve problems. A *closed family* views change and offered support as a threat, and resistance to outside influences is a strategy the family uses to maintain control. These attributes have an effect on the capacity of the family to adapt—to modify behavior and change as the situation demands (Clark, 2015; Kaakinen & Hanson, 2015).

Family systems theory encourages nurses to see the child and parents as participating members of a whole family (Kaakinen & Hanson, 2015). It encourages looking at the processes within the family and the relationships between subsystems (spouse, parent–child, and siblings) and suprasystems (the community within which it is embedded). Stress and crises motivate the family to mobilize its resources and to begin problem solving.

Using this perspective, the nurse can assess the effects of illness or injury on the entire family system and the reciprocal effects of the family on the illness or injury. Assessing how open or closed the family is to information and resources is important in planning nursing care. Open families will be more receptive to referrals and interventions from health professionals. The nurse will need to work with the closed family to establish trust and acceptance before the family is receptive to ideas and interventions proposed.

Family Stress Theory

Family stress theory focuses on the family's ability to cope and adjust to stressful events, such as having a child with a significant health condition (Ramisch, 2012). Most families know their resources and have developed coping strategies to deal with daily routine stressors (e.g., completion of household chores, homework). Family stressors may pile up from many sources, such as work demands, school issues, extended family demands, the desire to achieve quality family time, and community roles. Additional stressors may include inadequate finances, healthcare concerns, and relationship challenges.

Nonroutine stressors (such as surgery or the birth of a child) and unexpected events (a child's sudden illness or injury) are often more stressful because the family has not had time to review resources and prepare a response. A child's illness or injury affects every member of the family. Family members respond to this stress, sometimes in a way that changes interactions among family members and with the environment. By identifying how families respond to the stress of a child's illness or injury, nurses can provide support that may reduce the impact on the entire family.

No one theory is sufficient for viewing the needs and behaviors of all families. The theories previously described herein continue to evolve as researchers identify new or broadened explanations for behaviors, so it is difficult to attach one specific theorist to each family theory. When assessing families, you may find it useful to consider more than one of these theories to help you understand the full set of behaviors associated with individual families and to plan effective nursing interventions.

Family Assessment

To identify strategies for **coping** (the use of learned behavioral and cognitive strategies to manage or relieve perceived stress), nurses must be able to assess family strengths and support mechanisms and to determine when families have overextended their resources and need additional support. In some cases, nurses can provide the additional support needed. At other times, referral to other health professionals is appropriate to address the family's needs.

Children and families live within a variety of settings and interact with those settings in ways that directly or indirectly influence behaviors and learning. Because of these environmental influences on the family, it is important to consider the relationship of the family with the social networks within the community.

Family Stressors

A child's illness or injury affects every member of the family. Such a stressor demands a response from the family members that can change the way they interact with each other and with other people. Nurses need to identify and assess how families respond to the stress of illness or injury of a child or other family members because of the potential hardships it causes the entire family.

Family Strengths

Family strengths are the relationships, processes, and resources that families can use during times of adversity and change to manage stressors. Nurses can support families by helping them identify and use these strengths to manage the stressors associated with family challenges or crises. Strengths that enable families to develop and adapt to stressors include (Lester et al., 2013):

- Resources such as education, prior experiences, and finances
- Effective communication and collaborative problem solving
- Being emotionally aware and working to maintain emotional stability
- Developing shared meaning about the experience

Identify a family's **resilience**—the family's capacity to develop strengths and abilities to "bounce back" from stress and challenges. Resilience is often a dynamic interaction between protective processes (strengths and capacities) and vulnerabilities, such as life-event stressors, health status, or environmental risks (Herrman, Stewart, Diaz-Granados, et al., 2011). When a family can control and deal with events satisfactorily, its members gain a sense of competence, making them more resilient, in contrast to families who are overwhelmed by traumatic experiences. Resilience of children is discussed in Chapter 17.

Most families have the capacity to develop resilience. Nursing support may be needed to help family members learn new skills, make adaptations, and gain confidence in their abilities to manage the challenges of the child's health condition. Potential resources to foster resilience include the faith community, finances, social support, physical health, family flexibility, and family coping mechanisms. Families with fewer resources will be more susceptible to disruption when a healthcare crisis or event occurs.

Clinical Tip

Family strengths helpful in managing stressors include the following:

- *Communication skills:* The ability of family members to listen, gather information, and discuss their concerns in an honest and open manner
- *Shared family values and beliefs:* The family's common perceptions of reality and willingness to have hope and to appreciate that change is possible; family celebrations; family traditions
- *Intrafamily support:* The provision of support and reinforcement by extended family members to promote family cohesion and an atmosphere of belonging; family time and routines
- *Self-care abilities:* The family's ability to take responsibility for health problems and the demonstrated willingness of individual members to take good care of themselves
- *Problem-solving skills:* The family's use of negotiation in problem solving, using daily and prior life experiences as resources, and focusing on the present rather than past events or disappointments; effective utilization of healthcare resources
- *Community linkages:* Maintenance of active linkages with the community; reaching out to others in the social network including extended family and friends

Functional families use their strengths and a variety of coping strategies to successfully reduce stress. Coping strategies of dysfunctional families are generally defensive (e.g., denial of family problems, exploiting a family member, use of threats or withdrawal of affection and support, dominance and submissive patterns, and family substance abuse).

After developing a rapport and relationship with the family, the nurse can help families identify their strengths and areas for improvement that can lead to increased resilience. Focus on family competence and acknowledge and validate family members' emotions. Help families recognize that strengths and strategies used in prior life experiences may transfer to the current healthcare experience. When family members recognize the strengths they bring to the management of their child's healthcare problem, the family is more likely to become an effective partner in the process.

Collecting Data for Family Assessment

Establish a trusting relationship with the child and family to obtain an accurate and concise family assessment. Identify the primary concerns of the parent(s) and child, noting that they may be different. Acknowledge these multiple concerns and demonstrate respect for the diversity of the family. The goal is to obtain family information to plan nursing interventions that help the family care for the child and improve the child's outcomes while valuing each family member.

Information about the family is collected continuously during the healthcare process, through interviews, observations of family interactions, reports from other healthcare providers or agencies working with the family, and with a family assessment tool.

Additional data for the family assessment include the psychosocial history and daily living patterns (see Chapter 5). Observation of the home and family members is recommended in some cases to obtain valuable information about family functioning.

Family Assessment Tools

Family assessment tools help in gathering information about the family's functioning. Some tools specifically focus on family strengths, coping strategies, and family stresses. Learning about how the family nurtures its members, solves problems, and communicates may help identify strategies that can be effective for managing the child's health care. The nurse may learn how to work more effectively with the family, such as by collaborating with the family in planning for health maintenance and health promotion strategies.

GENOGRAM

Information about family structure can be illustrated on a **genogram** (a pedigree that displays information about a family's health history over at least three generations). (See Chapter 3 for examples of pedigrees.) Additional identifying features such as social class, occupation, place of residence, faith, and ethnicity may be added for the family assessment process.

FAMILY ECOMAP

An **ecomap** is an illustration of a family's relationships and social networks that may be prepared by nurses in partnership with family members. The nurse may learn information about how the family perceives or receives social support and the strength of family relationships with significant other persons and organizations. Community resources being used by the family and other potential community resources that may help promote the family's health may be identified. Figure 2–8 shows a sample ecomap.

Clinical Tip

Family assessment data that may be helpful include:

- Name, age, gender, and family relationship of all people residing in the household
- Family type, structure, roles, and values
- Cultural associations, including cultural norms and customs related to childrearing and infant feeding
- Faith-based group participation
- Support systems network, including extended family, friends, faith-based affiliations, and community associations
- Communication patterns, including language barriers
- Environmental data—place of residence, housing condition, number of persons living in the residence, sleeping arrangements, play areas, neighborhood characteristics

CALGARY FAMILY ASSESSMENT MODEL

Developed by Lorraine Wright and Maureen Leahey (2013), the Calgary Family Assessment Model uses three categories of information (structural, developmental, and functional family data) to assess a family's strengths and problems. The complete model is available in their textbook, *Nurses and Families: A Guide to Family Assessment and Intervention*. The model enables collection of extensive family information, and it can facilitate

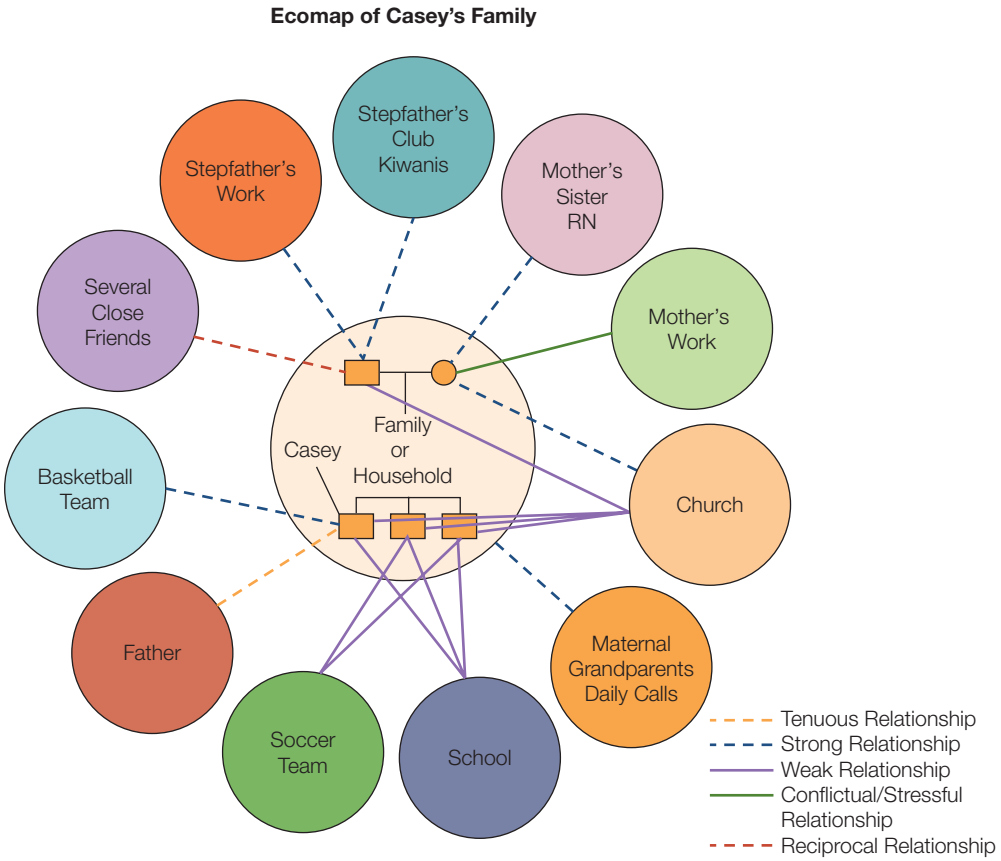

Figure 2–8 **An ecomap illustrates the family's relationships and interactions with groups and individuals in the immediate external environment.**

assessment of family challenges, such as problems integrating a treatment plan in family routines. A family genogram or ecomap may also be helpful in completing the assessment (Wright & Leahey, 2013).

HOME OBSERVATION FOR MEASUREMENT OF THE ENVIRONMENT (HOME)

The HOME Inventory is an assessment tool developed to measure the quality and quantity of stimulation and support available to a child in the home environment (Caldwell & Bradley, 1984). The tool is used to identify relationships between the home environment, child care, and a child's development (Hackman et al., 2013; Sarsour et al., 2011). Four age-specific scales are available (birth to 3 years, 3 to 6 years, 6 to 10 years, and 10 to 15 years). Examples of subscales contained in each age-specific HOME Inventory include parental responsivity, acceptance of child, the physical environment, learning materials, variety in experience, and parental involvement. Data are collected during an informal, low-stress interview and observation over 45 to 90 minutes in the home setting. The child's primary caregiver and the child must be present and awake so their interaction can be observed. Family members are encouraged to act normally. Assessment of the home environment may help identify nursing interventions that promote the child's growth and development, such as items in the home that can be used for toys and strategies for parent interaction with the child to promote learning.

Cultural Considerations

When caring for families, it is critical to consider the influence of culture, which may affect how a family responds to health-related issues. **Culture** has many definitions and is currently described as

> the combination of a body of knowledge, a body of belief, and a body of behavior. It involves a number of elements, including personal identification, language, thoughts, communications, actions, customs, beliefs, values, and institutions that are often specific to ethnic, racial, religious, geographic, or social groups. (U.S. Department of Health and Human Services, National Institutes of Health, 2013)

Culture is characterized by certain key elements, including the following:

- Culture is based on shared values and beliefs. Expected behaviors and roles emerge that are consistent with those values and beliefs. A belief system suggests what preventive health measures and treatment for diseases are sought and accepted. It may also state the importance of children, the family, other individuals, and the collective group, all of which can influence the choices people in the culture make regarding health.
- Culture is learned and dynamic. A child is born into a culture and starts learning the beliefs and practices of the group from birth. Children who are members of two cultural groups, such as African and immigrant, learn about both groups as they grow and develop. Immigrants have moved from one country to another to live and may face challenges when integrating the rules of the dominant culture. Children who have family members from two or more cultural groups integrate parts of the worldview from each group. Therefore, although culture is connected with groups, each individual's manifestation of his or her own cultural background will be unique. Culture evolves and adapts as new members are born into or join the group and as the surrounding social and physical environments change. For example, as first-generation immigrants enter a new country, they generally closely follow the cultural patterns of their native lands. As their children grow, the youth maintain some of the family cultural patterns but begin to incorporate some of the new culture (Figure 2–9).
- Culture is integrated into life and uses symbols. It is integrated through social institutions such as schools, houses of worship, friendships, families, and occupations. This provides a variety of opportunities for learning about one's culture. The sense of integration may be disrupted or harder to maintain if individuals move frequently and as cultures intertwine with each other. Symbols are an important way that many cultures communicate with each other and with the outside world. Language, dress, music, tools, and nonverbal gestures are symbols a culture uses to display and transmit the culture.

Race refers to a group of people who share biologic similarities such as skin color, bone structure, and genetic traits. Examples of races include White (sometimes called Caucasian or European American), Black (sometimes called African American in the United States), Hispanic, Natives (such as Native Americans, Alaskan Native, Hawaiian Native, and First Nation people of Canada), and Asian.

Ethnicity describes a "cultural group's sense of identification associated with the group's common social and cultural heritage" (Spector, 2013, p. 357). Examples of ethnic groups include Hmong, Jews, and Irish Americans. Even the mainstream or majority of groups usually identify with an ethnic group. Some beliefs and practices are common among certain ethnic groups, but it is important to avoid **stereotyping** individuals—that is, assuming that all members of a group have the same characteristics. The nurse should assess the woman or child and family to see which characteristics common to a group are possessed by

Figure 2–9 **Today very few communities are limited to one culture. The children in this multicultural choir are representative of the changes in demographics of many Western countries. Even though they may differ in cultural background, a common thread is found in their religious preference.**

SOURCE: Myrleen Pearson/PhotoEdit.

the patient rather than assume that because individuals identify themselves as a specific ethnicity they must practice certain customs.

Acculturation refers to the process of modifying one's culture to fit within the new or dominant culture. **Assimilation** is related to acculturation and is described as adopting and incorporating traits of the new culture within one's practice (Spector, 2013). Acculturation frequently occurs when people leave their country of origin and immigrate to a new country. Often, acculturation is associated with improved health status and health behaviors, especially if the immigration is associated with improved socioeconomic status, which leads to better nutrition and access to health care. This is frequently true for people who immigrate to the United States from a developing country. On the other hand, health sometimes declines with acculturation. For example, obesity is a problem that is growing rapidly within the United States and particularly among immigrant populations.

Cultural Assessment

In addition to the family assessment tools referred to earlier in this chapter, there are several tools (see Table 2–5) that can be used for cultural assessment of the family. Nurses must also consider contexts, such as the person's family, culture, work, community, history, and environment. The person must be in a state of balance within all personal and contextual parts. Illness occurs as a result of imbalance of one or all parts of the person (mind, body, spirit).

TABLE 2–5 Cultural Assessment Models

THEORIST	MODEL	DESCRIPTION	COMPONENTS/CONCEPTS
Dr. Madeleine Leininger	Sunrise Enabler	This guide can be used to examine a variety of influences on care and culture.	• Cultural values and lifeways • Political and legal factors • Economic factors • Educational factors • Kinship and social factors • Religious and philosophical factors • Technological factors (McFarland & Wehbe-Alamah, 2015, p. 25)
Dr. Larry Purnell	Model for Cultural Competence	Twelve major concepts are common to all cultures and can be assessed to provide important information about an individual family or group (Purnell, 2013).	• Overview, inhabited localities, and topography • Communication • Family roles and organization • Workforce issues • Biocultural ecology • High-risk behaviors • Nutrition • Pregnancy and childbearing practices • Death rituals • Spirituality • Healthcare practices • Healthcare providers (Purnell, 2013, p. 18)
Dr. Joyce Newman Giger and Dr. Ruth Davidhizar	Transcultural Assessment Model	The client is the center of care and culturally unique. Knowledge of the cultural heritage, beliefs, attitudes, and behaviors of the client is required to provide culturally competent care. This model is based on six phenomena that nurses must assess.	• Communication • Space • Social organization • Time • Environmental control • Biologic variations (Giger & Davidhizar, 2013, p. 5)
Dr. Rachel Spector	HEALTH Traditions Model	This model is predicated on the concept of holistic health and describes practices that can be used to maintain, protect, and restore health. Health is a complex, interrelated, and balanced state of the physical, mental, and spiritual.	• Physical—all physical aspects, such as anatomic organs, gender, age, nutrition, genetic inheritance, body chemistry, and physical condition • Mental—cognitive processes, such as memories, thoughts, and knowledge of such emotional processes as feelings, self-esteem, and defenses • Spiritual—both positive and negative learned spiritual practices and teachings, dreams, stories, and symbols; protecting forces; and metaphysical or innate forces (Spector, 2013, p. 91)

Upper Saddle River, NJ: Pearson.

Cultural Practices That Influence Health Care

FAMILY ROLES AND ORGANIZATION

A family's organization and the roles played by individual family members are largely dependent on cultural influence. For example, culture may determine who has authority (head of household) and is the primary decision maker for other members of the family. Nurses should be alert for roles and functions in families. Teaching may need to be directed to those responsible for decision making in order to effectively promote the child's health.

Culture also defines gender roles and the roles of the elderly and of extended family. In some cultures, major decisions for the family, including a child's health care, involve input from grandparents and other extended family members (Figure 2–10). Grandparents may even assume responsibility for care of the children in the family. In these cases, nurses must direct teaching for health promotion and demonstration for treatment procedures to the grandparent.

Family goals are also determined by cultural values and practices, as are family member roles and childrearing practices and beliefs. In some families, children are expected to take on responsibilities early and may be expected to perform tasks such as management of their own chronic disease and nutritional intake. In other families, children are given long periods to grow up and are not expected to manage healthcare needs. Examples of childrearing practices common to particular cultures are listed in Table 2–6. Realize that the practices listed are common in these cultures but not necessarily practiced by all members of that culture.

Figure 2–10 **Many cultures value the input of grandparents and other elders in the family or group. For example, in this multigenerational family, the grandmother's guidance is highly valued and significantly influences the family's childrearing practices.**

SOURCE: Wong yu liang/Fotolia

TABLE 2–6 Childrearing Practices of Selected Cultures

CULTURE	CHILDREARING PRACTICES
African American	Grandmothers play an important role in the care of children. Children are expected to demonstrate respectfulness, conformity to rules, obedience, and good behavior. Extended family is very important.
Amish	The family contains, on average, seven children. Childrearing is regarded as the highest priority for parents. Grandparents often provide care to children. Children are expected to continue with the Amish tradition. Children are expected to follow the rules as prescribed by the church district.
Appalachian	Large families are common. Strict parenting practices and physical punishment are common. Grandparents frequently provide care to children.
Arab American	The father is typically the disciplinarian. The child's character is considered a reflection of the family's influence. Children are expected to respect their elders and to have good behavior. Adolescents are expected to do well in their studies. Discipline may include physical punishment and shaming.
Chinese American	The family may lavish resources on the child. Children typically depend on family for all needs and may not be expected to earn their own money as adolescents. Male children are often more valued than female children. Children may be taught to avoid displaying their emotions/feelings. Children are expected to assist parents in the home (chores). High educational achievement is expected.
Mexican American	Children are closely protected and are not encouraged to leave the home. Extended family members frequently live close by. Children are expected to demonstrate respect for parents and elderly family members. Discipline may include physical punishment. Education is a priority.
Navajo Indian	Large families are important. Grandmothers are important decision makers in the family. Children are encouraged to make decisions and live and learn from those decisions. Children are taught to respect their elders and be respectful of traditions.

COMMUNICATION

Communication is the method by which members of cultural groups share information and preserve their beliefs, values, norms, and practices. Information is transmitted through both verbal and nonverbal methods. Verbal communication consists of spoken or written words, including tone and level of voice, language, verbal style and dialect, and written material.

Obviously, verbal communication is improved when a healthcare provider speaks the same language as the patient and family. Children are most likely to speak both the language of the parents and the healthcare providers and may appear to be likely interpreters. However, it is recommended that children never be used to interpret in healthcare situations due to the confidentiality needs of both parent and child. Additionally, if children are used as interpreters, it can create an imbalance in power that could adversely affect parental authority. Signs, posted literature, and brochures should be available in the languages of the children and families served. Even when children speak the language of the healthcare providers, written material must be provided at a level that the family can read and understand.

Language can also affect health literacy skills, as a large number of instructions are given in writing, including prescriptions and directions on medication bottles, signs hanging in health facilities, consent forms for procedures and surgery, insurance forms, directions for techniques or procedures, future appointment dates, and health promotion materials. Verify what the child and family can read and whether alternative methods should be used. Nurses can verbally give the information and provide paper and pencil so the family can take notes in their own language. Translation services should be available in all healthcare settings, including the pharmacy, the appointment desk, and for phone calls, to ensure access to services for all children and families served.

Clinical Tip

Speaking and reading may not occur in the same language. For example, an immigrant may read and speak fluently in a primary language and speak but not read the language of the new country. The immigrant's child may read and speak the language of the present country and speak but not read the native language of the family. Always ask about both reading and speaking preferences.

Nonverbal communication refers to body language such as posture, gestures, facial expressions, eye contact, and touch, as well as the use of silence. The nurse's use of nonverbal communication may hinder or help communication. Gestures and body language may be misunderstood or misinterpreted. For example, eye contact has different meanings among cultures. Silence is considered a sign of respect in some cultures. Watch for patterns in various cultures and alter your approach to be more congruent.

Touch is another form of nonverbal communication. The appropriateness of touch varies by culture. Adults commonly feel that it is acceptable to touch children of all ages, but this may not be accurate. Watch for responses from the child and family. Nurses must touch children to weigh them, take blood pressures, and give immunizations, but this does not mean that close touch is appropriate at all times.

TIME ORIENTATION

Cultures have specific values and meanings regarding time orientation. Cultural groups may place emphasis on the events of the past, those events that occur in the present, or those events that will occur in the future. Children reflect the time orientation of their families and the cultures in which they live. Time is also influenced by development so that young children sometimes do not understand the use of clocks, the importance ascribed to being "on time," or other time orientations.

Cultures that are oriented predominantly to the past may want to begin healthcare encounters with lengthy descriptions of past healthcare treatments, family history of diseases, or individual past experiences with health. There may be little interest in learning methods of adapting to or maintaining a new plan of care.

For cultures that are oriented predominantly to the present, little consideration may be given to either the past or the future. For example, adolescents commonly focus on the present and may not engage in preventive health practices for long-term health. Therefore, short-term goals often provide more incentive to adolescents.

Cultures that are oriented predominantly to the future, such as European American, may not focus on what is important at the present time. For example, the family focusing on the future may focus on the dreams they had for a child's education or sports performance and have trouble setting present goals for treatment of a disease such as juvenile arthritis. One commonly hears that it was a big adjustment to learn to "take one day at a time." Not living up to the family's expectation for his or her future success may be difficult for a child who has developed an illness that has a chronic course.

Time also refers to punctuality about schedules and appointments. In the United States, the predominant culture respects being on time and considers time valuable and not to be wasted. Other cultures may not emphasize a concern for time. This may be manifested by a family's inability to follow timed medication schedules or treatments or to show up as scheduled for an appointment. In these cases it is not intended as a sign of disrespect.

NUTRITION

Nutritional practices begin even before birth, as many cultural groups have beliefs that determine foods that are healthy to eat or should be avoided during pregnancy. Nutritional habits and patterns vary among cultures and are related to both religious practices and health beliefs. Certain cultures and religions have restrictions on or prescriptions about specific foods and preparation methods. Ritualistic behaviors involving eating and drinking—for example, on special occasions and holidays—are observed by most cultures. Many religions recommend fasts during specific holy seasons, such as Lent for Roman Catholics, Yom Kippur for Jews, and Ramadan for Muslims; however, in most cases, small children, pregnant women, the elderly, and sick individuals are not required to fast.

Additionally, some cultures value large size or may associate a healthy child with being "large." Other cultures value slimness and look down on individuals who are obese. Both of these views influence family eating patterns and expectations for the child; the child's self-esteem can therefore be influenced. The U.S. culture honors being slim in the media but reinforces eating and large size by the availability of fast food and positive image of large sports stars such as some football players, which can result in confusion about health and body image.

Nutrition may also be essential to the culture's practices for health promotion and care during illness. Health problems associated with specific cultures that may require dietary changes are also identified. Nutrition can be closely related to environmental situations, and families with few resources may not be

able to obtain or eat cultural foods due to access or financial issues. Nutrition plays a powerful role in maintaining health, so resources for nutritious and desired foods may be needed.

HEALTH BELIEFS, APPROACHES, AND PRACTICES

The family members' health beliefs influence their approaches and practices regarding health and illness. The young child has a view of health and illness connected with developmental understanding and gradually takes on the family's cultural view while growing older. Additionally, some families, when faced with a life-threatening illness of their child, may seek alternative health practices that are not considered part of their cultural heritage. This is especially true if the family becomes frustrated with traditional biomedical treatments that are unable to cure their child. See Table 2–7 for examples of health practices common to specific cultures. Nurses and other healthcare professionals should learn about the family's belief system and integrate all types of care that the family wishes as long as there is no danger to the child.

Clinical Tip

Some families believe in the hot and cold theory of disease, which subscribes to the thought that illnesses and diseases are a result of disruption in the hot and cold balance of the body. Therefore, consuming foods of the opposite variety can cure or prevent specific hot and cold illnesses. Hot and cold therapies related to healing are practiced in some African American, Asian, Latino, Arab, Muslim, and Caribbean cultures (Andrews & Boyle, 2012); see Table 2–8.

Faith-based belief and practice is an integral part of culture for some families. Views of religion and spirituality can shape their approaches and responses to a child's illness and guide practices to maintain health. Religious beliefs may influence the family's explanation of the cause of a child's illness, their perception of the severity of the illness, and choices of treatments for the illness, and can offer solace to the family and child. For these reasons, it is important to determine the influence of religion and spirituality within the family.

Faith and spirituality can be a source of great comfort and support for children who are ill and their families. Conversely, conflicts may arise between the family's religion or spirituality and biomedical care for the child. For example, the family's pursuit of specific religious therapies can serve as a barrier to biomedical care, because some parents may believe that their spiritual practices can substitute for medical treatment of the child. **Religion**, commonly referred to as **faith-based belief**, is an organized system of shared beliefs regarding the significance of the nature, cause, and purpose of life and of the universe. Religion is usually centered on the belief in or the worshipping of a supernatural or Supreme Being (such as God or Allah).

Spirituality refers to an individual's experience and own interpretation of a relationship with a Supreme Being. Children are spiritual beings and generally express their spirituality through behavior such as imaginative play, art, dance, and song (Lascar, 2013). Prayer, one of the most common expressions of religious faith, is a frequently used therapy in which many children and families engage (Lambert, Fincham, & Graham, 2011; Wachholtz & Sambamoorthi, 2011).

Specific differences in beliefs between families and healthcare providers are common in the following areas: help-seeking behaviors, causes of diseases or illnesses, death and dying, caretaking and caregiving, and childrearing practices.

TABLE 2–7 Health Practices of Selected Cultures

CULTURE	HEALTH PRACTICES
African American	Religious healing (laying on hands) Talismans (amulets or lucky charms) Herbal remedies/oils Use of healers: "Old woman" healers Voodoo healers Shamans Spiritualists Root doctors
Asian American	Acupuncture/acupressure Coin rubbing Cupping Herbs Hot and cold foods Massage Meditation Moxibustion (heat therapy) Qigong (combines meditation, movement, and regulation of breathing) Restoring energy between yin and yang Tai chi Tiger balm Use of healers: Physicians Herbalists Acupuncturists
European American	Amulets Healing rituals Dietary modifications Exercise Traditional medicine Use of healers: Traditional healthcare providers: physicians, nurses, and nurse practitioners
Hispanic or Latin American	Hot and cold foods Herbs Massage Prayers Religious medals Use of healers: Curanderos/curanderas Yerberos or jerberos (herbalists) Brujos/brujas (witches) Espiritistas (spiritualists) Sobadores
Native American	Ceremony Counseling Herbs and plants Healing touch/acupressure Medicine bundle Singing Pipe ceremony Drumming and chanting (prayer) Smudging Sun dance Sweat lodge (purification ceremony) Vision quest (a powerful ceremony) Use of healers: Medicine men or women Shamans

(2013). *Transcultural health care: A culturally competent approach* (4th ed.). Philadelphia, PA: F. A. Davis; Spector, R. E. (2013). *Cultural diversity in health and illness* (8th ed.). Upper Saddle River, NJ: Pearson.

In differing degrees these elements influence the cultural beliefs and values of an ethnic group, making the group unique. Misunderstandings may occur when the healthcare professional and the family come from different cultural groups. In addition, past experiences with health care may have made the family angry or suspicious of providers. Nurses must be able to recognize, respect, and respond to ethnic diversity in a way that leads to a mutually desirable outcome. The nurse must identify culturally relevant facts about the patient to provide culturally appropriate and competent care. For example, some cultural groups practice complementary and alternative therapies that are unknown to the nurse (see the section titled "Complementary and Alternative Modalities"). Although some of these therapies are beneficial or cause no harm, others may interact with prescribed medications and be harmful.

Clinical Tip

Avoid imposing your personal cultural values on the children and families in your care. By learning about the values of the different ethnic groups in the community—religious beliefs that have an impact on healthcare practices, beliefs about common illnesses, and specific healing practices—you can develop an individualized nursing care plan for each child and family.

Cultural competence refers to the ability of the nurse to understand and effectively respond to the needs of patients and families from different cultural backgrounds (Spector, 2013). Recognizing the influence of culture on one's beliefs, values, and healthcare practices is essential for the nurse in order to deliver culturally competent care. The nurse should also consider the potential that an extended family member may need to be consulted regarding the treatment plan for the child, especially if the child spends a lot of time with extended family members.

Nurses demonstrate appropriate strategies for delivering culturally sensitive care when they develop techniques in assessing the influence of culture on the child and family and incorporate that information into an individualized plan of care. When the family's cultural values are incorporated into the care plan, the family is more likely to accept and adhere to the recommended care, especially in the home care setting.

Culturally competent nurses find effective ways to work with the family to determine how they can incorporate prescribed therapies with their healthcare practices. Ensure that the child and family understand the problem or illness, treatment, and health promotion activities. Apply culturally sensitive techniques when dispelling any cultural myths. See *Developing Cultural Competence: Traditional Healthcare Providers*.

Professionalism in Practice Standards of Practice for Culturally Competent Nursing

Standards of Practice for Culturally Competent Nursing were developed to guide nursing practice. These standards focus on clinical practice, education, administration, and research. Emphasis is placed on the importance of provided culturally competent care to all patients and families (Douglas, Pierce, Rosenkoetter, et al., 2011). Identify and learn more about the cultures in the community where you provide nursing care so that you provide culturally competent care to your patients.

Developing Cultural Competence Traditional Healthcare Providers

When appropriate, collaborate with the family to determine the role traditional healthcare providers and other practitioners (e.g., folk healers, spiritualists) will have in the care of the child. Encourage collaboration and communication between practitioners to ensure continuity of care.

Nurses can also collaborate with a multidisciplinary team including social workers and language specialists to assist the family in receiving assistance with barriers to care such as transportation, financial issues, remote access, and others.

Complementary and Alternative Modalities

Complementary and alternative modalities (CAM) are generally described as healthcare approaches that are not considered to be part of conventional Western medicine (National Center for Complementary and Alternative Medicine [NCCAM], 2013a). Although the terms *complementary* and *alternative* are often used interchangeably, they have different meanings and applications. A **complementary therapy** may be defined as any procedure or product that is used as an adjunct to conventional medical treatment (Mitchell, 2013; NCCAM, 2013a). An example of a complementary therapy is the use of massage therapy in conjunction

with biomedical therapy, such as narcotic analgesics, for a child with cancer pain.

In contrast, an **alternative therapy** is usually considered a substance or procedure that is used in place of conventional medicine (NCCAM, 2013a). An example of an alternative therapy is the use of herbal medicines instead of traditional Western medical care for a child's health condition, such as surgery, radiation, prescribed medications, or other medical interventions.

The dramatic increase in complementary and alternative therapies that began in the final decade of the 20th century was probably the result of a combination of several factors:

- Increased consumer awareness of the limitations of conventional Western medicine
- Increased international travel
- Increased media attention
- Advent of the Internet

The NCCAM (2013a) classifies complementary health approaches into two main subgroups: natural products and mind and body practices. *Natural products* include herbs, vitamins, minerals, and probiotics (also referred to as dietary supplements). Examples of *mind and body practices* include acupuncture, massage therapy, meditation, relaxation, yoga, healing (therapeutic) touch, and hypnotherapy. Some examples of complementary and alternative modalities are provided in Table 2–9.

Safety Issues Concerning CAM Therapies

The misleading claims of usefulness, dosing safety of some products, and lack of manufacturing standards of natural products are just a few of the issues raised with the use of herbs and natural products. Parents often believe that herbs and natural products are less likely to be harmful than prescribed medications, failing to

TABLE 2–9 Selected Types of Complementary and Alternative Modalities

THERAPY	DESCRIPTION	POTENTIAL USE IN CHILDREN	NURSING IMPLICATIONS
Aromatherapy	Essential oils (extracts or essences) from flowers, herbs, and trees provide strong, pleasant odors to promote relaxation, health, and well-being.	The family may use candles or oils to promote a child's pain relief or to encourage the child's relaxation. Use of aromatherapy in the hospital may reduce nausea due to hospital odors.	Few side effects when used as directed; however, allergies to oils may worsen symptoms in a child with asthma and other pulmonary disorders. Caution families to avoid aromatherapy.
Dietary supplements	A product (other than tobacco) is taken by mouth that contains an ingredient intended to supplement the diet, such as vitamins, minerals, herbs or other botanicals, amino acids, and substances such as enzymes, organ tissues, and metabolites. Dietary supplements come in many forms, such as extracts, tablets, capsules, liquids, and powders. They have special labeling requirements.	Many parents administer daily multiple vitamins to their children. For example, echinacea is an herb that is used to treat colds and the flu and stimulate the immune system.	Assess the family's use of dietary supplements for the child. Determine potential interactions between supplements and prescribed medications. Teach parents about safe dosages and safe storage of vitamins and other dietary supplements for children. Herbs must be used with caution in children.
Massage	Therapists press, rub, and manipulate muscle and soft tissues to enhance function of those tissues and promote relaxation, well-being, and relief from pain.	Massage is beneficial in children who have discomfort related to teething; it reduces colic, promotes sleep, reduces pain related to procedures such as immunizations, and promotes growth of preterm infants (Fontaine, 2015). See Figure 2–11.	Assess the child for benefits of massage. Potential contraindications to massage therapy may include bleeding disorders, fractures, and an open or healing wound.
Therapeutic touch	In therapeutic touch, the healing force of the therapist affects the patient's recovery. Healing is promoted when the body's energies are in balance. By passing their hands over the patient, without touching the patient, healers can identify energy imbalances.	The family may enlist a spiritualist or other practitioner to perform therapeutic touch on the child to promote pain relief or a quicker recovery.	Assess the benefits of therapeutic touch on the child (e.g., pain relief). Partner with the family to establish other methods of pain relief if therapeutic touch is not effective.
Faith-based therapies	Prayer is a commonly used form of complementary therapy. Other faith-based therapies include faith healing, lying on hands, meditation, and anointing.	Families may include a variety of faith-based therapies, depending on the child's condition. Spiritual health may help improve quality of care, decrease anxiety, and increase positive feelings, such as hope, optimism, and freedom from regret.	Provide the child and family a private environment for faith-based practices. Assess for benefits of the therapies. Partner with the family to determine alternative methods of therapy if needed.

recognize that safety concerns exist. However, "natural" is not the same as safe, and many CAM products have not been evaluated for use in children. Examples of problems that may occur with the use of complementary and alternative modalities include:

- Interaction with prescribed medications (interferes with metabolism of medication or increases the effect of the prescribed medication, like an overdose)
- Side effect or allergic reaction directly associated with the product
- Substitution of the product for a prescribed medication that is potentially lifesaving
- Toxic effects because of contaminants or other additives in the product, or if the plant used for the herb was incorrectly identified

The use of CAM in the care of children must be addressed because of the limited research with this age group and developmental variations that may influence efficacy and safety. Although many CAM therapies may have been proven effective in adults, they may have little effect on children, or even be harmful. The National Institutes of Health and the Agency for Healthcare Research and Quality have set research agendas to investigate the effectiveness of CAM therapies for treatment.

Complementary and alternative modalities must be assessed for safety, including positive and negative benefits, cost, efficacy, and clinical usefulness. The use of herbs and natural products raises many issues, such as standards of products, misleading claims, safety related to megadoses of some products, and standardization of natural products. Determine the family's use of complementary and/or alternative medicine such as the type of remedies and healthcare practices used. Also determine the side effects, risks, and other implications to the child receiving this type of therapy. Partner with the family to ensure safe practices with the use of CAM products.

SAFETY ALERT!

Complementary and alternative therapies must be assessed for safety, including positive and negative benefits, cost, efficacy, and clinical usefulness. The use of herbs and natural products raises many issues, of which these are just a few: standards of products, misleading claims, and safety related to megadoses of some products. When the family does not disclose CAM use to the healthcare provider, the risk of interaction with conventional medicines and harm to the patient increases (Adams et al., 2013). See *Families Want to Know: CAM Therapies*.

Nursing Management

The goal of culturally competent family-centered nursing management is to assess and help families recognize their strengths and resilience. This information can then be used in collaboratively planning the nursing care with the child and family. See *Evidence-Based Practice: Investigating Culture and Healthcare Barriers*.

Nursing Assessment and Diagnosis

The presence of a newly acquired disability adds a dimension of developmental risk. The child and family members may respond with either psychologic or behavioral problems, or they may respond in a more positive manner.

Collect the psychosocial history and daily living patterns data from the family and child. Assessment of the culturally diverse child and family includes determining the family's healthcare practices such as health traditions, health beliefs, health-seeking behaviors, healthcare practitioner, and religion or spirituality.

Select the appropriate family assessment tool to collect information that can help evaluate the family's strengths and resources. Analyze the information collected and focus on key information that will help develop a plan of care for the child and family. Follow these steps:

- Determine how this condition influences family functioning.
- Identify how all the family members have responded to the child's acute condition and disability.

Families Want to Know

CAM Therapies

Once the nurse has been informed about CAM therapies used, potential side effects and risks can be considered, such as interactions between an herb and a prescribed medication. Partner with the family to promote the following safe practices for CAM use (NCCAM, 2013b):

- Ensure that your child has received an accurate diagnosis from a licensed healthcare provider and that CAM use does not replace or delay conventional medical care.
- If you decide to use CAM for your child, do not increase the dose or length of treatment beyond what is recommended. More is not necessarily better.
- If your child experiences an effect from a CAM therapy that concerns you, contact your child's healthcare provider.
- Store herbal and other dietary supplements out of the sight and reach of children.

- Obtain information about how the family is considering management of the child's care at home.
- Determine if other family issues or stressors must be integrated into the plan of care.
- Identify the family's expectations of different health professionals and facilities to help manage the child's care.
- Prepare an ecomap and genogram.

Examples of nursing diagnoses that may result from the family and home assessment include the following (NANDA-I © 2014):

- ***Coping: Family, Compromised,*** related to multiple simultaneous stressors
- ***Family Processes, Interrupted,*** related to child with a significant disability requiring alteration in family functioning
- ***Caregiver Role Strain, Risk for,*** related to child with a newly acquired disability and the associated financial burden
- ***Social Interaction, Impaired (Parents and Child),*** related to lack of family or respite support

Planning and Implementation

Families need support to increase resources and coping behaviors so they can successfully manage the multiple stressors of daily living along with a child's chronic condition.

Establishing a therapeutic relationship with the family is an important intervention. This relationship should be characterized by empathy and trust, as well as the development of mutually identified goals for the child's care. To help families develop resilience, focus on family competence and strengths. Acknowledge and validate their emotions. Provide information in a clear, timely, and sensitive manner. Ask questions that help direct the family's thinking rather than providing them with all the answers. Teach families to identify solutions until they are able to independently problem solve. Linkage with other families who have faced similar situations may be helpful.

EVIDENCE-BASED PRACTICE | Investigating Culture and Healthcare Barriers

Clinical Question

What barriers to providing accessible health care exist among ethnically diverse families with children?

The Evidence

Ferayorni, Sinha, and McDonald (2011) examined demographic characteristics, socioeconomic status, access to care, perceived barriers to care, compliance with follow-up care, and unmet health needs in foreign-born children who visited a pediatric emergency department. Parents of 385 children were interviewed during a visit to the emergency department and over the telephone 1 week after the visit. Twenty-three percent of these children did not have health insurance. Compared to children with health insurance, those who did not have coverage were less likely to have a regular healthcare provider and a regular place for health and dental care. Parents of 31% of uninsured children cited a perceived barrier to care. Barriers reported most often were language, lack of insurance and inability to pay, and transportation. Parents of 26 children reported unmet healthcare needs, with a slightly higher prevalence among uninsured children as opposed to insured children. Dental care was the most commonly reported unmet healthcare need. Uninsured children who were foreign born were primarily Spanish speaking, poorer, and had poor access to health care. This population was also more likely to use the emergency department for its healthcare needs.

Adorador, McNulty, Hart, and Fitzpatrick (2011) examined perceived barriers to immunizations in 108 Latino mothers of children in a low-income clinic. Results of the immunization survey revealed that 92% of mothers thought their children were up to date on their immunizations when health records indicated that only 42% were up to date. Barriers to immunizations identified by these mothers included the child being sick, transportation issues, no health insurance, affordability, language concerns, and childcare issues.

Taylor, Nicolle, and Maguire (2013) conducted interviews with 38 healthcare professionals to determine their perceptions of the barriers that ethnic minorities who spoke poor or no English encountered when seeking health care. Five key themes emerged from the interviews: language; low literacy; retention of information; lack of understanding; and attitudes, gender attitudes, and health beliefs.

Best Practice

Socioeconomic status is a theme in two of these studies. These families may not have health insurance, a regular healthcare provider, or adequate transportation. Nurses need to refer families to sources for healthcare services and then follow up to be sure the families were able to access care. Referrals to community health centers and instructions for transportation to the health setting are important for many families. A need for understandable information is another theme among most groups. Explaining why an immunization is needed as well as providing information about the child's condition are important nursing roles. Interpreters may be needed to provide this information. Referring the family to others from the same ethnic or racial group and assisting them in navigating complex systems such as school and social services may also be necessary. Cultural differences and practices were also cited as a barrier to health care. It is essential that healthcare providers become familiar with other cultures and be accepting of practices that are safe for the child. By being open to practices of other cultures, healthcare providers will find families more willing to share openly about how they treat their children. This may lead to an opportunity for education related to unsafe practices.

Clinical Reasoning

What is the process that immigrant families in your state or province must follow to secure health care for their children? How would you help to guide someone through this process? What cultural groups are common in your community? Do you speak their language? If not, what measures should you take to ensure that they understand the teaching offered in clinical settings? What type of support groups will be helpful for families when they have a child with special healthcare needs?

Assist the family to begin planning for ongoing care using family-centered principles:

- Identify the primary decision maker for the child's health care.
- Discuss the family's goals for managing the child's care in the home setting.
- Consider how the family's strengths and previous problem-solving experiences can be integrated into the intervention.
- Consider the family's ethnic and religious background in developing intervention recommendations. Assist the child and family to determine how they can incorporate prescribed therapies with their healthcare practices. Ensure that the child and family understand the child's illness, treatment, or health promotion. Apply culturally sensitive techniques when dispelling any cultural myths.
- Ask questions in a respectful and nonjudgmental manner to help identify a family's use of CAM, encouraging the parent to share the information.
- Offer the family one or more potential interventions rather than trying to force one intervention. Be open to modifying the intervention or devising an alternative intervention to better match the family's lifestyle or cultural preferences.
- Identify the type of support or assistance the family would like to have.
- Identify potential resources in the community that match the child's and family's needs for support. Collaborate with the family to discuss those resources and to select those that are acceptable to the family.
- Make sure the family has a care coordinator, especially when a family member seems to be unable to assume the case management role initially. Assist families in obtaining resources through such actions as role rehearsal, providing instructions and support when making an initial call, or connecting with another family support person who can help with resource linkage.
- Refer families with moderate or severe dysfunction to community resources for social support and counseling, as appropriate.

Evaluation

Expected outcomes of nursing care include:

- Collaboration of the child and family with an assigned case manager so that interventions are implemented as recommended by the nurse and healthcare team
- Appropriate care provided by the family to the child with an acquired disability

Chapter Highlights

- The family is defined as two or more individuals who are joined together by marriage, birth, or adoption and live together in the same household.
- Family-centered care is a philosophy of health care in which a mutually beneficial partnership develops between families and the nurse and also other health professionals. In this way, the priorities and needs of the family are addressed when the family seeks health care for the child.
- Various types of families exist and include the nuclear family, dual-career/dual-earner family, child-free family, extended family, extended kin network family, single-parent family, single-mother-by-choice family, blended or reconstituted nuclear family, binuclear family, heterosexual cohabitating family, and the gay and lesbian family.
- Parenting is a leadership role in the family in which children are guided to learn acceptable behaviors, beliefs, morals, and rituals of the family, and to become socially responsible contributing members of society.
- Discipline is a method for teaching rules that govern behavior or conduct. Punishment is the action taken to enforce the rules when a child misbehaves.
- The quality of the relationship between divorced parents has an important impact on their future relationships with their children. Better maintenance of family and kinship ties results when divorced parents are able to minimize the conflict and continue sharing parenting.
- The goal of foster care is to ensure the safety and well-being of vulnerable children by placing them in an approved living situation, away from the family of origin, that is legally coordinated by the state's child welfare system.
- Adoption is a legal relationship between a child and parents not related by birth in which the parents assume legal and financial responsibility for the child. Many children are adopted from foreign nations.
- Family theories help in understanding family functioning, environment–family interchange, family changes over time, and the family response to health and illness.
- Family development theories use a framework to categorize a family's progression over time according to specific, typical stages in family life.
- Family assessement tools are used to gather information about the family's functioning with regard to characteristics such as nurturing its members, problem solving, and communication. Information gathered helps the nurse work more effectively with the family in meeting the child's healthcare needs.
- Resilience is the family's capacity to develop strengths and abilities to bounce back from the stresses and challenges faced, and to eliminate or minimize negative concerns.

- Family strengths are the relationships and processes that support and protect families and family members during times of adversity and change. These strengths enable families to develop, adapt to change, and cope with challenges.
- Culture is a significant determinant of an individual's beliefs, behavior, and response to health and illness. Parental beliefs and behaviors can either promote the child's health care or impede preventive care, delay or complicate medical care, or result in the use of ineffective or harmful remedies.
- Cultural competence refers to the ability of the nurse to understand and respond effectively to the cultural needs of the child and family.
- A cultural assessment can assist the nurse in identifying cultural norms and in providing culturally appropriate nursing care. Providing spiritually sensitive care involves determining the current spiritual and religious beliefs and practices that will affect the child and family, accommodating these practices where possible, and examining one's own spiritual or religious beliefs to be more aware and able to provide nonjudgmental care.
- Complementary and alternative therapies are defined as diverse medical and healthcare systems, practices, and products that are not presently considered to be part of conventional medicine.

Clinical Reasoning in Action

Sixteen-year-old Casey is recuperating from injuries sustained in a motor vehicle crash in which he was the passenger. He was not wearing a seat belt and experienced a brain injury after striking the windshield. His cognitive and motor functions are impaired. Following a 7-day acute care hospital stay, he was moved to an inpatient rehabilitation hospital where he has been for the past 5 days. He is much more responsive to stimuli and to family members 12 days after his injury. Physical therapy is provided twice a day to promote range of motion and muscle tone and to prevent contractures. Plans are being made to discharge him to his home and provide him with outpatient rehabilitation care within the next 5 days. A case manager will be assigned to coordinate his healthcare services.

Casey lives with his mother, two half-brothers (10 and 6 years old), and stepfather. Both his mother and stepfather are employed full time and are trying to determine how to manage care for the teen when he returns home. Casey's grandparents live nearby and may provide some support to the family. Because Spanish is the language spoken primarily by the family, teaching materials are provided in both Spanish and English.

Casey is totally dependent for care, including bathing, toileting, feeding, and mobilizing. Although he is expected to regain self-care abilities, the impact of the injury on his cognitive ability and future functioning is unknown.

During the past 12 days, Casey's extended family has provided support to the family, but the level of support in the future weeks will decrease because of other family obligations. Casey's mother has already initiated a leave of absence from work so she can care for him when he returns home; however, this will mean the family has reduced income during that time period. Casey's younger brothers have been able to visit him, and they are very anxious because Casey cannot talk with them. They have been trying to avoid bothering their mother and father during this time, but they are wondering when life will be more normal and they can again participate in their usual after-school activities.

1. What information about the family strengths, needs, and resilience can be identified from the information just given?
2. What additional information would be helpful to know about family strengths and needs prior to developing a nursing care plan?
3. Based on your assessment of the family and the challenges facing the family members, list at least one nursing diagnosis that addresses issues important for planning nursing care for Casey and his family.
4. Describe the use of family-centered care principles in planning Casey's nursing care in collaboration with the family.

Chapter 3
Genetic and Genomic Influences

I came in for a sports physical, but I really want to be tested for Huntington disease. My mom's father died from Huntington when I was 8. My mom won't really talk about it, but I know she doesn't want to be tested. I have been doing some reading about Huntington disease, and I want to be tested. I mean, how can I plan my life if I don't know how long I'm going to be able to enjoy it?

—Sarah, 16 years old

Learning Outcomes

3.1 Explain the role of genetic and genomic concepts in health promotion, disease prevention, screening, diagnostics, selection of treatment, and monitoring of treatment effectiveness.

3.2 Elicit a family health history and construct a genetic pedigree.

3.3 Incorporate knowledge of genetic and genomic influences and risk factors into assessment, planning, and implementation of nursing care.

3.4 Integrate basic genetic and genomic concepts into child and family education.

3.5 Understand implications of genome science on the nursing role with particular attention to ethical, legal, and social issues.

3.6 Discuss the significance of recent advances in human genetics and genomics and their impact on healthcare delivery.

Partnering With Families: Meeting the Standard of Genetic Nursing Care Delivery

Completion of the Human Genome Project in 2003 heralded the dawn of the genomic era of health care. It has long been known that some diseases occur due to specific gene defects. **Genetic diseases** have traditionally been thought of as inherited diseases caused by a defect in a single gene. Although "typical" genetic diseases have enormous health consequences for affected individuals and families, they have relatively little impact on the health of most people. The Human Genome Project decoded human deoxyribonucleic acid (DNA), revealing the sequence of its 3 billion "letters" (also called bases or nucleotides). Research associated with the Human Genome Project has revealed virtually all diseases to have a genetic component. The human **genome** is the entire DNA sequence of an individual, and the study of **genomics** takes a holistic view of gene function. Human genomics is the study of all DNA in the human genome, including how genes interact with each other and with environmental, psychosocial, and cultural factors. Essentially all diseases and health conditions have both genetic and environmental components, but the genetic contribution to various diseases varies widely (Figure 3–1).

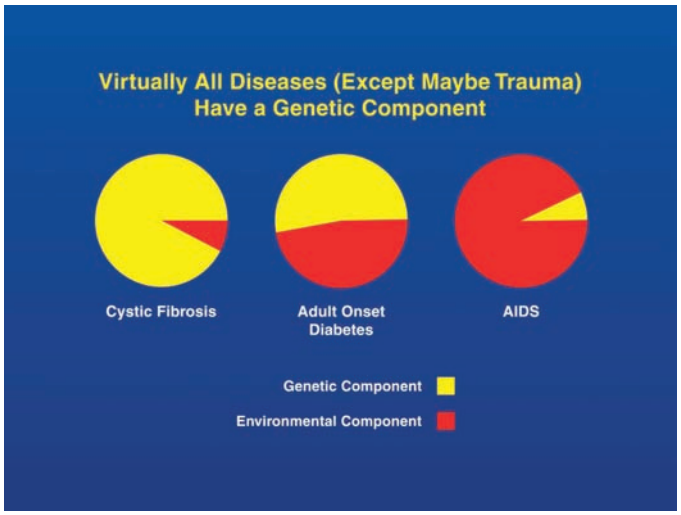

Figure 3–1 Although the causes for nearly all diseases and health conditions have both genetic and environmental components, the relative contribution of genetic and environmental influences varies widely. At one end of the spectrum lie "traditional" genetic diseases, such as cystic fibrosis (CF). Although CF is caused by a gene alteration, its morbidity and mortality vary according to environmental effects such as medical management. On the other hand, AIDS is an infectious disease that will not occur without environmental exposure to HIV. Still, there are genetic alterations that cause some people to be resistant to HIV infection. In type 2 diabetes, the genetic and environmental contributions are fairly equivalent.

DNA is central to our state of health because of its role in determining the set of proteins an individual has available to carry out specific physiologic functions. There are about 21,000 genes in the human genome, and each gene directs the formation of one or more proteins (Lander, 2011). Proteins include enzymes, cell receptors, ion channels, structural molecules, antibodies, and other molecules necessary for biologic function. Good health is dependent on normal gene structure (or sequence) and normal gene function (or expression). Gene sequence, which is the order of the gene's nucleotides or bases, determines whether a protein encoded by the gene has the correct amino acid sequence so that it can function normally. Normal gene function means that genes are expressed (i.e., translated and transcribed to make proteins) at the appropriate time and in appropriate amounts to support normal physiologic function.

Gene expression, which is affected by all manners of environmental and **epigenetic** effects, is therefore just as important as gene sequence. Genetic abnormalities may cause too much or too little of a specific protein, or perhaps a dysfunctional protein, to be formed. Sometimes the altered protein is sufficient to cause disease; this is the case with traditional genetic diseases such as cystic fibrosis and sickle cell disease. More often, multiple genetic variations, together with environmental factors, increase risk for disease. Both traditional genetic disorders and common complex diseases such as heart disease, stroke, diabetes, and cancer are now known to be related to variation in gene sequence and gene expression. Research has uncovered many of the genetic and environmental factors that increase risk for disease, leading to development of new treatments that range in scope from promoting healthy lifestyles to specific genetic therapies. Knowledge gained from human genome research is anticipated to transform health care across the entire continuum of care, allowing care to be tailored to each person's individual risk for disease. Genomic information is already being used to personalize health promotion and disease prevention, screening, treatment, and monitoring of treatment effectiveness (Green, Guyer, & National Human Genome Research Institute, 2011).

Nurses must be prepared to deliver genetically competent care in many healthcare settings to individuals, families, communities, and populations. Nurses in newborn nurseries and mother–baby units may be the first to suspect a newborn has a genetic condition. Pediatric nurses often care for children with genetic conditions who may require frequent hospitalization. Nurses in general and specialty clinics must be prepared to help asymptomatic individuals and families who are increasingly seeking information about their risk for an inherited disease or condition. Parents who order direct-to-consumer genetic tests may bring questions about their results to nurses. For these and other reasons, nurses must achieve genetic and genomic literacy in order to deliver competent care in the genomic era.

The translation of genetic and genomic knowledge to clinical care requires nurses to integrate new genetic knowledge into their nursing practice. This expectation was formally established in 2007 by the American Nurses Association (ANA) and the International Society of Nurses in Genetics (ISONG) in a joint statement, *Genetics/Genomics Nursing: Scope and Standards of Practice*. This document, now in its second edition (2016), outlines the levels of genetic knowledge required of all registered nurses, including basic and advanced practice nurses in general practice as well as those who specialize in providing genetics services. In addition, a set of essential competencies in genetics and genomics has been defined and endorsed by nearly 50 nursing organizations. These competencies represent the minimal level of genetic and genomic competency expected of every registered nurse across all practice settings (Consensus Panel on Genetic/Genomic Nursing Competencies, 2009). Examples of nursing activities that reflect genetic and genomic competence include:

- Identifying risk for disease by collecting a family history and drawing a three-generation pedigree
- Helping individuals and families to understand the implications and limitations of genetic testing
- Administering gene-based therapies
- Providing nondirective counseling to assist families who have questions or concerns about their reproductive risks
- Recognizing signs and symptoms, such as dysmorphic features or hypotonia, that may indicate a genetic condition in a newborn
- Anticipating variable responses among individuals to "standard" medication doses, due to pharmacogenetic effects
- Ensuring the delivery of genetically competent care for the child and family—for example, ensuring that a child about to start thiopurine treatment has completed pharmacogenetic testing

- Helping individuals and families identify credible sources of genetic information
- Applying concepts of health promotion and health maintenance to assist children and families who are at increased risk to develop common chronic conditions, such as heart disease, to make informed lifestyle choices
- Partnering with families affected by genetic conditions, including providing advocacy, supporting the child's and family's decisions, teaching, facilitating appropriate referrals, clarifying information, and providing further information about available resources and services
- Partnering with the community to educate the public about genetics
- Supporting legislation to protect genetic information and to protect those with genetic conditions from discrimination
- Applying knowledge of the ethical, legal, and social implications of genetic information

Through informed application of fundamental genetic and genomic concepts, nurses can significantly improve the nursing care provided to children and their families. In fact, understanding and applying these concepts is an essential part of child and family nursing.

Impact of Genetic Advances on Health Promotion and Health Maintenance

Health promotion and health maintenance for children and their families are foundational for all nursing care (see Chapters 6 through 9). The genomic era offers a promise of precision health care based on an individual's or a population's risk for disease, which varies according to the set of genes they inherited, cultural influences, and a multitude of environmental factors to which they are exposed. Although some people may be aware that they carry an altered gene associated with a specific disease, most individuals do not know details of their genetic makeup or how their genetic inheritance influences their future health. This is particularly true for common conditions such as heart disease and diabetes, for which risk varies with inheritance of a number of altered genes and is modified by lifestyle factors such as diet and physical activity. Having specific knowledge about one's genetic makeup and associated increased risk for disease provides a basis for health screening and may provide motivation for people to maintain a healthy lifestyle. Imagine, then, if people knew their statistical risks for inheriting or developing disease, based on their specific genotype. Health promotion and health maintenance teaching and nursing interventions would be targeted to individuals according to their disease risk. Children and families may experience increased motivation to adhere to lifestyle choices and health screenings that are personalized according to their disease risk. Precision health care is a major goal in the genomic era (Collins & Varmus, 2015).

With knowledge of how genetic variations influence health, the pediatric nurse can ensure health teaching and early detection of complications from genetic conditions with emphasis on primary and secondary health promotion and disease prevention. For example:

- Nurses should ensure informed consent for newborn screening and provide teaching and support to families whose infants have positive screens.
- Nurses should recognize hypotonia (reduced muscle tone, limited voluntary movement, reduced strength, and joints with increased range of motion) in newborns and advocate for a referral for the infant to be evaluated by a genetic specialist (Prows, Hopkin, Barnoy, et al., 2013).
- A child who screens positive for scoliosis (see Chapter 29) should be assessed for axillary freckling and café au lait spots, due to the relationship between scoliosis and neurofibromatosis.
- Screening for Marfan syndrome (see Chapter 21) should be a part of all sports physicals, due to the lethal cardiovascular complication of aortic dilation. This can be accomplished by assessing for common characteristics such as myopia, scoliosis, tall stature, long fingers and thumbs, a hollow chest, and an arm span greater than the height.
- Nurses should both teach and support families regarding any specific interventions necessary to avoid complications in children with genetic conditions. Examples are the importance for children with phenylketonuria (PKU) to maintain a phenylalanine-free diet for life, and the need to maintain children with sickle cell disease (see Chapter 23) on penicillin.

Professionalism in Practice Using the People-First Approach

The nurse must incorporate a person-first philosophy and use genetic terminology that promotes an individual's positive self-image. When communicating genetic concerns to children, families, other healthcare providers, or the public, take care to use words that do not reflect value.

Use the term **wild type gene** or *expected gene* or *unaltered gene* (rather than "normal" gene) and *altered gene* or *disease-producing gene* (rather than "mutated" or "abnormal" gene).

Name the diagnosis rather than apply the label. For example, newborn Sammy, who exhibits Down syndrome, should not be identified as the "Down baby" but as Sammy who has Down syndrome. And describe Sally as having (a diagnosis of) autism, not as being autistic.

Also, the term *cognitive disability* or *intellectual disability* is preferred (rather than "mental retardation").

Source: Adapted from Snow, K. (n.d.). *People first language.* Retrieved from http://www.disabilityisnatural.com/images/PDF/pfl09.pdf

- When caring for the child with Down syndrome (see Chapter 28), the pediatric nurse can help the parents shift from the more expected and traditional focus of disease management to health promotion and protection by teaching parents about the established guidelines for exams and screenings specific to children with Down syndrome.

Early diagnosis allows early intervention with health-promoting care specific to a genetic diagnosis, promoting achievement of maximal function, better health, and improved quality of life for children affected with genetic alterations. The pediatric nurse must be able to identify available community-based and genetic-based resources to assist the child or adolescent and the family with strategies to support both health promotion and health maintenance activities.

Genetic Basics

A basic knowledge of the cell, DNA, cell division, chromosomes, and genes is essential to deliver the genetic standard of care to children, adolescents, and their families.

The **cell** is the basic unit of life and the working unit of all living systems. Life starts as a single cell, but the developed human body is made up of trillions of cells. These cells share common features such as a nucleus that contains 46 chromosomes and **organelles** such as mitochondria. Cells are specialized in appearance and function, according to their location. For example, pancreatic cells function much differently than nerve cells.

All human cells, except red blood cells, contain a complete set of DNA molecules, which are long sequences of nucleotides. A nucleotide is a base with an attached sugar and phosphate group. Four different bases, designated A, C, T, and G, make up DNA. The order, or sequence, of these bases provides exact instructions for protein building. The entire DNA in a human cell is referred to as the **human genome**. Most of the DNA is organized into chromosomes, which are contained in the cell nucleus. A small amount of DNA is found in the mitochondria, which is discussed later in this section. Each person's genome is unique, with the exception of monozygotic twins, who are derived from the same fertilized ovum and therefore share identical DNA.

Each cell nucleus contains about 6 feet of DNA that is tightly wound and packaged into 23 pairs of chromosomes, making a complete set of 46 chromosomes. The set includes 22 pairs of **autosomes**, which are by tradition numbered according to size, with chromosome 1 being the largest. There are two copies of each autosome, one inherited from the mother and the other from the father. Copies of a chromosome pair are called **homologous chromosomes**. The 23rd chromosome pair, the **sex chromosomes**, determines an individual's sex. A female has two copies of the X chromosome (one copy inherited from each parent), and a male has one X chromosome (inherited from his mother) and one Y chromosome (inherited from his father). The structure and number of chromosomes can be shown by preparing a **karyotype**, or picture of an individual's chromosomes (Figure 3–2). Sperm and ova represent exceptions to the 23–pair rule because each contains only a single chromosome from each homologous pair.

Cell Division

Mitosis and meiosis are the two types of cell division in humans. **Mitosis** takes place in somatic or tissue cells of the body, allowing the formation of new cells. Cell division by mitosis results in two cells called daughter cells that are genetically identical to the original cell and to each other. Mitosis is responsible for rapid human growth in early life and also replaces cells lost daily from skin surfaces and the lining of gastrointestinal and respiratory tracts.

Meiosis is also known as reduction cell division. Meiosis occurs only in the reproductive cells of the testes and ovaries and results in the formation of sperm and oocytes (**gametes**). Meiosis is similar to mitosis in that it is a form of cell division; however, through a series of complex mechanisms, the amount of genetic material is reduced to half. Each gamete contains a single copy of each of the 22 autosomes, plus a single sex chromosome. This is critical to ensure that when two gametes combine during fertilization, the correct total number of chromosomes (46) is present in the offspring's cells. The other purpose of meiosis is to make new combinations of genetic material through processes of crossing over and independent assortment. New combinations are necessary to promote diversity in the human population. **Crossing over** results from an exchange or shuffling of material between homologous chromosomes inherited from the father and mother. This exchange results in new intact chromosomes that represent a patchwork of maternal and paternal genetic material. Only the Y chromosome does not have the ability to cross over, since it lacks a homologous mate. **Independent assortment** means that chromosome pairs segregate randomly into one or another gamete, further enhancing the genetic diversity that is possible at fertilization.

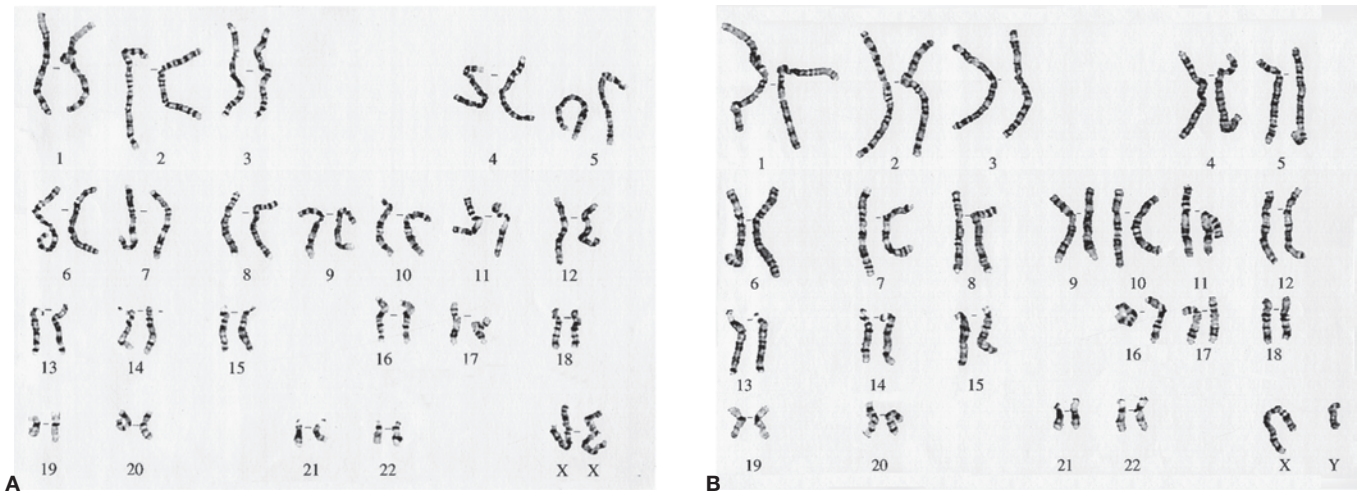

Figure 3–2 **A karyotype is a picture of an individual's chromosomes. It depicts the number and structure of the 22 pairs of autosomes and the sex chromosomes. *A*, Female. *B*, Male.**

Chromosomal Alterations

Alterations in chromosomes sometimes occur during cell division (meiosis or mitosis) and are classified as alterations in either chromosome number or chromosome structure. The clinical consequences of both types of alterations vary according to the amount of DNA involved.

ALTERATIONS IN CHROMOSOME NUMBER

An increase or decrease in chromosome number is called **aneuploidy**. Aneuploidy is the result of an error during cell division, most often when **nondisjunction** occurs during meiosis. With nondisjunction, paired homologous chromosomes do not separate before migrating into egg or sperm cells. This creates a gamete with either two copies or no copies of a particular chromosome. When such a gamete is fertilized by a normal gamete with all 23 chromosomes, a **zygote** that is **monosomic** (missing one member of a chromosome pair) or **trisomic** (having three homologous chromosomes instead of the usual two) results.

In general, humans do not tolerate either extra or missing DNA very well. Most monosomic or trisomic conceptions result in early pregnancy loss. For example, Turner syndrome is the only monosomic condition that is compatible with life. Trisomies involving chromosomes with small numbers of genes may result in live births. Examples are trisomy 13 (Patau syndrome), trisomy 18 (Edwards syndrome), and trisomy 21 (Down syndrome). Each of these aneuploidies produces clinical features that vary according to the chromosome that is duplicated. It is not a coincidence that the three trisomic conditions that are not universally lethal involve duplication of chromosomes containing the smallest number of genes (Pierce, 2014).

Mosaicism. Monosomy and/or trisomy can also occur during mitosis, resulting in an individual with two, or occasionally more, separate cell lines with different chromosomal makeup. This is known as **mosaicism**. The earlier in development the error occurs, the more cells that will be abnormal. The converse is also true. The degree to which a person is affected by this chromosomal error varies. For example, individuals with mosaic Turner syndrome may show varying degrees of infertility or short stature, and an individual with mosaic Down syndrome may have a higher intelligence level than children whose every cell has three copies of chromosome 21.

STRUCTURAL CHROMOSOMAL ALTERATIONS

Inversion. A chromosomal **inversion** occurs when a chromosome breaks in two places and the piece between the breaks turns end for end and reattaches within the same chromosome. An inversion changes the DNA sequence for that portion of the chromosome. Inversion often results in *balanced* rearrangements, because the amount of DNA in the chromosome remains normal. The clinical consequences of an inversion depend on how much chromosomal material is involved and where the inversion occurs. For example, an inversion that occurs between genes may have no effect on health, whereas an inversion within the gene that codes for factor VIII, a clotting factor, is an important cause of hemophilia A.

Deletion and Duplication. Chromosomal alterations sometimes occur when unequal crossing over or abnormal segregation causes a chromosome to have a missing segment (deletion) or an additional segment (duplication) of genetic material. These are called *unbalanced* rearrangements. Conditions associated with unbalanced rearrangements may be incompatible with life or cause altered physical and/or mental development. An example is cri du chat syndrome, caused by a large deletion on chromosome 5. Children with cri du chat have microcephaly (a small head), significant intellectual disability, and a peculiar cry during infancy that sounds like a cat mewing (Schaaf, Zschocke, & Potocki, 2012).

Translocation. **Translocation** occurs when two, usually nonhomologous, chromosomes exchange segments of DNA. A translocation that results in a correct amount of chromosomal material but a new arrangement is a *balanced translocation*. The individual who has a balanced rearrangement has all the chromosomal material present and therefore does not usually have any physical or mental disabilities. However, individuals with a balanced translocation are at high risk to produce gametes with unbalanced rearrangements. This leads to increased risk of pregnancy loss or having children with mental and/or physical disabilities due to missing or extra genetic material. In about 4% of cases of Down syndrome, the extra chromosome 21 is due to a translocation (Schaaf, Zschocke, & Potocki, 2012). When a child with Down syndrome is born, it is important to conduct a chromosome study to determine if the cause is nondisjunction or translocation. Translocation is unrelated to maternal age, but it carries a significantly greater recurrence risk with subsequent pregnancies.

Genes

In addition to understanding chromosomal alterations, the nurse must have knowledge of genes—what they are, their function, and the consequences of gene alterations. The nurse must understand the inheritance of gene alterations in order to design appropriate nursing interventions and teach the child, adolescent, and family at risk for or with a known genetic condition. Also, as genetic influences on common chronic disease are better understood, knowledge of gene function and inheritance has become increasingly relevant in health promotion and health maintenance.

A **gene** is a small segment of a chromosome that can be identified with a particular function, most commonly protein production. Each chromosome contains many genes arranged in a linear order. Genes that reside on autosomes (i.e., chromosomes 1 through 22) come in pairs, with one copy on each homologous chromosome. Each gene copy, or **allele**, is inherited from a different parent; therefore, pairs of alleles likely have differences in their nucleotide sequence. These differences may be so minor that they don't affect gene function at all, or they may disrupt or totally disable the gene. An individual who has two functionally identical alleles of a gene is said to be **homozygous** (*homo* = same) for that gene. An individual whose alleles for a particular gene function differently is said to be **heterozygous** (*hetero* = different) for that gene. As previously discussed, genes on the sex chromosomes of males are unpaired, because the X and Y chromosomes contain different genes.

Genes have a specific location on a designated chromosome; this is called the *genetic locus*. Gene mapping has documented the locus for most human genes. For example, it is known that the Huntington gene is located at the tip of chromosome 4, whereas the gene associated with cystic fibrosis is

on chromosome 7. It is important to remember that all people share the same set of genes. For example, not only people with Huntington disease have the Huntington gene. All people (with probable rare exceptions) have two copies of the Huntington gene, and people who carry a particular mutation in one of their Huntington genes will develop disease. In everyday language, people tend to use a kind of shorthand that infers that particular genes are "disease genes." Someone might say, for example, "I have the *BRCA* gene" when they mean their *BRCA* gene has a mutation that increases their risk for cancer. The *BRCA* gene itself is a tumor suppressor gene found in all people that, when functioning normally, protects against cancer. Nurses should try to be precise in their language to avoid reinforcing common misconceptions.

Genes are described as *altered* or *mutated* when a change has taken place in their nucleotide sequence. Such a change may or may not result in an altered protein product; a gene alteration that does not change the protein product is called a *polymorphism* or *silent mutation.* Other changes in nucleotide sequence, perhaps at a locus some distance from the gene itself, may affect gene expression—a gene's activity in making protein. Smaller, non-DNA molecules are also involved in gene expression; these epigenetic effects can cause genes to be overexpressed (making more than expected protein product), underexpressed (making less than expected), or expressed at a time in development when the gene is normally inactive. The observable, outward expression of an individual's entire physical, biochemical, and physiologic makeup, as determined by the person's genotype and environmental factors, is referred to as **phenotype**. Phenotype may be expressed as physical appearance such as curly or straight hair or physiologic function such as signs or symptoms of a disease.

FUNCTION AND DISTRIBUTION OF GENES

It is believed that only about 1% of the human genome is actually represented by genes (McCarthy, McLeod, & Ginsburg, 2013). The vast majority of human DNA does not encode proteins. In humans, protein-coding DNA is organized into about 21,000 genes (Lander, 2011); each individual's particular set of genes represents his or her **genotype**. These 21,000 genes are responsible for encoding hundreds of thousands of proteins that carry out all physiologic functions. An error, or mutation, in a gene can disrupt the order of amino acids that make up that gene's protein product. A protein with an incorrect amino acid may assume the wrong three-dimensional shape and, because protein function is dependent on protein shape (or configuration), the protein may not function as expected. Proteins are highly specialized and perform virtually all cellular functions. They form structures, transmit messages between cells, fight infection, direct genes to turn on or off, metabolize nutrients and drugs, and sense light, taste, and smell. Drug receptors, antibodies, and ion channels are proteins. When proteins do not function normally, health may be impaired.

Gene activity in making proteins (gene expression) can change moment to moment in response to thousands of intra- and extracellular signals. An example is the mechanism that stimulates cells to produce insulin after eating a candy bar. After eating, a gene on chromosome 11 of pancreatic cells is activated and produces insulin. Although the insulin gene is present in all nucleated cells of the body, it is functional only in insulin-secreting pancreatic cells.

MITOCHONDRIAL GENES

Chromosomes in the cell nucleus are not the only site where genes reside. Mitochondria (organelles involved in energy metabolism, known as the "powerhouse" of the cell) also contain a small amount of DNA. Mitochondrial DNA (mtDNA) contains 37 genes with roles in generating energy (in the form of adenosine triphosphate [ATP]) from glucose (Turnpenny & Ellard, 2012). Cells requiring large amounts of energy contain more mitochondria than other cells. Mitochondrial DNA is inherited from the mother in a unique *matrilineal* pattern. This occurs because mitochondria are located in the tail of the sperm, which detaches at fertilization. A female with a mitochondrial gene mutation will consequently pass that mutation to all her children, whereas an affected male will not pass a mtDNA mutation to any of his children (Turnpenny & Ellard, 2012). Clinical manifestations occurring as a result of mitochondrial gene alterations primarily affect high-energy tissues such as brain and cardiac and skeletal muscle.

HUMAN GENETIC VARIATION

The Human Genome Project and other genetic studies have shown that humans are remarkably similar to each other at the DNA level. On average, any two humans vary in less than 1% of their nucleotide sequence. Much of human variation can be attributed to single-nucleotide (or "single-letter") changes in DNA sequence. DNA sequencing of hundreds of individuals around the globe has shown that single nucleotide changes occur at about 38 million sites (or loci) across the genome (The 1000 Genomes Project Consortium, 2012); the rest of the genome is identical in ≥99% of individuals. These single-letter variations are called **single nucleotide polymorphisms** or SNPs (pronounced "snips"). Most SNPs are benign, although collectively they account for much phenotypic variation in appearance and risk for disease. They have been mapped to the human genome, and the resulting SNP maps are of enormous value to researchers. For example, scientists studying the genetics of type 2 diabetes mellitus have compared SNP patterns in large numbers of individuals with and without the disease to identify genetic variations associated with this common multifactorial disease. Such **genome-wide association studies** (GWAS) are uncovering the genetic contribution to common chronic conditions that cause most of the disease burden in developed countries.

In recent years, DNA research has identified **copy number variation** as an additional source of human genetic variation. In some individuals, stretches of DNA of variable size (up to 3 million bases and sometimes containing entire genes) are missing or replicated one or more times. Copy number variants (CNVs) appear to be fairly common; on average, each person is believed to have about 100 CNVs of various sizes (Lander, 2011). A CNV that contains an entire gene may result in more than expected gene product. In some cases, copy number variation has been associated with disease, birth defects, or the rate of metabolism of some drugs (Pierce, 2014).

GENE ALTERATIONS AND DISEASE

An alteration in the DNA sequence of a gene may cause a defective protein to be formed, which may have clinical significance. Gene alterations can be inherited, or they can be acquired. Mutations inherited from one or both parents (hereditary mutations) are also known as *germline mutations* because the mutation exists in the reproductive cells or gametes. Consequently, the DNA in every cell of that offspring will have the gene alteration, which can then be transmitted to following generations.

The second kind of gene alteration is an acquired, or somatic, mutation. These are mutations that occur in the DNA of cells of an individual at any time throughout a lifetime. They result from errors during cell division (mitosis) or from environmental influences such as radiation, toxins, or viral infections. Acquired mutations are also called sporadic or *de novo*

mutations. Most cases of cancer, for example, are due to somatic mutations. Somatic mutations are not passed from one generation to another.

Single-gene alterations are responsible for more than 5000 hereditary diseases such as cystic fibrosis, Duchenne muscular dystrophy, and phenylketonuria (Online Mendelian Inheritance in Man [OMIM], 2014). Each of these disorders is relatively rare, although collectively they affect 1 of every 200 newborns (Schaaf, Zschocke, & Potocki, 2012). Although they are of enormous consequence to affected families, they constitute a relatively small portion of the total public health burden.

Genes vary enormously in size, but all are very long, containing tens of thousands or even hundreds of thousands of base pairs. Consequently, mutations can occur at various different loci within a gene and result in a wide variety of signs and symptoms. For example, the cystic fibrosis transmembrane conductance regulator (*CFTR*) gene on chromosome 7 contains about 250,000 base pairs and encodes a protein that forms a chloride channel. More than 1000 different *CFTR* mutations that disrupt the chloride channel have been identified (Turnpenny & Ellard, 2012). Some of these mutations cause cystic fibrosis; others are associated with milder disorders such as absence of the vas deferens, pancreatitis, and rhinosinusitis. Most genetic tests for cystic fibrosis will detect only the most common *CFTR* mutations.

Alterations as small as a single nucleotide are known to cause disease. Sickle cell disease is such a disorder: A single A-for-T substitution in the *HBB* gene causes an incorrect amino acid (valine) to be inserted at a site in the protein product (β-globin) normally occupied by a different amino acid (glutamic acid). The altered β-globin protein is then incorporated into hemoglobin molecules. Under conditions of low oxygen tension, the altered β-globin causes red blood cells to assume an abnormal, sickle-like shape. This leads to vascular occlusion and hemolytic anemia (Turnpenny & Ellard, 2012).

In other situations, multiple gene alterations along with environmental factors contribute to disease or health conditions. These conditions are said to be **multifactorial**. Most common chronic disorders—including hypertension, heart disease, type 2 diabetes, and most cancers—are multifactorial, as are several birth defects. Alterations in regulatory genes may also occur. Regulatory elements are stretches of DNA sequence, usually located between genes, which control gene expression or activity in making proteins. They include gene promoters, enhancers, silencers, and other control mechanisms and are important in maintaining homeostasis. Mutation of a regulatory gene might lead to the loss of expression of a gene, unexpected expression in a tissue in which it is usually silent, or a change in the time when a gene is expressed. Small, non-DNA molecules are also known to affect gene function; these epigenetic factors are of great interest in genetics research.

GENE ALTERATIONS THAT DECREASE RISK OF DISEASE

Although gene mutations are commonly associated with disease, they can also be helpful and decrease the risk of disease. For example, having a single copy of some genes known to cause autosomal recessive disorders can provide protection against disease. Individuals with a single altered sickle cell disease (SCD) gene are less likely to develop malaria. Another protective gene alteration involves a deletion in the *CCR5* gene, which encodes a cell receptor to which the human immunodeficiency virus (HIV) binds. Persons who have two copies of the altered *CCR5* gene are almost completely resistant to infection with HIV type 1, and those who are heterozygous for the deletion (have one copy of the altered gene) experience markedly delayed progression from the point of HIV infection to the development of AIDS (Lewis, 2015). As genome research continues, more beneficial gene alterations are being identified.

Principles of Inheritance

Knowledge of inheritance prepares nurses to offer and reinforce genetic information to children, adolescents, and their families. Genetic knowledge may be important in assisting patients with care management and reproductive decision making. Nurses should apply basic principles of inheritance to risk assessment and teaching; these include (a) nearly all genes are paired, (b) only one gene of each pair is transmitted (passed on) from each parent to an offspring, and (c) one copy of each gene in the offspring comes from the mother and the other copy comes from the father. Understanding of Mendelian patterns of inheritance is based on these principles.

Classic Mendelian Patterns of Inheritance

Conditions that are caused by a mutation or alteration of a single gene are known as *monogenic* or *single-gene disorders.* More than 5000 known single-gene disorders have been catalogued, with detailed information posted to a searchable public database, the Online Mendelian Inheritance in Man (OMIM, 2014). Single-gene disorders are known as *Mendelian disorders* because they are predictably passed on from generation to generation following Mendel's laws of inheritance. Monogenic disorders that occur due to a mutation on an autosome (chromosome numbers 1 through 22) are most commonly inherited in an autosomal dominant or autosomal recessive pattern. Disorders due to a mutation on one of the sex chromosomes are inherited in an X-linked, or occasionally Y-linked, pattern. See Table 3–1.

DOMINANT VERSUS RECESSIVE DISORDERS

For some disorders, the presence of a single altered gene allele is enough to cause disease; these disorders are said to be **dominant**. An individual who is heterozygous for a dominant disorder will therefore have (or express) the disorder, despite the presence of one normally functioning allele. Other disorders occur only when both alleles of a gene pair are altered. In these **recessive** disorders, the gene product produced from a single unaltered gene is sufficient to perform the expected function and maintain homeostasis. Because most human genes reside on autosomes, the most common inheritance patterns are therefore called *autosomal dominant* or *autosomal recessive.*

AUTOSOMAL DOMINANT

More than half of the known Mendelian conditions are autosomal dominant (AD). Examples include neurofibromatosis, achondroplasia (dwarfism), Marfan syndrome, Huntington disease, and familial hypercholesterolemia. By definition, AD disorders involve altered genes on autosomes rather than the sex chromosomes X and Y. Disease occurs in AD disorders despite the presence of one unaltered gene, and most individuals with AD disorders are heterozygous for the disease-producing gene. Homozygous dominant conditions can occur, but they are generally much more severe or lethal and frequently result in early pregnancy loss. For example, the child who is born homozygous for achondroplasia (dwarfism with short stature and short limbs) is much more severely affected than a heterozygous child and usually will not survive early infancy.

TABLE 3–1 Selected Genetic Conditions Inherited in a Mendelian Pattern

GENETIC CONDITION	DESCRIPTION	INHERITANCE PATTERN
Achondroplasia	Abnormal bone growth resulting in short stature	Autosomal dominant More than 80% of cases represent a new mutation
Beta-thalassemia	Reduced synthesis of hemoglobin A resulting in anemia	Autosomal recessive
Cystic fibrosis	Complex multisystem disease leading to end-stage lung disease	Autosomal recessive
Duchenne muscular dystrophy	Progressive disease leading to atrophy of skeletal and/or cardiac muscle	X-linked recessive
Fragile X syndrome	Minimal-to-moderate intellectual disability due to trinucleotide repeat expansion	X-linked recessive Anticipation is demonstrated
Gaucher disease	Several subtypes, but all are lipid storage diseases due to enzyme deficiency	Autosomal recessive
Hemophilia A	Bleeding disorder due to deficient factor VIII clotting activity	X-linked recessive About 30% of cases represent a new mutation
Marfan syndrome	Connective tissue disorder with cardiovascular, ocular, and skeletal involvement	Autosomal dominant 25% of cases represent a new mutation
Neurofibromatosis (NF-1)	Variable expression with café au lait spots and benign cutaneous and subcutaneous neurofibromas	Autosomal dominant 50% of cases represent a new mutation
Phenylketonuria (PKU)	Enzyme deficiency results in accumulation of phenylalanine, inhibiting brain and cognitive development	Autosomal recessive
Sickle cell disease	Abnormal hemoglobin causes vaso-occlusive events and chronic anemia	Autosomal recessive
Tay-Sachs disease	Fatal neurodegenerative disorder of lipid accumulation due to enzyme deficiency	Autosomal recessive

Source: Information adapted from Online Mendelian Inheritance in Man (OMIM). Retrieved March 14, 2014, from http://omim.org/

Inheritance Risk in Autosomal Dominant Conditions. Because the gene alteration in AD conditions occurs on an autosome rather than a sex chromosome, both males and females have an equal chance of being affected. There is a 50% chance that an affected parent will pass the altered disease-producing gene on to a child. Nurses must remember and teach families that each pregnancy is an independent event with a 50% chance of an affected child, no matter how many of a couple's previous children inherited the altered gene. Family histories will often reflect this 50% inheritance rate as well as both males and females being affected. An affected child always has an affected parent, who in turn also has an affected parent (Figure 3–3). Exceptions to this inheritance pattern occur when the condition is due to a spontaneous new mutation, as discussed later in this chapter.

AUTOSOMAL RECESSIVE

Autosomal recessive (AR) conditions occur when both copies of the same gene in an individual are altered. Generally, AR conditions are more severe and have an earlier onset than conditions with other patterns of inheritance. Examples of AR conditions include cystic fibrosis, sickle cell disease, Tay-Sachs disease, and most inborn errors of metabolism. Like autosomal dominant disorders, AR conditions involve genes on one of the 22 autosomes. A condition is called "recessive" when two altered copies of a gene are needed to express the condition. A child born with a recessive condition has therefore inherited one altered gene from each parent. Both parents are **carriers** of the condition. Usually carriers do not exhibit signs or symptoms; however, exceptions to this general rule are increasingly being discovered. Sickle cell disease (SCD) provides an example: Although individuals with a single copy of the altered gene are usually asymptomatic, they can develop symptoms in situations of extreme physical exertion, dehydration, or high altitude (Bender & Seibel, 2014). The heterozygous or carrier state for SCD (known as sickle cell trait) actually affords some evolutionary benefit, because a single copy of the altered gene provides some resistance to malaria. Individuals

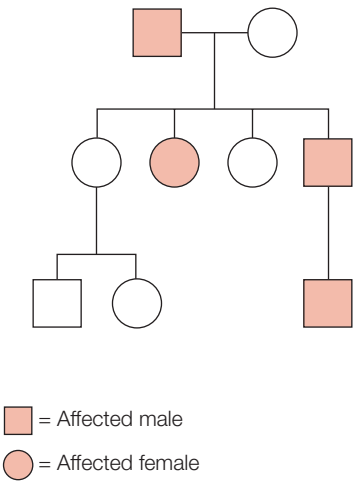

Figure 3–3 Autosomal dominant pedigree: One parent is affected. Statistically, 50% of offspring will be affected, regardless of gender.

whose ancestors are from malaria-endemic areas are therefore more likely to carry an altered sickle cell gene. See *Developing Cultural Competence: Ancestral or Ethnic Groups and Autosomal Recessive Inheritance*. Because carrier status usually confers no symptoms, parents are often unaware of their carrier status until they have an affected child.

Developing Cultural Competence Ancestral or Ethnic Groups and Autosomal Recessive Inheritance

Because the prevalence of autosomal recessive conditions varies around the globe, certain recessive genetic conditions are more common in particular populations. This is why nurses should ask about the country of origin of an individual's ancestors when collecting a family history. In populations in which individuals tend to marry within their own community or even their own extended family, autosomal recessive conditions are especially common. This is known as the "founder effect." For example, Ellis-van Creveld syndrome, an inherited condition in which polydactyly (extra fingers) and other structural defects occur, is commonly found among the Old Order Amish population of Pennsylvania (OMIM, 2014).

Examples of disorders that occur more frequently in specific populations are as follows.

Ashkenazi Jewish—Tay-Sachs Disease, Gaucher Disease, Cystic Fibrosis

Carrier rates for several autosomal recessive diseases are particularly high in the Ashkenazi (Eastern European) Jewish population. For example, carrier frequency for Tay-Sachs disease and cystic fibrosis are approximately 100 times higher in this group compared to non-Jewish populations. Specific carrier screening is often targeted to individuals of Ashkenazi Jewish descent.

Turkish, Irish, East Asian Populations, Pennsylvania Amish—Phenylketonuria (PKU)

Carrier rates as high as 1 in 26 have been found in Turkish populations. The PKU gene is rare in Japanese, Finnish, Ashkenazi Jewish, and African populations (Mitchell, 2013).

Mediterranean (Italians, Greeks), Middle Eastern, Central and Southeast Asian, Indian, Far East, African—β-Thalassemia

High gene frequency of β-Thalassemia in these populations is most likely related to selective pressure from malaria. The highest incidences are reported in Cyprus and Sardinia (with 12% to 14% carrier rates) and southeast Asia (Origa, 2015).

Northern European—Cystic Fibrosis (CF)

Cystic fibrosis is the most common life-limiting autosomal recessive condition in individuals with Northern European ancestors. Carrier rates among Caucasians in North America are about 1:25, compared to 1:65 for African Americans (Strom et al., 2011).

Sub-Saharan African, Mediterranean, Middle Eastern, Indian, Caribbean, and Populations from Parts of Central and South America—Sickle Cell Disease

The prevalence of sickle cell trait is about 10% among African Americans. Approximately one in every 300 to 500 African American infants born in the United States has sickle cell disease (Bender & Seibel, 2014).

Inheritance Risk in Autosomal Recessive Conditions. Because AR conditions do not involve genetic material on the sex chromosomes, males and females have an equal chance of inheriting the altered genes and exhibiting the condition. When both parents are carriers of an autosomal recessive gene alteration, each pregnancy presents the same inheritance risks. Each child born to carrier parents has a 25% chance of inheriting two copies of the altered gene and having the condition, a 50% chance of inheriting only one altered gene copy and being a carrier, and a 25% chance of inheriting two unaltered genes and thus neither being affected nor being a carrier (Figure 3–4). Remembering that each pregnancy is an independent event, these probability percentages remain constant with each pregnancy, no matter how many affected or unaffected children a family already has. This is often a difficult concept for parents to grasp, and the nurse should carefully evaluate the parent's level of understanding of this important detail about inheritance.

The transmission percentages stated previously apply when both parents are carriers of an autosomal recessive condition. Percentages will change if only one parent is a carrier or if a parent is homozygous for the condition. The nurse must be able to teach a parent about these simple inheritance percentages.

X-LINKED

X-linked conditions are the result of an altered gene on the X chromosome. Examples include hemophilia A and Duchenne muscular dystrophy. Recall that the sex chromosomes are unevenly represented in males and females. Males, with their single X chromosome, have just one copy of each gene that resides on the X chromosome. Any altered X gene will consequently be expressed in males, because an unaltered allele is not present for "backup." Females have two copies of each X gene, and the unaltered gene generally compensates for an altered allele, making the female a carrier.

Inheritance Risk in X-Linked Conditions. In families with X-linked disorders, a pattern of maternal transmission is seen. Females who are carriers of X-linked conditions have a 50% chance of passing the altered gene to their offspring. Any daughter who receives the altered gene is likely to receive an unaltered X chromosome from her father and therefore be a carrier like

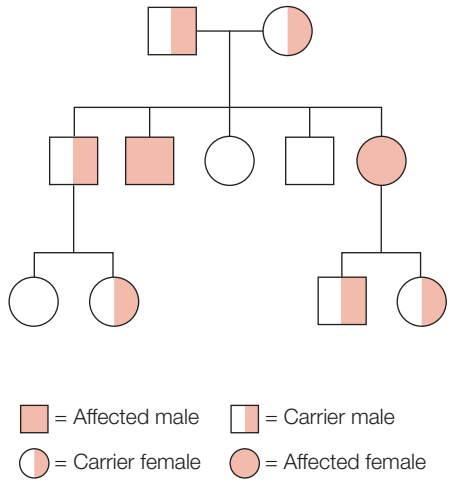

Figure 3–4 Autosomal recessive pedigree: Both parents are carriers. Statistically, 25% of offspring will be affected, regardless of gender.

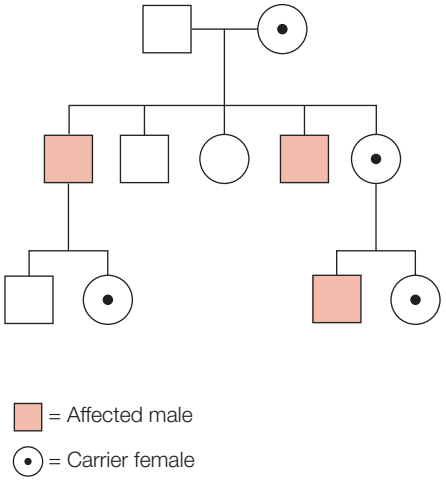

Figure 3–5 X-linked recessive pedigree: The mother is the carrier. Statistically, 50% of male offspring will be affected, and 50% of female offspring will be carriers.

her mother. Sons of carrier mothers, however, have no backup X chromosome. Therefore, a son who inherits the altered X will display the condition and go on to pass that altered X to each of his daughters, who will then be carriers of the altered gene. A male can never transmit an altered gene on the X chromosome to his sons, because only Y chromosomes are transmitted from fathers to sons (Figure 3–5).

X Inactivation. Early in embryonic life, within a week of fertilization, one of the X chromosomes inherited by females is inactivated. This process results in equalizing the expression of X-linked genes in the two genders. Each female receives an X chromosome from her mother (maternal X) and one from her father (paternal X). The inactivation of either the maternal or paternal X chromosome is random. However, once that X has been inactivated in any given cell, all the cell's descendants (through mitosis) contain the same inactive X chromosome. Therefore, females are mosaic for X-linked genes; some cells will express genes from the maternal X chromosome, whereas other cells will express genes from the paternal X. Females who inherit altered genes on an X chromosome therefore show variable expression, because the gene alteration will be present in only some cells. Expression of symptoms can vary from extremely mild to a full manifestation of the condition. For example, female carriers of X-linked ocular albinism may have pigment deficiencies of their iris and ocular fundus (Turnpenny & Ellard, 2012).

Y-LINKED DISORDERS

Because the Y chromosome has very few genes, alterations on the Y chromosome are not often associated with health problems. The Y chromosome does contain genes associated with spermatogenesis, and alterations in those genes can cause male infertility (Turnpenny & Ellard, 2012).

Variability in Classic Mendelian Patterns of Inheritance

In addition to classic Mendelian inheritance patterns, nurses must be prepared to help families understand several other concepts that affect risk for inheriting a genetic disorder. These concepts include the following common variations in traditional Mendelian patterns of inheritance.

PENETRANCE

Penetrance is the probability that a gene will be expressed phenotypically. It is an "all or none" concept in that a gene is considered to be penetrant if it is expressed to any degree (Lewis, 2015). Penetrance can be measured in the following way. In a certain group of individuals with the same genotype, what percentage of them will exhibit any signs or symptoms of the condition? If the number is less than 100%, then that condition is said to show *reduced* or *incomplete penetrance*. For example, both achondroplasia and Huntington disease exhibit 100% penetrance, because every individual with one copy of the altered gene will exhibit signs and symptoms of the disease.

VARIABLE EXPRESSIVITY

The term *expressivity* is used to describe the degree to which a phenotype is expressed. When people with the same genetic makeup (genotype) exhibit signs or symptoms with varying degrees of severity, the phenotype is described as showing *variable expression*. Variable expression is common in the autosomal dominant condition neurofibromatosis (NF-1). Although neurofibromatosis has 100% penetrance, members of the same affected family often exhibit variation in degree of signs or symptoms (Friedman, 2014).

NEW MUTATION

When there is no previous family history of a condition, the disease may be caused by a spontaneous new mutation. A new mutation is said to be sporadic, or *de novo.* Mutation rates have been estimated for a number of inherited disorders and vary widely due to a number of factors, only some of which are understood. Diseases with high new mutation rates include neurofibromatosis type 1, achondroplasia, Duchenne muscular dystrophy, and hemophilia A and B. Determining whether a genetic condition is due to an inherited or a *de novo* mutation has important implications in calculating a family's recurrence risk.

ANTICIPATION

Anticipation is said to occur when successive generations in a family exhibit earlier onset of symptoms and more severe signs and symptoms of certain diseases. Anticipation occurs in disorders characterized by unstable repeat expansions, which are DNA sequences that consist of repeating units of three or more nucleotides, for example CAGCAG . . . CAG. Repeat units have a tendency to expand, or accumulate repeats, during meiosis, especially during spermatogenesis. As a result, the number of repeats tends to increase in successive generations. More than a dozen diseases, most neurologic in nature, result from unstable repeat expansions. These include Huntington disease, fragile X syndrome, and myotonic dystrophy (Schaaf, Zschocke, & Potocki, 2012).

IMPRINTING

The expression of a few genetic conditions varies depending on whether the altered gene is inherited from the mother or the father. This differential gene expression is due to genomic imprinting. Imprinting takes place before gametes are formed, when certain genes are chemically marked as having maternal or paternal origin. After conception, the imprint controls gene expression so that only one allele, either maternal or paternal, is expressed. If the unsilenced (active) allele carries a mutation, disease may result. A well-studied example of imprinting involves a deletion in a gene on chromosome 15 that causes two very different disorders depending on whether the altered gene comes from the mother or the father. Prader-Willi syndrome, characterized by hypotonia in infancy, excessive eating habits

TABLE 3–2 Common Birth Defects and Conditions With a Multifactorial Cause

Neural tube defects	A neural tube defect (NTD) is a condition that occurs early during fetal development with incomplete closure of the neural tube. Severity of the disorder varies, depending on which part of the tube does not close. Anencephaly, meningomyelocele, and spina bifida are examples of NTD. Recurrence risk is increased in families with an affected child, but that risk can be modified by maternal dietary folic acid supplementation (Turnpenny & Ellard, 2012).
Congenital heart defects	Most congenital heart defects are thought to be of multifactorial cause. A number of genes have been associated with patent ductus arteriosus, atrial or ventricular septal defects, and other heart defects. In some states, newborn screening for critical congenital heart disease is performed routinely using pulse oximetry (Bradshaw & Martin, 2012).
Cleft lip and palate	Cleft lip and/or palate (CL/P) occur due to failure of bony fusion early in gestation. While rare gene mutations can cause CL/P, most cases are thought to be multifactorial. The more severe the malformation, the higher the family's recurrence risk is for future pregnancies (Tobias, Connor, & Ferguson-Smith, 2011).
Autism spectrum disorder	Although the etiology of autism spectrum disorder remains poorly understood, most experts believe it to be multifactorial. Twin studies suggest a strong genetic component, with 60% to 90% concordance between identical twins. A number of environmental influences have been suspected to influence the development of autism as well, including environmental exposures, viral infections, and maternal stress (Johnson, Giarelli, Lewis, et al., 2013).

leading to obesity, and mild-to-moderate intellectual disability, is due to a deletion on chromosome 15 that is inherited from the father. Angelman syndrome is due to a similar deletion in the same gene on chromosome 15, but it is inherited from the mother. The clinical presentation is very different. Individuals with Angelman syndrome have severe intellectual disability, absent speech, an uncoordinated gait, seizures, and a happy, sociable disposition (Schaaf, Zschocke, & Potocki, 2012).

UNIPARENTAL DISOMY

In cases of uniparental disomy, the child inherits both copies of a chromosome pair (or homologous parts of a chromosome pair) from the same parent instead of one copy from each parent. If there are no altered genes on these chromosomes, the child may not be affected by this event. However, if the chromosomes contain an altered gene for an autosomal recessive disease, the child will receive both altered genes and express the disease. For instance, if a child inherits two altered copies of chromosome 7 from a mother who is a carrier for cystic fibrosis, the child will then exhibit signs and symptoms of cystic fibrosis.

Multifactorial Inheritance

Most inherited traits, such as eye and skin color, are polygenic. That is, they occur as a result of variations on several genes. Most diseases and health conditions are polygenic as well, and the expression of those altered genes is often modified by environmental influences. These are called *multifactorial conditions* and include many birth defects such as cleft lip and palate, pediatric conditions such as autism and asthma, and adult-onset conditions such as cancer and heart disease. Because the term *polygenic* does not imply the influence of the environment, the term *multifactorial* is preferred terminology. The relative contribution of genetic and environmental influences varies across disorders.

Multifactorial conditions aggregate in families but do not follow the characteristic Mendelian patterns of inheritance seen with single-gene conditions. Recurrence risk varies among multifactorial conditions, but is usually less than that of Mendelian conditions. Recurrence risk is calculated from population studies and expressed as a percentage; for some disorders, recurrence risk is not easily predicted. Recurrence risk varies according to the number of affected family members, the degree of relationship, and sometimes the severity of the defect. As examples, the recurrence risk for cleft lip or cleft palate in a family with one affected child is 4%, whereas recurrence risk for pyloric stenosis is as high as 10% (Turnpenny & Ellard, 2012). See Table 3–2.

Collaborative Care

Many health professionals work together in the screening, diagnosis, identification, and treatment of genetic disorders. The goals of collaborative care are early diagnosis through assessment and testing, development of an effective treatment plan combined with psychosocial support to enhance coping, and referral to a genetic specialist when needed.

Diagnostic Procedures

Genetic testing is available for both chromosomal and gene-based alterations, and the entire landscape of genetic testing is changing rapidly. New methodologies have not only expanded the number of conditions for which genetic testing is available, but, to an even greater degree, reduced the cost. Increasingly, genetic testing is offered directly to consumers, who receive limited counseling about test results. Patients and families are likely to have limited or incorrect understanding about the types of genetic tests available and what information those tests are able and not able to provide, and they may access unreliable sources for information. Further, interpreting results of genetic testing can be complex. As described later in this chapter, a test for cystic fibrosis may be reported as negative, but the significance of that finding depends on how many of the multiple CF-causing mutations were included in the test. The pediatric nurse needs knowledge of available genetic tests and their implications to assist patients and their families as they weigh choices regarding genetic testing. See Box 3–1.

Box 3–1 What Is a Genetic Test?

A genetic test involves the analysis of chromosomes, DNA, RNA, genes, or gene products (e.g., enzymes and other proteins) to detect variations related to disease or health. Whether a laboratory method is considered a genetic test also depends on the intended use, claim, or purpose of a test. For example, amino acid analysis to detect metabolic disorders such as PKU is considered a genetic test, but the use of this same analysis to monitor general nutritional status is not (U.S. Department of Health and Human Services, 2008).

RECOMMENDATIONS FOR GENETIC TESTING

Genetic tests are useful to diagnose disease, predict risk of future disease, inform reproductive decision making, and manage patient care. Guidelines regarding who should be tested and when to test are available for some genetic conditions. However, new knowledge accumulates rapidly, and recommendations for practice often lag behind research findings by several years.

CATEGORIES OF GENETIC TESTS

Genetic tests have been used for some time to detect heritable conditions that are passed from generation to generation. In general, genetic tests are categorized based on their intended use or purpose and the approach or methodology they utilize. Categories of genetic tests according to their purpose are displayed in Table 3–3. Genetic tests may analyze DNA, products of DNA, or other substances that indicate a genetic defect. DNA itself can be analyzed on a number of levels, from karyotyping an entire set of chromosomes to examining a specific gene for a mutation. Tests of DNA products (RNA or proteins) are sometimes done to measure gene function or expression. Some genetic tests measure metabolites that accumulate when individuals lack a specific enzyme due to a gene mutation.

It is especially important for the pediatric nurse to understand the difference between screening tests, which are used in populations to find individuals at risk for a disorder, and diagnostic tests, which are required to make a diagnosis. Newborn screening is carried out on most newborns in developed countries to identify children who may have a genetic disease such as a metabolic or endocrine disease or hemoglobinopathy. Many of these disorders are exceedingly rare. In recent years, a laboratory technique called *tandem mass spectrometry* has allowed greatly expanded newborn screening with little increase in laboratory cost. Issues around expanded newborn screening are of considerable interest, in part due to issues of follow-up. Even the most specific of screening tests will result in false-positive results, which must be followed up with a diagnostic test. The cost of follow-up testing is significant both in terms of parental anxiety and financial burden (DeLuca, Zanni, Bonhomme, et al., 2013). See Chapter 7 for further description of newborn screening.

Diagnostic tests are performed to confirm a diagnosis in a symptomatic child or adult. Diagnostic tests may be ordered when a child is suspected of having a specific disorder based on clinical presentation or screening test results. Sometimes diagnostic testing is carried out prenatally to identify genetic disease such as a trisomy in a fetus.

DIAGNOSING CHROMOSOMAL ALTERATIONS

Cytogenetics describes the microscopic examination of chromosomes to reveal large alterations such as additions, deletions, breaks, and rearrangements or rejoinings (translocations). Prenatally, amniocentesis and chorionic villi sampling (CVS) can be undertaken to provide specimens for cytogenetic examination. After a child is born, chromosomal diagnostic examination can be accomplished with a blood, skin, or buccal cell sample. Cytogenetic testing includes karyotyping, as described earlier in this chapter, and molecular cytogenetic techniques, which are capable of detecting submicroscopic DNA variations too small to be seen on a karyotype.

DIAGNOSING GENE ALTERATIONS

Recent advances in molecular genetic technology along with the mapping of the human genome have resulted in tremendous expansion of available genetic testing. Genetic testing is currently available for more than 4000 disorders, with new tests constantly being added (GeneTests, 2015). DNA-based tests involve sophisticated new technology that permits the detection of DNA sequence changes as small as a single nucleotide. These tests can be performed on blood, bone marrow, amniotic fluid, fibroblast cells of the skin, or buccal cells from the mouth. Genetic testing can examine DNA (to determine specific nucleotide sequence), RNA (to measure gene expression), or proteins (to analyze gene products). Some tests can be performed quickly; others require several days to weeks, or occasionally several months, before results are reported. Test results may be delayed because of the complexities of interpreting test data, rather than delays in the laboratory testing itself.

Genes are very long DNA sequences made up of hundreds of thousands of nucleotides (or base pairs). Alterations at various sites along a gene may alter its function and cause disease. As an example, the *CFTR* gene (which in an altered form causes cystic fibrosis) is 230,000 base pairs long, and nearly 2000 different *CFTR* mutations have been identified (U.S. CF Foundation, 2011). Most of these mutations are exceedingly rare; the most common (named delta F508) is found in about two thirds of affected individuals (Schaaf, Zschocke, & Potocki, 2012). Although DNA testing is capable of detecting any of these alterations in DNA sequence, it is not feasible to test for all of them. Currently available *CFTR* tests detect up to 98 different mutations; most panels test for 23 to 25 mutations. Thus, the chance of missing an uncommon mutation varies, depending on which test is selected. Also, mutation detection rates are higher in patients of European ancestry than other populations. Therefore, a "negative" CF

TABLE 3–3 Categories of Genetic Tests

TYPE OF TEST	DESCRIPTION
Diagnostic testing	Used to establish a diagnosis of a genetic disorder in an individual who is symptomatic or has had a positive screening test.
Prenatal testing	Testing to identify a fetus with a genetic disease or condition. Some prenatal testing is offered routinely; other testing may be initiated due to family history or maternal factors.
Newborn screening	Testing of a newborn to identify babies at risk for a condition that may require immediate initiation of treatment to prevent death or disability.
Preimplantation testing	Following in vitro fertilization (IVF), testing to identify embryos with a particular genetic condition.
Carrier testing	Testing in an asymptomatic individual to identify carrier status for a genetic condition.
Presymptomatic and predictive testing	Offered usually to asymptomatic individuals to detect genetic conditions that occur later in life. • *Presymptomatic testing* detects mutations that, if present, are likely or certain to eventually cause symptoms (an example is Huntington disease). • *Predictive or predispositional testing* detects mutations that increase the likelihood that symptoms will develop (such as *BRCA1* and *BRCA2* testing).

test must be interpreted with caution and an eye on how many mutations were included in the test. This is just one of the limitations of genetic testing that nurses must understand in order to provide genetically competent care. See *The Role of the Nurse in Genetic Testing* later in this chapter.

Tests of gene expression are available as well. For example, **microarray analysis** can detect levels of messenger RNA in cells, which indicates which genes are "turned on" or actively being expressed. Microarray analysis is especially useful to examine tumor cells—for example, to see if an oncogene is being overexpressed and thereby stimulating proliferation of cancer cells.

Other genetic tests examine gene products or metabolites of gene products, rather than the makeup of the gene itself. One example is a biochemical test for PKU. PKU is caused by an alteration in the gene encoding the enzyme phenylalanine hydroxylase (PAH), which breaks down dietary phenylalanine. The PKU test actually measures phenylalanine levels, which are markedly elevated in individuals with PAH deficiency. Many of these biochemical tests have been in use for years.

Quality and Accuracy of Genetic Tests

Genetic nurses express concern that genetic tests are becoming available very quickly with little regulation of the companies offering them. The quality, accuracy, and reliability of genetic test results are not measured against any common standard. Of perhaps greater concern is the interpretation of genetic test results. Even if a test per se is accurate and reliable, companies are free to apply their own criteria to interpret the results. Growth in direct-to-consumer marketing of genetic tests has resulted in increasingly accessible and affordable testing without the benefit of oversight by a healthcare provider. In most cases, little or no education is provided for the individual undergoing testing, nor is counseling or follow-up uniformly provided. Individuals may make hard and irrevocable life-altering decisions after receiving test results, so accuracy and reliability, along with professional counseling, are essential (Beery & Workman, 2012).

Professionalism in Practice ELSI

Since its inception, the National Human Genome Research Institute has designated a percentage of its budget to examining the ethical, legal, and social implications (ELSI) of genetic and genomic information. Genetic testing raises many questions that have been addressed by ELSI. Genetic exceptionalism, the idea that genetic information should be treated differently than other health information, continues to be a subject of great interest and little consensus. Proponents of genetic exceptionalism point out that genetic information is unique and deserving of special consideration and protection because it is predictive, is potentially stigmatizing, and may reveal information about family members other than the patient undergoing testing. The contrasting view points out that other information is also predictive (consider blood cholesterol and risk for cardiovascular disease) and stigmatizing (for example, information about sexually transmitted infections).

Federal health privacy protection, as mandated under the federal Health Insurance Portability and Accountability Act (HIPAA) privacy rule, does not afford special protection to genetic information, treating it as being no more sensitive than other health-related information. However, by 2008 the majority of states had enacted legislation taking the exceptionalist view, providing protection against discrimination based on genetic information and penalties for violating genetic privacy (U.S. Department of Health and Human Services, 2008). These laws were implemented in response to public concerns that individuals might be reluctant to seek potentially beneficial genetic testing without some guarantee about the confidentiality, privacy, and security of that information. For example, an individual may have health coverage for a genetic test but be unwilling to submit the claim due to concerns about the insurance company "owning" the information in the test result. Federal legislation to prohibit discrimination based on genetic information in health insurance and employment (the Genetic Information Nondiscrimination Act, or GINA) was implemented in November 2009. As a federal law, GINA offers protection to Americans in all states.

Nursing Management

By simply integrating genetic and genomic concepts into assessment, observation, and history gathering, the pediatric nurse can improve the standard of care delivered and have a positive impact on the child and family. The pediatric nurse does not need to be a genetic expert, but baseline knowledge and heightened awareness of genetic and genomic issues will support appropriate assessment and referral to genetic specialists as needed.

Family Risk Assessment

GENETIC FAMILY HISTORY

While gathering a family history, the nurse must look for genetic information that might indicate the need for referral to a genetic specialist. Examples that would indicate a family may benefit from a genetic referral include a family history of conditions known or suspected to be genetic, several family members with the same condition, intellectual disability or learning difficulties, dysmorphic features or congenital anomalies, neonatal or pediatric death of unknown cause, recurrent miscarriage, or established genetic carrier status.

PEDIGREES

Pediatric nurses and all other health professionals should know how to collect a three-generation family history, record the history in a pedigree, and "think genetic." Information to document in a family history includes:

- First name of all family members with age or year of birth
- Any medical conditions or diseases, including age at diagnosis
- Age and cause of death
- Infertility or no children by choice
- Pregnancy complications with gestational age indicated
- Adoption status
- Ancestry
- Consanguinity

A **pedigree** is a graphic representation or diagram of a family's medical history and genetic relationships (Figure 3–6). Standard format, nomenclature, and symbols for pedigrees were adopted in 2008 (Bennett, French, Resta, et al., 2008). A pedigree is constructed around a designated "index" patient, called the **proband** (if the patient is affected with the genetic disorder of interest) or **consultand** (if the patient seeks genetic counseling without being known to have the disorder). A finished pedigree provides a clear, visual representation of a family's medical data and biologic relationships at a glance. A pedigree identifies affected individuals in the immediate and extended family and can identify family members who might benefit from a genetic consultation. A pedigree can also illustrate patterns of inheritance and clusters of multifactorial conditions. On the basis of the pedigree, risk assessment, genetic referral and/or reproductive risk teaching for the individual and family can occur. The visual nature of a pedigree enhances a family's learning and can be used to clarify misunderstandings or misconceptions about inheritance. If completed correctly and comprehensively, a pedigree allows all healthcare professionals working with the child or family to quickly see what history and background information has been collected.

All registered nurses, regardless of academic preparation, practice setting, role, or specialty, are expected to be able to elicit a three-generation family history and document that information in the form of a pedigree, using standardized symbols and terminology (Consensus Panel on Genetic/Genomic Nursing Competencies, 2009). It is important to gather a three-generation family pedigree even if the nurse believes this is a first occasion of the condition within a family. A condition without any identifiable inheritance pattern on the pedigree may be due to a new mutation or variable expressivity. Throughout the process of gathering family history assessment data, the nurse must protect family confidentiality at all times. A pedigree is different from a personal health history in that it reflects information about multiple individuals, which greatly increases the risk for harm if confidentiality is broken. A pedigree may reveal sensitive details that include infertility problems, reproductive decisions, or incorrectly assigned paternity that may not be known by a current partner or other family members. Other sensitive issues include pregnancies conceived by technology, a history of suicides, drug or alcohol abuse, and same-sex relationships.

Challenges inherent in recalling the family history include the parents' inability to remember conditions that have been surgically repaired and then forgotten. Parents may fail to report conditions thought not to be genetic or that have been attributed incorrectly to other causes. Also, parents may be reluctant to reveal sensitive information, particularly information unknown to other family members.

Instructions for creating a pedigree from family history information are beyond the scope of this text but are readily available online. See the National Human Genome Research Institute's website. Nurses should be able to identify and access resources for pedigree construction for their own use or for families to use. In fact, families are encouraged to collect and record their own family history in a form that can be shared within the family as well as with healthcare providers. The U.S. Surgeon General's Family History Initiative is a national campaign to promote the collection of family histories. The Initiative provides a web-based program that allows individuals to easily record and save their information, as well as print their family pedigree (http://www.hhs.gov/familyhistory/).

GENETIC PHYSICAL ASSESSMENT

The pediatric nurse in any healthcare setting should also "think genetic" when performing physical assessment (see Chapter 5). An early finding by the nurse will provide the child and family with an opportunity for a genetic referral and more specialized health care.

Major and Minor Anomalies

Dysmorphology refers to the study of human congenital defects or abnormalities of body structure that begin before birth. Traditionally, congenital anomalies have been included under the umbrella of genetic disorders whether they occur due to a gene alteration or another cause of abnormal embryonic or fetal development. Dysmorphic anomalies can occur anywhere in the body, but are perhaps most often associated with facial features. As a routine part of patient assessment, the nurse should screen for both minor and major anomalies. A **minor anomaly** or malformation is an unusual morphologic feature that in itself is of no serious medical or cosmetic concern to the individual or family. The presence of a single minor anomaly is relatively common, occurring in approximately 10% of newborns, and is usually of no consequence (Turnpenny & Ellard, 2012). Some minor anomalies

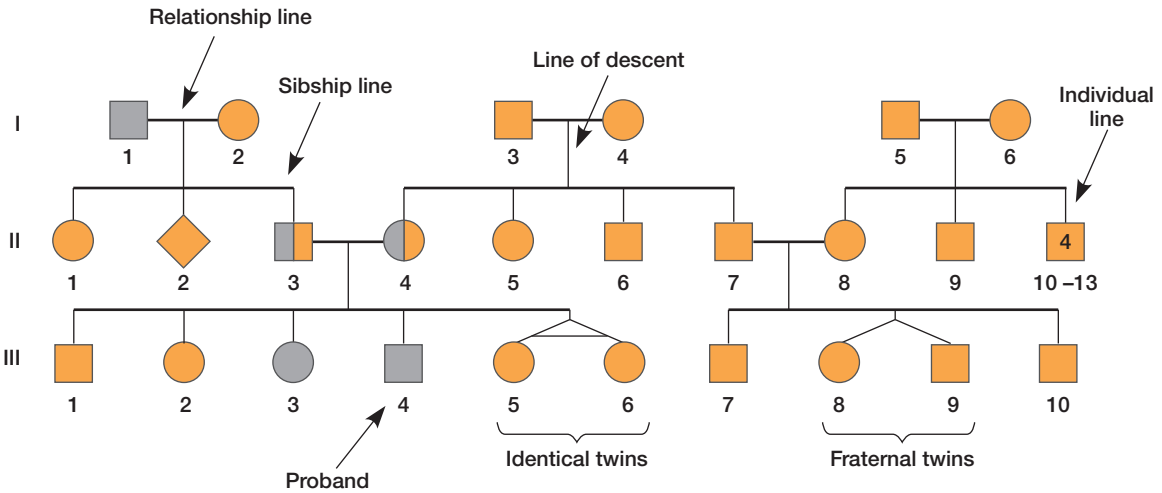

Figure 3–6 **Sample three-generation pedigree.**

are merely family traits or are present in certain ethnic groups. Minor anomalies include such traits as wide-set eyes, single palmar creases, café au lait patches, low anterior hairline, preauricular (in front of the ears) pits and tags, broad face, or mild proportionate short stature. Examples of variations associated with ethnic origin include upward-slanting eyes or prominent epicanthal folds among individuals of Asian descent.

The appearance of multiple minor anomalies in an infant is of greater concern. Fewer than 1% of newborns have two minor anomalies, and fewer still have three or more. But of those infants who do have multiple minor anomalies, many will also have a major anomaly or an underlying genetic condition. Therefore, the nurse who notes multiple minor anomalies in a newborn or child should consider the possibility of a major anomaly or an underlying genetic condition and advocate for a genetic referral. For example, a newborn who is hypotonic and has a single palmar crease with up-slanting eyes that do not resemble his parent's eyes should be evaluated for Down syndrome.

About 2% to 3% of all children have a **major anomaly**, defined as a serious structural defect present at birth that may have severe medical or cosmetic consequences, interfere with normal functioning of body systems, lead to a lifelong disability, or even cause an early death. Congenital heart defects, cleft lip and/or palate, myelomeningocele, duodenal atresia, and craniosynostosis are considered major anomalies, as is developmental disability. Some major anomalies are present at birth but are not apparent, such as deafness, various skeletal dysplasias, and some types of congenital heart defects (Turnpenny & Ellard, 2012).

A **syndrome** is a collection of multiple anomalies, major or minor, that occur in a consistent pattern and have a common cause. For example, Down syndrome is the cause of a variety of anomalies that can appear in multiple body systems, including the eyes, ears, hair, mouth and tongue, heart, and brain. A **sequence** is a collection of anomalies that occur as a chain of events initiated by a single problem. As an example, Potter sequence begins with prenatal failure of renal development, which leads to small amounts of amniotic fluid, which in turn causes growth restriction. An **association** is a group of abnormalities of unknown cause that occur together more often than is expected by chance (Schaaf, Zschocke, & Potocki, 2012).

The nurse can identify clues to genetic problems by examining the child and considering the physical characteristics of the parents and other family members (see *Assessment Guide: The Child With Selected Dysmorphic Physical Features*). Nurses may even ask to look at family photographs and examine them for common dysmorphic features and family traits. Several standardized craniofacial measurements have been defined, and tables are available displaying normal values according to age, so that dysmorphic facial features are more easily identified (Figure 3–7). By advocating for a genetic referral, the pediatric nurse can make a difference in the child's state of health.

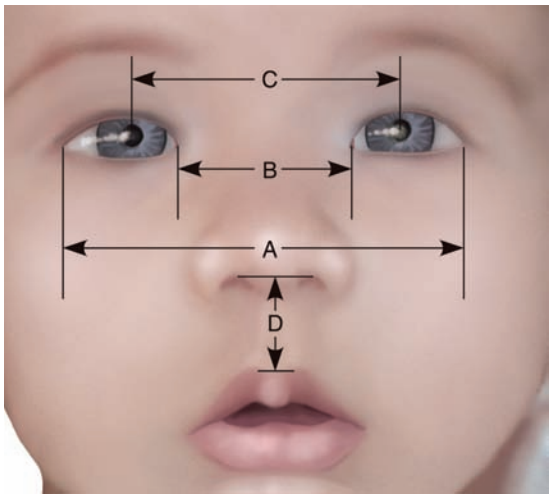

Figure 3–7 Classic facial measurements for genetic assessment with a focus on facial features. *A*, Outer intercanthal distance. *B*, Intercanthal distance. *C*, Interpupillary distance. *D*, Philtrum length.

THE ROLE OF THE NURSE IN GENETIC TESTING

Many people have misconceptions about genetic testing. Nurses play an important role in teaching parents and children about the implications and limitations of genetic tests to ensure that they make informed decisions. The nurse should promote communication, autonomy, and privacy when helping families. Recognizing that genetic testing affects families, and not just individuals, the nurse should use a family perspective when assisting parents and children who are making decisions about genetic testing. Not all family members will want to know their genetic risks. All voices should be heard, and each family member's decision should be respected, whether it is to participate in genetic testing or to decline. To ensure autonomy, a nondirective approach is critical. Nurses must take care to avoid imposing their own values or personal opinions onto patients and families. Finally, as with all aspects of delivering genetic nursing care, privacy and confidentiality are paramount.

Genetic Testing Issues of Minors

In order to support, advocate for, and educate children, adolescents, and their families, the pediatric nurse must have knowledge of issues related to genetic testing of minor children. Parents may request genetic testing for their minor children without foreseeing the consequences associated with a positive finding. Nurses have a critical role in providing information and anticipatory guidance for families considering genetic testing.

The primary focus of genetic testing in children is to promote the child's well-being, and guidelines generally recommend that genetic testing in children only be conducted if the results would affect medical management soon after testing. With this in mind, nurses should help families to clearly understand why a genetic test is being done.

In general, four reasons have been suggested to consider genetic testing of minors. The first is if the testing offers an immediate medical benefit for the child in terms of disease prevention or early treatment. Newborn screening is an example of testing designed to promote the health of children, and consensus statements by several professional groups support mandatory offering of newborn screening for all children (Ross, Saal, David, et al., 2013). Diagnostic genetic testing for children with symptoms of a genetic condition is also broadly supported, because establishing a diagnosis informs health management for the child as well as reproductive decision making by the family. Predictive testing in asymptomatic children for conditions that cause morbidity at a young age or for specific health promotion, screening, or treatment is also recommended. An example is familial adenomatous polyposis (FAP). Children with a family history of FAP should be tested for the altered gene, because screening by colonoscopy is recommended for affected individuals during adolescence (Munck, Gargouri, Alberti, et al., 2011). Genetic counseling and informed consent are essential prior to predictive genetic testing in minors (Ross et al., 2013).

ASSESSMENT GUIDE | The Child With Selected Dysmorphic Physical Features*

Skull	Asymmetric head/face	Fontanels too large or small
	Brachycephaly (short, broad head shape) (see Figure 27–11)	Frontal bossing (prominent central forehead)
	Craniosynostosis (premature closing of skull sutures)	Microcephaly or macrocephaly
	Flattened or prominent occiput	Micrognathia (small jaw)
		Prognathism (projection of jaw beyond that of the forehead)
Extremities	Abnormally positioned feet	Hypoplastic (very small) or absent nails
	Arachnodactyly (long fingers or toes)	Hypotonia (diminished muscle tone)
	Brachydactyly (short fingers or toes)	Loose joints
	Camptodactyly (permanent flexion of fingers or toes)	Polydactyly (extra fingers and/or toes)
	Clinodactyly (curved fingers or toes, most often the fifth finger)	Rocker bottom feet
		Single transverse palmar crease (see Figure 5–33)
	Edema of the hands or feet	Syndactyly (webbing between fingers and toes)
	Extremely long/thin or short extremities	
Ears	Ear tags or pits	Hearing loss
	Ears that are posteriorly rotated	Low-set or malformed ears
Hair	Excessive body hair	Large section of white hair in otherwise pigmented hair
	Unusual hairline or hair distribution	Sparse or brittle hair
Eyes	Blue sclera	Extreme myopia (nearsightedness)
	Different colored eyes	Hypertelorism (widely spaced eyes)
	Down-slanting eyes	Hypotelorism (closely spaced eyes)
	Epicanthal folds inconsistent with ethnicity (see Figure 5–7)	Short palpebral fissures (distance between inner and outer canthus of eyes)
	Extreme hyperopia (farsightedness)	Up-slanting eyes (see Figure 5–8)
Skin	Axillary freckling (see Figure 27–12)	Hirsutism (excessive hair)
	Café au lait spots (see Figure 27–12)	Hyperelastic skin
	Excessive skin	Leaf-shaped white markings
	Extremely loose or thin skin	Syndactyly (webbing between fingers and toes)
Mouth	Cleft lip with or without cleft palate (see Figure 25–1)	Early loss of teeth
	Large or small tongue	Late eruption of teeth
	Misshapen, missing, or extra teeth	Smooth or abnormal philtrum
		Thin upper lip
Other	Abdominal wall defect	Seizures
	Ambiguous genitalia	Short, webbed neck
	Cryptorchidism (undescended testicle)	Single umbilical artery
	Hernia (inguinal or umbilical)	Small or widely spaced nipples
	Hypospadias	Multiple fractures
	Hypogonadism	Unusual cry (catlike/mewing, hoarse, weak)
	Obesity	Unusually tall or short stature
	Scoliosis	Webbed neck

**This list is not all-inclusive but is meant to increase the nurse's awareness of assessment findings that may be significant and require a referral to a genetic specialist.*

A second kind of situation occurs when an adolescent is facing a reproductive decision of his or her own. If the adolescent has a family history of a genetic condition, the individual might be interested in genetic testing such as carrier screening that offers no specific medical benefit to the adolescent other than family planning. Recall Sarah, the young woman in the opening scenario who wanted to be tested for Huntington disease. Might genetic testing affect her reproductive decisions?

A third situation occurs when a parent or child requests predictive genetic testing for future planning in the absence of any immediate benefit. This situation may arise with inherited adult-onset disorders such as Huntington disease, certain cancers, or familial (early-onset) Alzheimer disease. An older child who has a relative with such a disorder may wish to know whether he or she carries the altered gene to plan for a life career or to make relationship decisions such as marriage. Parents sometimes request predictive or carrier testing for their children who are well below reproductive age. In the genetics community, there is widespread consensus that predictive genetic testing for minors in the absence of targeted preventive, surveillance, or treatment interventions should be deferred until a child reaches the age of majority (Ross et al., 2013). In most states that age is 18 years.

Finally, a family member may request genetic testing for a child when the test results are entirely for the benefit of another family member, with no direct benefit to the child. This may occur during DNA linkage studies, in which multiple blood samples from both affected and unaffected individuals within a family are analyzed and compared to identify a specific DNA alteration for

diagnosing a genetic condition in that particular family. Another example is genetic testing for the purpose of human leukocyte antigen (HLA) matching prior to stem cell donation. Because HLA-matched siblings are often preferred as stem cell donors, parents may request this testing, which offers no clinical benefit for the child but may benefit immediate family members. Such testing is supported by consensus in pediatric and genetic communities (Ross et al., 2013).

In recent years, advances in genomic knowledge and increasing availability of genomic testing have blurred the issues around testing in minors. Consider, for example, carrier screening. It is generally agreed that when carrier status is identified on newborn screening, those results should be communicated to the family (Ross et al., 2013). While routine carrier testing when carrier status has no medical relevance during minority is not recommended, carrier screening may be appropriate for adolescents under certain circumstances. Examples are sickle cell trait screening for some athletes and carrier screening for adolescents who are pregnant or considering reproduction. Predispositional testing, which can be ordered direct-to-consumer (i.e., without benefit of professional guidance), is also complex. Consider a child who is tested and found to have a genetic predisposition to type 2 diabetes. Typically, the disease risk is moderately elevated—perhaps two to three times the population risk. Does knowledge of that genetic test have immediate medical benefit for the child? Does the potential benefit outweigh any harm that may accompany the knowledge? Issues such as these are of great interest in genomic medicine, but clear guidelines have yet to be established.

The pediatric nurse must be aware of these potential situations and know that decisions to perform genetic tests on children and adolescents are not made easily. Unless the potential benefits of testing outweigh the potential harms to the child, a genetic test is not justified and should be postponed until the child is capable of making an informed decision. Amidst a rapidly changing landscape of genomic testing, and recognizing the difficult issues and lack of consensus around genetic testing in children and minors, the genetics community is working to develop standardized practice recommendations to guide clinical decision making (Ross et al., 2013).

Communication with the child and family about genetic testing should include an assessment of the positive and negative outcomes of the test. Are there existing treatments for the condition being tested? What are the potential psychologic issues associated with a positive or negative test? Who will be affected by the test results? Will the test results be shared with extended family members? The nurse has an important role in educating adolescents and parents about issues around genetic testing to ensure that they are making informed decisions. The nurse should also consider the decision-making ability of the child. There is little consensus regarding the age at which children may be able to take part in a decision-making process involving genetic testing, and it is imperative for the nurse to be an advocate for the child.

Ensuring Informed Consent for Genetic Testing

The pediatric nurse is responsible for alerting children and their families of their right to make an informed decision prior to *any* genetic testing, with consideration of the special circumstances arising from the family's social, cultural, and community life. All genetic testing should be voluntary, and it is the nurse's responsibility to ensure that the consent process includes discussion of the risks and benefits of the test, including potential physical or psychological harm or societal injury due to stigmatization or discrimination. Ross and colleagues (2013) suggest using a consent process similar to that conducted before an elective medical procedure. Providing informed consent involves more than just presenting a form and asking patients to sign; rather, nurses must ensure patients fully understand both the process of the testing and potential implications (Badzek, Henaghan, Turner, et al., 2012). For example, tests may reveal unexpected genetic alterations unrelated to the indication for which the test was ordered, and the management of such **incidental findings** should be explained during the consent process. The nurse should be aware that health insurance policies may not cover genetic testing, which is often very expensive. Even if the insurance benefit will cover the test, and despite protections afforded by law, many individuals are fearful of discrimination based on genetic test results that are included in their medical record. The pediatric nurse should inform the child and the family of their right to know who will have access to the genetic test results.

Ensuring Confidentiality and Privacy for Genetic Testing

Issues of confidentiality and privacy are of particular concern when genetic information is involved. Results of genetic tests can be far reaching beyond usual concerns about health information. Tests may reveal information about other family members who did not consent to testing and who may not want to know (or have other family members know) that information. Current legal protection of genetic information is limited to health insurance and employment, but other concerns remain. Can genetic information be released to the courts, military, schools, or adoption agencies? Would a child with a known gene alteration for Huntington disease be offered a college scholarship for the best law school? The technology that has made genetic testing possible has far outpaced the ability of health policy makers and legislators to put in place systems to protect genetic information. Not only should nurses be diligent about protecting patients' genetic information but they should also discuss with patients and families the potential implications when sensitive test results are shared, either intentionally or inadvertently. Such anticipatory guidance is a key nursing role in patient advocacy (Consensus Panel on Genetic/Genomic Nursing Competencies, 2009).

Psychosocial Issues

Pediatric nurses must be prepared to assist children and families to manage anxiety related to genetic testing. Uncertainty and stress associated with making a decision to undertake genetic testing may extend into weeks or even months before results are available. That stress may be increased or relieved once test results are known. Although receiving favorable test results may decrease anxiety for the family or the individual, problems may occur and the pediatric nurse must be prepared to address them. For example, concerns about carrier status may interfere with development of intimacy and interpersonal relationships. A positive test result may lead to feelings of unworthiness or disturbed self-image. Survivor guilt may affect children with negative results if their siblings test positive. Younger children may blame themselves, thinking they did or said something to cause the gene alteration. The adolescent carrying a gene alteration for a late-onset disease may have an increased tendency for risky behaviors. The adolescent who has inherited an altered disease-producing gene may foster resentment toward the parent who carries the altered gene. Parental guilt may exist for passing the altered gene to the child. Finally, parent–child bonds may be altered if parents become either overprotective or overly permissive. The parent and other family members may unconsciously form lowered expectations for the child or adolescent. Nurses must use counseling interventions to assist patients to process, adjust to, and use genetic information.

Planning and Implementation

The pediatric nurse is responsible for comprehensively delivering the standard of care to children and families, while being aware of limitations of his or her own knowledge and expertise (Consensus Panel on Genetic/Genomic Nursing Competencies, 2009). Although nurses without specialized training and credentialing in genetics are not expected to assume the role of genetic professionals, they do have critical roles in providing genomic health care. Often, nurses have more direct patient interaction than other health professionals and maintain a particularly high level of trust with patients. Nurses therefore are well positioned to recognize a patient or family who may be at increased risk for a genetic condition. In general, nurses are expected to (1) integrate genetic and genomic concepts into a comprehensive nursing assessment including documenting that history in the form of a pedigree, (2) recognize significant genomic information in the family history, (3) apply knowledge of local or regional services to explain available genetic services to patients, and (4) facilitate a genetic referral when appropriate (Consensus Panel on Genetic/Genomic Nursing Competencies, 2009; Jacobs & Patch, 2013).

GENETIC REFERRALS AND COUNSELING

After gathering assessment data that incorporate genetic concepts, the pediatric nurse is able to partner with children and their families by initiating a referral to genetic specialists if there are indicators for a genetic referral (see Clinical Tip). The nurse should provide the family with information about the advantages of a referral to a genetic specialist and the disadvantages of not following through with the referral. The nurse should inform the child and family that a genetic referral can provide information and answer questions they may have concerning genetic health. Families should be encouraged to address all their concerns with the genetic specialist, who will be able to answer questions regarding genetic conditions, inheritance, availability of treatment, and economic, insurance, and future implications of genetic conditions. Initiating or facilitating the referral of a child with a suspected genetic problem to a geneticist, genetic clinical nurse specialist, or genetic clinic is an expected nursing responsibility in the same way as referrals to a dietitian or a social worker. When in doubt, the pediatric nurse should contact the advanced practice genetic clinical nurse, genetic counselor, or geneticist to discuss concerns.

Clinical Tip

The following are indications for pediatric referral to a genetic specialist:

- If the child or family reports a known or "believed" genetic condition in the family
- Single major or multiple minor congenital anomalies
- Dysmorphic features that are not familial
- Developmental delay or regression
- A known or suspected metabolic disorder
- Speech problems
- Learning disability
- Failure to thrive
- Delays in physical growth, unusual body proportions, or low muscle tone
- Abnormal or delayed development of secondary sex characteristics or sex organs
- Extremely short or tall stature
- Blindness or cataracts in infants or children
- Deafness
- Hypotonia in an infant or child
- Seizures in newborns or infants
- Skin lesions such as café au lait spots

FAMILY PREPARATION FOR GENETIC REFERRALS AND GENETIC COUNSELING

Not knowing what to expect from a genetic referral is common, and fear of the unknown may cause anxiety for both the child and family. To facilitate a genetic referral to genetic specialists, the pediatric nurse should educate the child and family so they know what to expect during and after a genetic evaluation.

Usually before the first genetic evaluation visit, the parents will be contacted to provide a detailed medical and family history and to make an appointment for genetic consultation. The parent should be prepared to give as exact a family history as possible so that a detailed three-generation pedigree can be constructed. The parents should be informed that a genetic consultation can last several hours. During the appointment, a genetic clinical nurse, genetic counselor, and/or physician will perform an initial interview with the parents and their child. A geneticist will examine the child and possibly the parent(s) in order to establish an accurate diagnosis. Tests may be ordered. These may include chromosome analysis, DNA-based testing, radiographs, biopsy, biochemical tests, developmental testing, or linkage studies.

After the exam and the completion of any applicable testing, the geneticist or genetic counselor will discuss the findings with the parents and/or child and make recommendations. The discussion will include the natural history of the condition, its pattern of inheritance, current preventive or treatment options, and risks to the child or family. The visit will include opportunities for questions and answers and assessment and evaluation of the family's understanding. It is typical for information retention to be very low for a family facing a new genetic diagnosis. This makes it imperative for the nurse to reinforce genetic concepts at a later time when the individual or family is ready.

As the visit concludes, the child and parents can expect that appropriate referrals will be made, available services will be discussed, and a follow-up visit may be scheduled. A summary of the information is usually sent to the family. The child's healthcare provider will receive a report if requested by the individual or parents.

Genetic healthcare providers present the individual and the family with information to promote informed decisions. They are also sensitive to the importance of protecting the individual's autonomy. A challenge during any visit to a genetic specialist is in providing nondirective counseling. Families should be permitted to make decisions that are not influenced by any biases or values from the nurse, counselor, or geneticist. Many families are accustomed to practitioners and nurses providing direction and guidance in their decision making, and families may be uncomfortable with a nondirectional approach. They might believe that the nurse or healthcare provider is withholding very bad news. Health professionals should present all indicated options and discuss the positive and negative aspects of each option, employing therapeutic listening and communication skills.

FAMILY TEACHING

The pediatric nurse must be aware of available genetic resources and participate in education about genetic disorders and health promotion and prevention. Informing children and their families of what to expect from a genetic referral and clarifying and reinforcing information obtained during a genetic referral or genetic test results are also important.

Cultural and religious beliefs and values of the individual and family must be assessed by the nurse prior to teaching. Gene alterations may be viewed as uncontrollable, as occurring secondary to cultural beliefs such as a stranger looking at the infant, or as a "punishment." A family's readiness to learn can be influenced by cultural or religious beliefs and values. Obtaining educational materials in the primary language of the child or family will help facilitate the teaching–learning experience.

The nurse must be aware of common inheritance misconceptions such as a parent's belief that with a 25% recurrence risk, after one child is affected the next three children will be unaffected, or with a 50% recurrence risk every other child will be affected. The recurrence risk *for each pregnancy* should be continually stressed by the nurse. Families often believe that certain family members have inherited a genetic condition because they look like or "take after" a relative with a genetic condition. When new gene alterations or mutations are found or even discussed, families will often express surprise. Because no one else in the family has the condition, they perceive the trait or condition cannot be inherited. Helping families understand basic, relevant genetic concepts is fundamental to delivering competent genetic nursing care.

Psychosocial Care

In order to provide holistic care, the nurse should identify the psychosocial needs and expectations of the child and family, as well as their cultural, spiritual, value, and belief systems. Denial of a genetic diagnosis is common, and nurses must be aware of the family's state of acceptance. Nurses must often help alleviate anxiety or guilt in the child or family. Anxiety related to uncertainty is common when awaiting diagnosis or test results, but individuals also experience anxiety from not understanding the future implications of a confirmed genetic disease. Guilt may be associated with knowledge of a genetic condition being "in the family." It is important for the nurse to reassure parents that the genetic condition is not the result of something they did or did not do during pregnancy. The nurse should encourage open discussion and free expression of fears and concerns. Guilt and shame are common as a family deals with the loss of the expectation and dream of a healthy child, grandchild, niece, or nephew. Reinforce to parents that genetic alterations are caused by changes within a gene and not by superstitions related to sin or other cultural beliefs. As mothers, fathers, and extended family members provide continuous care for the individual with a genetic condition, depression can result. Depression can also occur in the individual with the condition. The nurse must maintain awareness of the possibility of depression and be proactive in obtaining support for the individual or family. See Chapter 28.

The nurse also is responsible for assessing the family's coping mechanisms and available family, spiritual, cultural, and community support systems. The nurse can refer the individual or family to a support group; however, it is important to have permission from the child or family before providing a support group with their names and contact information. Electronic sources of genetic information abound and are unregulated; many of them are proprietary, offering expensive genetic testing that may have little scientific basis. Nurses should help families select and evaluate credible websites and online discussion groups.

Another key role for the nurse is to help families with the often difficult task of communicating genetic information such as inheritance patterns to extended family members. Cultural values of autonomy and privacy come into play when a person considers whether to communicate genetic information to extended family members who may also carry the altered gene. Family members often have difficulty understanding that some genetic conditions have variable expressivity. Members of the extended family often feel shock and profound guilt upon learning that they carry the gene alteration that has caused their loved one to have a genetic condition.

Managing Care Through Advocacy

The pediatric nurse must continually advocate for the child and family and support their decisions even if the decisions contradict the nurse's own ideals and morals. Therefore, careful self-assessment of feelings is essential for nurses to recognize when their own attitudes and values may affect care (Consensus Panel on Genetic/Genomic Nursing Competencies, 2009). Coping with genetic revelations and making genetic-related treatment decisions are difficult activities for everyone. The nurse must remember that families will need resources and support and also help in gathering information about reproductive options.

Evaluation

Expected outcomes of delivering nursing care with a genetic focus include:

- The child and family will make informed and voluntary decisions related to genetic health issues.
- The child and family will accurately identify:
  - Basic genetic concepts and simple inheritance risk probabilities
  - What to expect from a genetic referral
  - The influence of genetic factors in health promotion and health maintenance
  - Social, legal, and ethical issues related to genetic testing

Visions for the Future

Nurses are often the primary caregivers to whom children and their families turn for information, guidance, and clarification of ideas. Genetic and genomic competency among nurses is essential, not only to provide direct care but also to function as informed members of the community and greater society. As advances in genome science are increasingly translated to health care, the role of nurses not only remains vital but also increases in breadth. For example, the Precision Medicine Initiative, launched in the United States in 2015, aims to tailor health care to people's unique characteristics, including their personal genome (Collins & Varmus, 2015). Precision medicine will target care, including health promotion and disease prevention plans, pharmacotherapeutics, and cancer treatment, based on each person's unique genome. Genome-based care is anticipated to expand genetic testing and include new interventions such as gene therapy. As genomic health care becomes the standard of care, the nurse's role expands not only to delivering that care, but also to explaining the care and the implications of care to clients and families. Nurses must acquire foundational understanding of genetic and genomic concepts, maintain currency as genomic discovery is translated to practice, and be ready to discuss trends and changes with children, adolescents, and their families.

Chapter Highlights

- All diseases and health conditions have both genetic and environmental influences.
- Recent advances in genome science are expected to transform health care to "precision" care, which applies genomic knowledge about an individual to individualize health care.
- Nurses are expected to achieve competency in delivering genome-based care.
- Human DNA is organized into 46 chromosomes—44 autosomes and 2 sex chromosomes, which contain about 21,000 genes.
- Errors in chromosome number (aneuploidy) or chromosome structure (e.g., deletions) can impair health.
- Having the correct amount of DNA is critical to health; in most cases, having an extra or a missing chromosome is lethal.
- Large chromosomal alterations can be seen in a karyotype; very small alterations can be detected using molecular methods.
- The primary function of the human genome, which contains about 21,000 genes, is to encode proteins that carry out all physiologic functions.
- Different forms of a gene that occupy the same place on a pair of chromosomes are alleles. Humans normally have two alleles for each gene—one inherited from each parent.
- More than 99% of DNA sequence (i.e., the order of the A-T-C-G bases) is identical between individuals.
- Errors or mutations in DNA can disrupt health by encoding faulty proteins that do not function as expected, by causing too much or too little of a protein to be formed, or by causing a protein to be formed at the wrong time during development.
- When both alleles for particular gene function the same, the individual is said to be homozygous for that gene; if the alleles function differently, the individual is heterozygous for the gene.
- Single-gene (Mendelian) diseases are typically rare and occur when specific genes are altered; environmental influences usually contribute minimally to the disease process.
- Complex (multifactorial) diseases and health conditions are common and usually occur when multiple gene alterations collectively increase or disease risk; environmental influences usually have significant impact, which can increase risk or be protective.
- Most DNA is located in the cell nucleus, but mitochondria also have a small amount of DNA that encodes proteins critical to energy production. Mitochondrial DNA is inherited from the mother.
- Single-gene conditions follow Mendelian patterns of inheritance; multifactorial conditions do not.
- Several types of genetic tests are available and vary in intended use, implications, and limitations.
- The nurse must be aware of the ethical, social, legal, cultural, and spiritual issues related to the delivery of genetic care.
- A federal law (GINA) offers special protections regarding genetic information in the areas of health care and employment.
- A genetic pedigree is a graphic representation of a family's medical history that is used increasingly as a screening tool to identify people who may be at increased risk for disease.
- All registered nurses should be able to elicit and depict a three-generation family health history in the form of a genetic pedigree, using standard format, symbols, and terminology.
- Congenital anomalies may indicate a genetic condition is present, and nurses should carefully assess newborns and children for dysmorphic features.
- Nurses have an important role in educating clients about genetic testing, promoting informed decision making, and obtaining informed consent.
- Genetic testing of minors has particular implications that require careful consideration.
- Basic genetic nursing involves initiating a referral to genetic specialists.
- Providing psychosocial support is a critical part of genome-based nursing care.

Clinical Reasoning in Action

Recall 16-year-old Sarah from the chapter-opening scenario. While at the sports clinic for a routine physical, she questions the nurse about being tested for Huntington disease. Huntington disease (HD) is a progressive disorder of motor, cognitive, and psychiatric disturbances. Symptoms typically present between ages 35 and 44 years, with a median survival time of 15 to 18 years after onset. HD is inherited in an autosomal dominant pattern. Sarah's maternal grandfather died from HD. Sarah has been reading about HD and is interested in being tested. Her mother strongly objects; she does not want to know her own Huntington status.

Sarah's mother, Diane, is of western European Caucasian descent. Sarah's knowledge about her father is limited. She knows that he is a third-generation Filipino American but has no medical information on him or his extended family.

Sarah's grandmother on her mother's side has three sisters and two brothers. The two brothers died of myocardial infarctions at the ages of 37 and 55 years, respectively. Sarah's maternal grandfather had no brothers but had two sisters. Her maternal grandfather died at age 62 years of Huntington disease. The sisters are alive and well and have no medical problems.

Diane has two brothers and two sisters. She is the youngest of the siblings. Her oldest brother, Ken, was diagnosed 10 years ago with Huntington disease at age 41 years. Ken has two daughters ages 21 and 25 years. Sarah is very close to these cousins, and she knows that they have no medical problems beyond seasonal allergies and migraine headaches. Diane's other brother, Brian (age 38 years), has recently had bouts of depression and has noticed slight difficulties in coordination and involuntary movements. Brian and his wife, Sally, adopted a son, Dave, with Down syndrome, and he is 19 years old. Sarah's brother is age 12 years and does not have any medical problems.

1. What further data would you gather from Sarah before referring her to a genetic specialist?
2. What are the signs and symptoms of Huntington disease? The prognosis? Is it linked to any ethnic group?
3. Create a family pedigree for Sarah based on the family information she has provided. What does the pedigree reveal, and what nursing actions would you plan for Sarah?
4. What are the implications for Sarah's family if her test is positive for HD? What if her result is negative?
5. Should Sarah be tested at this time? Give a rationale for your answer.

Chapter 4
Growth and Development

We want to help our adopted daughter Irena grow into a healthy and special child. She had challenges in her short life in Romania that we can only imagine. We worry about how we can help her grow and develop.

—Mother of Irena, age 2

Learning Outcomes

4.1 Describe the major theories of development as formulated by Freud, Erikson, Piaget, Kohlberg, social learning theorists, and behaviorists.

4.2 Recognize risks to developmental progression and factors that protect against those risks.

4.3 Plan nursing interventions for children that are appropriate for each child's developmental state based on theoretical frameworks.

4.4 Explain contemporary developmental approaches such as temperament theory, ecologic theory, and the resilience framework.

4.5 Identify major developmental milestones for infants, toddlers, preschoolers, school-age children, and adolescents.

4.6 Synthesize information from several theoretical approaches to plan assessments of the child's physical growth and developmental milestones.

4.7 Describe the role of play in the growth and development of children.

4.8 Use data collected during developmental assessments to implement activities that promote development of children and adolescents.

Children develop as they interact with their surroundings. They learn skills at different ages, but the order in which they learn them is universal. Development is affected by factors such as nutrition and cultural practices, as well as the social situation in the country or neighborhood. While each child will develop in a unique manner influenced by genetic makeup, life experiences, and the interactions among these factors, certain principles of development assist parents and the nurse in fostering positive adaptations for the child.

This chapter covers general principles of growth and development and explores several theories related to childhood development, as well as their nursing applications. Each age group, from infancy through adolescence, is described in detail. Developmental milestones, physical and cognitive characteristics, play patterns, and communication strategies are presented, as are conditions that interfere with usual developmental progression. The information provided helps guide developmentally appropriate care for children in each age group and in a variety of situations. These concepts can be applied when caring for all children, including those in special situations.

Principles of Growth and Development

It is essential to understand the concepts of growth and development when learning to care for children. A skilled pediatric nurse integrates knowledge of physical growth and psychosocial

development into each child healthcare encounter. **Growth** refers to an increase in physical size. It represents quantitative changes such as height, weight, blood pressure, and number of words in the child's vocabulary. **Development** refers to a qualitative increase in capability or function. Developmental skills, such as the ability to sit without support or to throw a ball overhand, unfold in a complex manner influenced by the relationship between the child's innate capabilities and the stimuli and support provided in the environment. The quantitative and qualitative changes in body organ functioning, ability to communicate, and performance of motor skills develop over time and are key components in the process of planning pediatric health care.

Each child displays a unique maturational pattern during the process of development. Although the exact age at which skills emerge differs, the sequence or order of skill performance is uniform among children. Skill development proceeds according to two processes: from the head downward, and from the center of the body outward.

- **Cephalocaudal development** (Figure 4–1) proceeds from the head downward through the body and toward the feet. For example, at birth an infant's head is much larger proportionately than the trunk or extremities. Similarly, infants learn to hold up their heads before sitting and to sit before standing. Skills such as walking that involve the legs and feet develop last in infancy.
- **Proximodistal development** (see Figure 4–1) proceeds from the center of the body outward toward the extremities. For example, infants are first able to control the trunk, then the arms; only later are fine motor movements of the fingers possible. As the child grows, both physical and cognitive skills differentiate from general to more specific skills. Pediatric nurses use these concepts of predictable and sequential developmental direction to analyze the infant's and child's present state and to partner with parents to plan ways to encourage and support the next emerging developmental abilities.

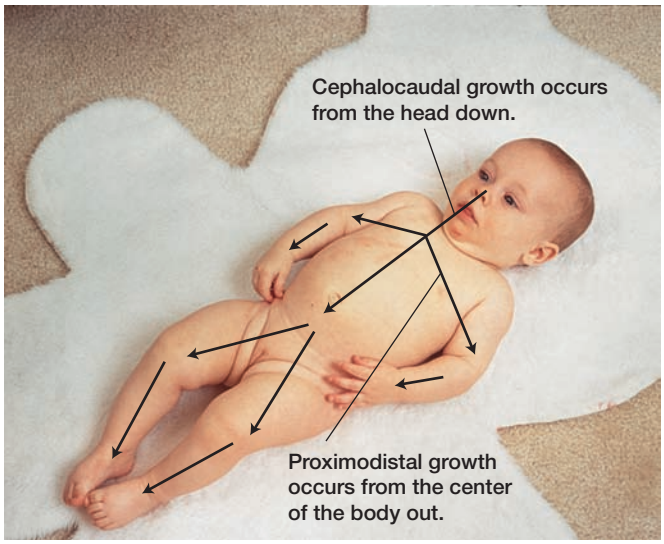

Figure 4–1 **Cephalocaudal and proximodistal development. In normal cephalocaudal growth, the child gains control of the head and neck before the trunk and limbs. In normal proximodistal growth, the child controls arm movements before hand movements. For example, the child reaches for objects before being able to grasp them. Children gain control of their hands before their fingers; that is, they can hold things with the entire hand before they can pick something up with just their fingers.**

During the childhood years, extraordinary changes occur in all aspects of development. Physical size, motor skills, cognitive ability, language, sensory ability, and psychosocial patterns all undergo major transformations. Nurses study normal patterns of development to identify children who demonstrate unexpected developmental findings. These assessments can guide the nurse in planning interventions for the child and family, such as referring the child for a diagnostic evaluation or rehabilitation, or teaching the parents how to provide adequate stimulation for the child. Nurses use **anticipatory guidance** to predict upcoming developmental tasks or needs of a child and to perform appropriate teaching related to them. When development is proceeding normally, nurses use their knowledge of these normal patterns to provide approaches based on the child's cognitive and language ability, to offer appropriate toys and activities during illness, and to respond therapeutically during interactions with the child. See Chapters 7 to 9 for specific application of developmental surveillance into health promotion visits. For situations with special challenges, such as in adoptions, additional interventions may be needed (see *Growth and Development*).

Growth and Development

About 15% of annual adoptions in the United States, or over 7000, are international adoptions. China, South Korea, Russia, Ethiopia, Uganda, Ukraine, and Haiti are among the most common countries of origin for orphans being adopted in the United States (U.S. Department of State, 2015). All adoptions can be stressful for the new parents and child, but international adoptions pose a unique set of circumstances that influence the child's development.

Parents need to protect themselves and others from infectious diseases when traveling to bring home a child from another country. They should consult their local health district and healthcare providers for a list of recommended immunizations for the country they are visiting. They should also obtain a list of medications and supplies to carry for themselves and the child, such as antidiarrheal medicine, decongestants, analgesics, bandages, and hand sanitizer (Children's Hospital of Philadelphia, 2012).

Parents require counseling to learn about cultural practices, language, and other differences they may encounter. Once they bring the child home, they will need support as the child grows to integrate the child's history and culture into their family. The moment when the child meets an adoptive parent may be seen as joyous by the parent but it can be traumatic for the young child, who is being separated from familiar adults. Parents need preparation for establishing trust with the child (Children's Hospital of Philadelphia, 2012).

The adopted child should be examined once home for length, weight, and head circumference. If growth is delayed, continued monitoring and dietary interventions will be needed. The psychosocially based problem of *avoidant/restrictive food intake disorder* (formerly called *eating disorder of infancy and childhood* or *failure to thrive*) should also be considered. (See Chapter 14 for a thorough discussion of this condition.) Parasitic infection and chronic diseases are possible causes of continuing growth abnormalities. Perform developmental screening to provide a baseline for future developmental observations. Frequent physical and psychosocial assessments will be needed, and teaching is provided for parents to enhance development.

SAFETY ALERT!

Although a primary purpose of understanding and monitoring development is to be able to apply anticipatory guidance so that parents and nurses can provide the child with appropriate toys and experiences, there is also a very important link between safety and development. Developmental knowledge provides information about the major illness and accident risks for each age group as well as preventive techniques. For example, a 6-month-old child should never be left alone on a high surface, preschoolers must be carefully monitored while playing, and teenagers must demonstrate responsibility before being allowed to drive. As you read this chapter, try to identify the physical, cognitive, and social reasons that guide the safety precautions to be taken with children of various ages.

Major Theories of Development

Child development is a complex process. Many theorists have attempted to organize their observations of behavior into a description of principles or a set of stages. Each theory focuses on a particular facet of development. Most developmental theorists separate children into age groups by common characteristics (Table 4–1).

Freud's Theory of Psychosexual Development

THEORETICAL FRAMEWORK

Sigmund Freud (1856–1939) was a physician in Vienna, Austria. His work with adults experiencing a variety of neurologic disorders led him to develop an approach called *psychoanalysis*, which explored the driving forces of the unconscious mind. These psychoanalytic techniques led Freud to believe that early childhood experiences form the unconscious motivation for actions in later life. He believed that sexual energy is centered in specific parts of the body at certain ages. Unresolved conflict and unmet needs at a certain stage lead to a fixation of development at that stage (Dunn & Craig, 2013).

Freud viewed the personality as a structure with three parts: The *id* is the basic sexual energy that is present at birth and drives the individual to seek pleasure; the *ego* is the realistic part of the person, which develops during infancy and searches for acceptable methods of meeting impulses; and the *superego* is the moral/ethical system, which develops in childhood and contains a set of values and a conscience (Dunn & Craig, 2013). The ego diverts impulses and protects itself from excess anxiety by use of **defense mechanisms**, including regression to earlier stages and repression or forgetting of painful experiences such as child abuse (Table 4–2).

TABLE 4–1 Developmental Age Groups

DEVELOPMENTAL STAGE	AGE GROUP	CHARACTERISTICS
Infancy	Birth to 12 months	Includes infants or babies up to 1 year of age, all of whom require a high level of care in daily activities.
Toddlerhood	1–3 years	Characterized by increased motor ability and independent behavior.
Preschool	3–6 years	The preschooler refines gross and fine motor ability and language skills and often participates in a preschool learning program.
School age	6–12 years	Begins with entry into a school system and is characterized by growing intellectual skills, physical ability, and independence.
Adolescence	12–18 years	Begins with entry into the teen years. Mature cognitive thought, formation of identity, and influence of peers are important characteristics of adolescence.

TABLE 4–2 Common Defense Mechanisms Used by Children

DEFENSE MECHANISM	DEFINITION	EXAMPLE
Regression	Return to an earlier behavior	A child who has been previously toilet trained becomes incontinent when a new infant is born into the family.
Repression	Involuntary forgetting of uncomfortable situations	An abused child cannot consciously recall episodes of abuse.
Rationalization	An attempt to make unacceptable feelings acceptable	A child explains hitting another because "he took my toy."
Fantasy	A creation of the mind to help deal with unacceptable fear	A hospitalized child who is weak pretends to be Superman.

Clinical Reasoning **International Adoption Counseling**

Michael and Alyssa had tried for several years to have a biologic child. After an unsuccessful in vitro fertilization, they decided to try to adopt a child. They explored opportunities with adoption agencies and learned that international adoption would be possible for them. They adopted 2-year-old Irena from Romania several months ago. Irena appears small for her age, but she seems to be thriving in her new environment. She is learning to say a few English words and is responding appropriately to care and interactions.

Despite thorough investigation of Michael and Alyssa by the adoption agency, they received only scant information about Irena's history. They were told that she was left at an orphanage by her birth mother when she was about 7 months old; the birth mother stated that the pregnancy and birth were normal. According to reports, the birth mother had decided to relinquish the child because she had two older children to care for and her husband had left home nearly a year before and had not been heard from since.

How can you work with Michael and Alyssa to ensure special attention to Irena's growth and healthcare needs, such as physical growth, language, and social skills? Consider both assessment and planned interventions.

What will Irena's cultural needs be as she grows older? How can Michael and Alyssa prepare to tell her about her adoption and background someday?

STAGES

Oral (Birth to 1 Year). The infant derives pleasure largely from the mouth, with sucking and eating as primary desires.

Anal (1 to 3 Years). The young child's pleasure is centered in the anal area, with control over body secretions as a prime force in behavior.

Phallic (3 to 6 Years). Sexual energy becomes centered in the genitalia as the child works out relationships with parents of the same and opposite sexes.

Latency (6 to 12 Years). Sexual energy is at rest in the passage between earlier stages and adolescence.

Genital (12 Years to Adulthood). Mature sexuality is achieved as physical growth is completed and relationships with others occur.

NURSING APPLICATION

Freud emphasized the importance of meeting the needs of each stage in order to move successfully into future developmental stages. The crisis of illness can interfere with normal developmental processes and add challenges for the nurse striving to meet an ill child's needs. For example, the importance of sucking in infancy guides the nurse to provide a pacifier for the infant who cannot have oral fluids. The preschool child's concern about sexuality guides the nurse to provide privacy and clear explanations during any procedures involving the genital area. It may be necessary to teach parents that masturbation by the young child is normal and to help parents deal with it through distraction or refocusing. The adolescent's focus on relationships suggests that the nurse should include questions about significant friends during history taking. Table 4–3 summarizes techniques the nurse can use to apply these theoretical concepts to the care of children.

Erikson's Theory of Psychosocial Development

THEORETICAL FRAMEWORK

Erik Erikson (1902–1994) studied Freud's theory of psychoanalysis under Freud's daughter, Anna. He later established his own developmental theory, which describes psychosocial stages during eight periods of human life. Five of Erikson's eight stages apply to children and are described below. For each stage, Erikson identified a crisis—that is, a particular challenge that exists for healthy personality development to occur (Erikson, 1963, 1968). The word *crisis* in this context refers to normal maturational social needs rather than to a single critical event. Each developmental crisis has two possible outcomes. When needs are met, the consequence is healthy and the individual moves on to future stages with particular strengths. When needs are not met, an unhealthy outcome occurs that will influence future social relationships.

STAGES

Trust Versus Mistrust (Birth to 1 Year). The task of the first year of life is to establish trust in the people providing care. Trust is fostered by provision of food, clean clothing, touch, and comfort. If basic needs are not met, the infant will eventually learn to mistrust others.

Autonomy Versus Shame and Doubt (1 to 3 Years). The toddler's sense of autonomy or independence is shown by controlling body excretions, saying no when asked to do something, and directing motor activity and play. Children who are consistently criticized for expressions of autonomy or for lack of control—for example, during toilet training—will develop a sense of shame about themselves and doubt in their abilities.

Initiative Versus Guilt (3 to 6 Years). The young child initiates new activities and considers new ideas. This interest in exploring the world creates a child who is involved and busy. Constant criticism, on the other hand, leads to feelings of guilt and a lack of purpose.

Industry Versus Inferiority (6 to 12 Years). The middle years of childhood are characterized by development of new interests and by involvement in activities. The child takes pride in accomplishments in sports, school, home, and community. If the child cannot accomplish what is expected, however, the result will be a sense of inferiority.

Identity Versus Role Confusion (12 to 18 Years). In adolescence, as the body matures and thought processes become more complex, a new sense of identity, or self, is established. The self, family, peer group, and community are all examined and redefined. The adolescent who is unable to establish a meaningful definition of self will experience confusion in one or more roles of life.

NURSING APPLICATION

Erikson's theory is directly applicable to the nursing care of children. Health promotion and health maintenance visits in the community provide opportunities for helping caregivers meet children's needs. Parents benefit from learning what the child's developmental tasks are at each stage and from discussing ideas about how to encourage healthy psychosocial development. Such discussions also may highlight parental concerns and provide a forum for reassurance about normal developmental characteristics, such as a child who does not follow through on each activity as a preschooler or tries different hairstyles each month as an adolescent.

The child's usual support from family, peers, and others is interrupted by hospitalization. The challenge of hospitalization also adds a situational crisis to the normal developmental crisis a child is experiencing. Although the nurse may meet many of the hospitalized child's needs, continued parental involvement is necessary both during and after hospitalization to ensure progression through expected developmental stages (see Table 4–3).

Piaget's Theory of Cognitive Development

THEORETICAL FRAMEWORK

Jean Piaget (1896–1980) was a Swiss scientist who wrote detailed observations of the behavior of his own and other children. Based on these observations, Piaget formulated a theory of cognitive (or intellectual) development. He believed that the child's view of the world is influenced largely by age and maturational ability. Given nurturing experiences, the child's ability to think matures naturally (Ginsberg & Opper, 1988; Piaget, 1972). The child incorporates new experiences via **assimilation** and changes to deal with these experiences by the process of **accommodation**. An example of assimilation occurs when the infant uses reflexes to suck on objects that touch the lips. With more experience the infant accommodates to learn that not all objects are pleasant to suck and cognitive structures change to integrate and learn from the experiences.

TABLE 4–3 Nursing Applications of Theories of Freud, Erikson, and Piaget

AGE GROUP	THEORIST/DEVELOPMENTAL STAGE	CHARACTERISTICS OF STAGE	NURSING APPLICATIONS
Infant (birth to 1 year)	Freud: Oral stage	The baby obtains pleasure and comfort through the mouth.	When a baby is not able to take foods or fluids, offer a pacifier if not contraindicated. After painful procedures, offer a baby a bottle or pacifier or have the mother breastfeed.
	Erikson: Trust versus mistrust stage	The baby establishes a sense of trust when basic needs are met.	Hold the hospitalized baby often. Offer comfort after painful procedures. Meet the baby's needs for food and hygiene. Encourage parents to room in. Manage pain effectively with use of pain medications and other measures.
	Piaget: Sensorimotor stage	The baby learns from movement and sensory input.	Use crib mobiles, manipulative toys, wall murals, and bright colors to provide interesting stimuli and comfort. Use toys to distract the baby during procedures and assessments.
Toddler (1–3 years)	Freud: Anal stage	The child derives gratification from control over body excretions.	Ask about toilet training and the child's rituals and words for elimination during admission history. Continue child's normal patterns of elimination in the hospital. Do not begin toilet training during illness or hospitalization. Accept regression in toileting during illness or hospitalization. Have potty chairs available in hospital and childcare centers.
	Erikson: Autonomy versus shame and doubt stage	The child is increasingly independent in many spheres of life.	Allow self-feeding opportunities. Encourage child to remove and put on own clothes, brush teeth, or assist with hygiene. (*A*) If immobilization for a procedure is necessary, proceed quickly, providing explanations and comfort.
	Piaget: Sensorimotor stage (end); preoperational stage (beginning)	The child shows increasing curiosity and explorative behavior. Language skills improve.	Ensure safe surroundings to allow opportunities to manipulate objects. Name objects and give simple explanations.
Preschooler (3–6 years)	Freud: Phallic stage	The child initially identifies with the parent of the opposite sex but by the end of this stage identifies with the same-sex parent.	Be alert for children who appear more comfortable with male or female nurses, and attempt to accommodate them. Encourage parental involvement in care. Plan for playtime and offer a variety of materials from which to choose.
	Erikson: Initiative versus guilt stage	The child likes to initiate play activities.	Offer medical equipment for play to lessen anxiety about strange objects. (*B*) Assess children's concerns as expressed through their drawings. Accept the child's choices and expressions of feelings.

A

B

AGE GROUP	THEORIST/DEVELOPMENTAL STAGE	CHARACTERISTICS OF STAGE	NURSING APPLICATIONS
	Piaget: Preoperational stage	The child is increasingly verbal but has some limitations in thought processes. Causality is often confused, so the child may feel responsible for causing an illness.	Offer explanations about all procedures and treatments. Clearly explain that the child is not responsible for causing an illness in self or family member.
School age (6–12 years)	Freud: Latency stage	The child places importance on privacy and understanding the body.	Provide gowns, covers, and underwear. Knock on door before entering. Explain treatments and procedures.
	Erikson: Industry versus inferiority stage	The child gains a sense of self-worth from involvement in activities.	Encourage the child to continue schoolwork while hospitalized. Encourage the child to bring favorite pastimes to the hospital. (*C*) Help the child adjust to limitations on favorite activities.
	Piaget: Concrete operational stage	The child is capable of mature thought when allowed to manipulate and see objects.	Give clear instructions about details of treatment. Show the child equipment that will be used in treatment.
Adolescent (12–18 years)	Freud: Genital stage	The adolescent's focus is on genital function and relationships.	Ensure access to gynecologic care for adolescent females and testicular examinations for adolescent males. Provide information on sexuality. Ensure privacy during health care. Have brochures and videos available for teaching about sexuality.
	Erikson: Identity versus role confusion stage	The adolescent's search for self-identity leads to independence from parents and reliance on peers.	Provide a separate recreation room for teens who are hospitalized. (*D*) Take health history and perform examinations without parents present. Introduce adolescent to other teens with same health problem.
	Piaget: Formal operational stage	The adolescent is capable of mature, abstract thought.	Give clear and complete information about health care and treatments. Offer both written and verbal instructions. Continue to provide education about the disease to the adolescent with a chronic illness, as mature thought now leads to greater understanding.

STAGES

Sensorimotor (Birth to 2 Years). Infants learn about the world by input obtained through the senses and by their motor activity. Six substages are characteristic of this stage.

Use of Reflexes (Birth to 1 Month). The infant begins life with a set of reflexes such as sucking, rooting, and grasping. By using these reflexes, the infant receives stimulation via touch, sound, smell, and vision. The reflexes thus pave the way for the first learning to occur.

Primary Circular Reactions (1 to 4 Months). Once the infant responds reflexively, the pleasure gained from that response causes repetition of the behavior. For example, if a toy grasped reflexively makes noise and is interesting to look at, the infant will grasp it again.

Secondary Circular Reactions (4 to 8 Months). Awareness of the environment grows as the infant begins to connect cause and effect. The sounds of bottle preparation will lead to excited behavior. If an object is partially hidden, the infant will attempt to uncover and retrieve it.

Coordination of Secondary Schemes (8 to 12 Months). Intentional behavior is observed as the infant uses learned behavior to obtain objects, create sounds, or engage in other pleasurable activities. **Object permanence** (the knowledge that something continues to exist even when out of sight) begins when the infant remembers where a hidden object is likely to be found; it is no longer "out of sight, out of mind." However, the concept of object permanence is not fully developed. The infant knows the parent well, objects to new people, and seems very worried when the parent leaves. Other caretakers may be rejected because the infant does not understand that the parent will return. This phase of "stranger anxiety" is quite common and heralds the infant's growing recognition of and desire to be cared for by the parent.

Tertiary Circular Reactions (12 to 18 Months). Curiosity, experimentation, and exploration dominate as the toddler tries out actions to learn results. At this age, children turn objects in every direction, place them in their mouths, use them for banging, and insert them in containers as they explore their qualities and uses.

Mental Combinations (18 to 24 Months). Language provides a new tool for the toddler to use in understanding the world. Language enables the child to think about events and objects before or after they occur. Object permanence is now fully developed as the child actively searches for objects in various locations and out of view. The child who has had successful separations from the parents followed by their return, such as hours spent in another's home or childcare center, begins to understand that the missing parent will return.

Preoperational (2 to 7 Years). The young child thinks by using words as symbols, but logic is not well developed. Two substages characterize this stage.

Preconceptual Substage. During the preconceptual substage (2 to 4 years), vocabulary and comprehension increase greatly but the child is egocentric (i.e., unable to see things from the perspective of another).

Intuitive Substage. In the intuitive substage (4 to 7 years), the child relies on transductive reasoning (drawing conclusions from one general fact to another). For example, when a child disobeys a parent and then falls and breaks an arm that same day, the child may ascribe the broken arm to bad behavior. Cause-and-effect relationships are often unrealistic or a result of magical thinking (the belief that events occur because of thoughts or wishes).

Additional characteristics noted in the thought of preschoolers include *centration*, or the ability to consider only one aspect of a situation at a time, and *animism*, or giving life to inanimate objects because they move, make noise, or have certain other qualities.

Concrete Operational (7 to 11 Years). Transductive reasoning has given way to a more accurate understanding of cause and effect. The child can reason quite well if concrete objects are used in teaching or experimentation. The concept of conservation (that matter does not change when its form is altered) is learned at this age.

Formal Operational (11 Years to Adulthood). Fully mature intellectual thought has now been attained. The adolescent can think abstractly about objects or concepts and consider different alternatives or outcomes.

NURSING APPLICATION

Piaget's theory is essential to pediatric nursing. The nurse must understand a child's thought processes in order to design stimulating activities and meaningful, appropriate teaching plans. What activities could be planned for a hospitalized child based on his or her expected cognitive level? How can cognitive development be encouraged in a school-age child receiving home health services? Understanding a child's concept of time suggests how far in advance to prepare that child for procedures. Similarly, decisions about offering manipulative toys, reading stories, drawing pictures, or giving the child reading material to explain healthcare measures depend on the child's cognitive stage of development (see Table 4–3).

Kohlberg's Theory of Moral Development

THEORETICAL FRAMEWORK

Lawrence Kohlberg (1927–1987) was a German theorist who used Piaget's cognitive theory as a basis for his theory of moral development. He presented stories involving moral dilemmas to children and adults and asked them to solve the dilemmas. Kohlberg then analyzed the motives they expressed when making decisions about the best course to take. Based on the explanations given, Kohlberg established three levels of moral reasoning. Although he provided age guidelines, he stated that they are approximate and that many people never reach the highest (postconventional) stage of development (Santrock, 2012).

STAGES

Preconventional (4 to 7 Years). Decisions are based on the desire to please others and to avoid punishment.

Conventional (7 to 12 Years). Conscience, or an internal set of standards, becomes important. Rules are important and must be followed to please other people and "be good."

Postconventional (12 Years and Older). The individual has internalized ethical standards on which to base decisions. Social responsibility is recognized. The value in each of two differing moral approaches can be considered and a decision made.

NURSING APPLICATION

Decision making is required in many areas of health care. Children can be assisted to make decisions about health care and to

consider alternatives when available. Keep in mind that young children may agree to participate in research simply because they want to comply with adults and appear cooperative. Guidelines for child participation in research are available (see Chapter 1).

Parents can be provided with information so that they can assist their children in moral judgments. Encourage talking with a child or adolescent about how a particular decision was made. Parents can then add information and help the child learn to integrate more factors into decision making. Talking about the process is important in helping children progress to higher moral development stages. Focusing on the feelings of others, using positive discipline techniques, and clearly identifying positive and negative behaviors are important.

Social Learning Theory

THEORETICAL FRAMEWORK

Originally from Canada, psychologist Albert Bandura (1925–) has conducted research at Stanford University for many years. He believes that children learn attitudes, beliefs, customs, and values through their social contacts with adults and other children. Children imitate (or model) the behavior they see; if the behavior is positively reinforced, they tend to repeat it. The external environment and the child's internal processes are key elements in social learning theory (Bandura, 1986, 1997a).

Bandura believes that an important determinant of behavior is self-efficacy, or the expectation that someone can produce a desired outcome. For example, if adolescents believe they can avoid use of drugs or alcohol, they are more likely to do so. A child who has confidence in his or her ability to exercise regularly or lose weight has a greater chance of success with these behavior changes. Parents who have confidence in their ability to care adequately for their infants are more likely to do so (Bandura, 1997b). See *Evidence-Based Practice: Concept of Self-Efficacy* for further examples of application of the concept of self-efficacy.

NURSING APPLICATION

The importance of modeling behavior can readily be applied in health care. Children are more likely to cooperate if they see adults or other children performing a task willingly. A frightened child may watch another child perform vision screening or have blood drawn and then decide to allow the procedure to take place. Contact with positive role models is useful when teaching children and adolescents self-care for chronic diseases such as diabetes. Give positive reinforcement for desired performance.

Nurses can use the concept of self-efficacy to increase the chance of success with lifestyle behavior changes. For example, encouraging youth who are trying to quit smoking, providing them with role models, and pointing out parental successes with their children all demonstrate methods of fostering self-efficacy.

Behaviorism

THEORETICAL FRAMEWORK

John Watson (1878–1958) was an American scientist who applied the research of animal behaviorists, such as Pavlov and Skinner, to children. Pavlov and, later, Skinner worked with animals, presenting a stimulus such as food and pairing it with another stimulus such as a ringing bell. Eventually the animal being fed began to salivate when the bell rang. As Skinner and, then, Watson began to apply these concepts to children, they showed that behaviors can be elicited by positive reinforcement, such as a food treat, or extinguished by negative reinforcement, such as

EVIDENCE-BASED PRACTICE | Concept of Self-Efficacy

Clinical Question

How can nurses use the concept of self-efficacy when planning interventions for children and families?

The Evidence

Parental self-efficacy is the belief that parents can manage a range of tasks and situations in caring for their children. Higher self-efficacy scores in parents were predictive of greater success in treatment of young children who were overweight (Davies, Terhorts, Nakonechny, et al., 2014). The authors of this literature review also established an Internet site to provide information and enhance self-efficacy in parents regarding healthy lifestyles for children (Davies et al., 2014).

Mothers who have a greater degree of self-efficacy about ability to breastfeed are significantly more likely to begin and to continue breastfeeding. A Breastfeeding Self-Efficacy Scale has been developed to identify risk and protective factors that influence the self-efficacy of new mothers. Evaluating breastfeeding self-efficacy in Hispanic women was able to inform the topics for teaching that would best promote breastfeeding (Joshi, Trout, Aguirre, et al., 2014).

An intervention with over 1000 students in grades 5 and 6 was effective in increasing youth self-efficacy regarding television viewing time and decreasing television viewing time (Salmon et al., 2011).

Best Practice

In addition to providing information about health behaviors, nurses need to integrate methods to increase self-efficacy in teaching projects with families. Assessments should be designed to identify self-efficacy of parents and children around health topics of interest. When planning interventions to encourage health behaviors in children and adolescents, assess the youth's beliefs that the new behaviors are important and that they can be adopted. Include interventions that demonstrate that others have adopted the health behaviors and plan approaches to enhance the child's belief in ability to change.

Clinical Reasoning

Plan a teaching project about the importance of physical activity and healthy eating for presentation to a group of 12-year-olds. What approaches will enhance the self-efficacy of the children? How would interventions to enhance self-efficacy differ for young elementary school children from those in middle or high school? What theoretical approaches discussed earlier in this chapter help you understand the cognitive abilities of children at various ages and suggest ways to influence their self-efficacy?

scolding or withdrawal of attention. Watson believed that he could make a child into anyone he desired—from a professional to a thief or beggar—simply by reinforcing behavior in certain ways (Santrock, 2012).

NURSING APPLICATION

Behaviorism has been criticized for being simplistic and for its denial of people's inherent capacity to respond willfully to events in the environment. However, this theory does have some use in health care. When particular behaviors are desired, healthcare providers can establish positive reinforcement to encourage these behaviors. Using behavioral techniques, nurses may influence the behavior of children by giving a sticker to a child after a physical examination or a blood draw. Parents often use reinforcement in toilet training and other skills learned in childhood.

Ecologic Theory

THEORETICAL FRAMEWORK

There is controversy among theorists concerning the relative importance of heredity versus environment—or nature versus nurture—in human development. **Nature** refers to the genetic or hereditary capability of an individual. **Nurture** refers to the effects of the environment on a person's performance (Figure 4–2). Piaget believed in the importance of internal cognitive structures that unfold at their appointed times, given any environment that provides basic opportunities. He emphasized the strength of nature. The behaviorist John Watson, on the other hand, believed that behaviors are primarily shaped by environmental responses; he thus stressed the predominance of nurture. Contemporary developmental theories increasingly recognize the interaction of nature and nurture in determining the child's development.

Urie Bronfenbrenner (1917–2005), a professor at Cornell University, formulated the ecologic theory of development to explain the unique relationship of the child with all of life's experiences or systems (Bronfenbrenner, 1986, 2005; Bronfenbrenner, McClelland, Ceci, et al., 1996). **Ecologic theory** emphasizes the presence of mutual interactions between the child and these various settings or systems. Neither nature nor nurture is considered of more importance. Bronfenbrenner believed each child brings a unique set of genes—as well as specific attributes such as age, gender, health, and other characteristics—to his or her interactions with the environment. The child then interacts in many settings at different levels or systems (Figure 4–3).

Figure 4–2 **An example of nurturing. Children exposed to pleasant stimulation and who are supported by an adult will develop and refine their skills faster. Group activities such as these provide an opportunity for both motor skill and psychosocial development. Can you identify which skills are being developed?**

LEVELS/SYSTEMS

Microsystem. This level is defined as the daily, consistent, close relationships such as home, child care, school, friends, and neighbors. For the child with a chronic illness requiring regular care, the healthcare providers may even be part of the microsystem. In the ecologic model, the child influences each of the settings in the microsystem, in addition to being influenced by them, with reciprocal interactions.

Mesosystem. This level includes relationships of microsystems with one another. For example, two microsystems for most children are the home and the school. The relationships between these microsystems are shown by parents' involvement in their children's school. This involvement, in turn, influences the effects of the home and school settings on the children.

Exosystem. This level is composed of those settings that influence the child even though the child is not in close daily contact with the system. Examples include the parents' jobs and the governing board of the local school district. Although the child may not go to the parents' workplaces, the child can be influenced by policies related to health care, sick leave, inflexible work hours, overtime, or travel, or even by the mood of the boss (through its impact on the parent). Likewise, when a local school board votes to ban certain books or to finance a field trip, the child is influenced by these decisions; the child, in turn, can help establish an atmosphere that will guide future school board decisions.

Macrosystem. This level includes the beliefs, values, and behaviors expressed in the child's environment. Culture is a powerful influence in the macrosystem, as is the political system. For instance, a democratic system creates different beliefs, values, and even eating practices than an anarchic system.

Chronosystem. This final level brings the perspective of time to the previous settings. The time period during which the child grows up influences views of health and illness. For example, the experiences of children with influenza in the 19th versus the 20th century were quite different. The age of the parent, child, and other family members also influences views of health.

NURSING APPLICATION

Nurses use ecologic theory when they assess the child's settings to identify influences on development. Table 4–4 provides an assessment tool based on this theory. Interventions are planned to enhance the strengths of the child's settings and to improve on areas that are not supportive.

Temperament Theory

THEORETICAL FRAMEWORK

In contrast to behaviorists such as Watson or maturational theorists such as Piaget, Stella Chess and Alexander Thomas recognize the innate qualities of personality that each individual brings to the events of daily life. They, like Bronfenbrenner, believe the

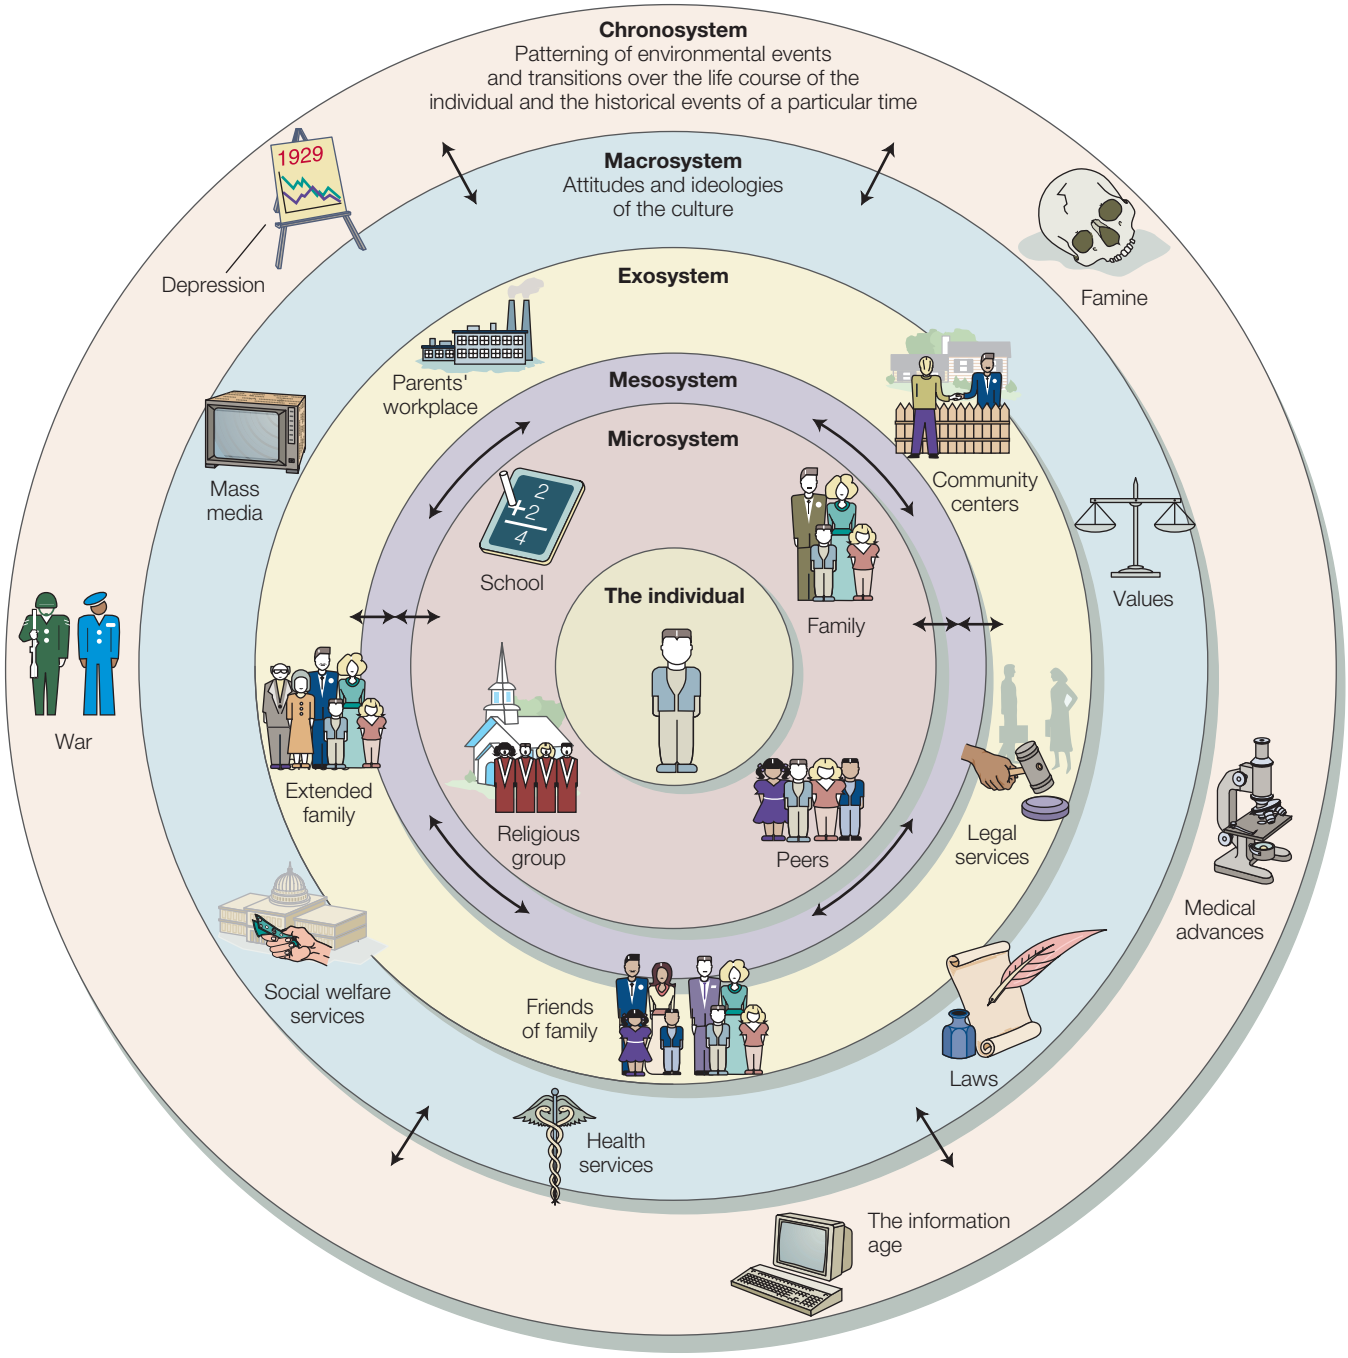

Figure 4–3 **Bronfenbrenner's ecologic theory of development views the individual as interacting within five levels or systems.**

SOURCE: Data from Santrock, J. W. (2007). *Life-span development*. Madison, WI: Brown & Benchmark. Based on Bronfenbrenner's (1979, 1986) works in Contexts of child rearing: Problems and prospects. *American Psychologist*, *34*, 844–850; Ecology of the family as a context for human development: Research perspectives. *Developmental Psychology*, *22*, 723–742.

child is an individual who both influences and is influenced by the environment. However, Chess and Thomas focus on one specific aspect of development—the wide spectrum of behaviors possible in children—identifying nine parameters of response to daily events (Table 4–5). Their theory is based on a research study titled the New York Longitudinal Study, which began with infants in 1956 and has continued into the adulthood of these participating individuals. By careful observations of responses to life events, Chess and Thomas identified characteristics of personality that provide the basis for the study on temperament. Infants generally display clusters of responses, which are classified into three major personality types (Table 4–6). Although most children do not demonstrate all behaviors described for a particular type, they usually show a grouping indicative of one personality type (Chess & Thomas, 1995, 1996, 1999).

Recent research demonstrates that personality characteristics displayed during infancy are often consistent with those seen later in life. Predicting future characteristics is not possible, however, because of the complex and dynamic interaction of personality traits and environmental reactions.

TABLE 4–4 Assessment of Ecologic Systems in Childhood—Bronfenbrenner

MICROSYSTEMS	MESOSYSTEMS	EXOSYSTEMS	MACROSYSTEMS	CHRONOSYSTEMS
Parents Significant others in close contact Childcare arrangements School Neighborhood contacts Clubs Friends, peers Religious community (e.g., churches, synagogues, mosques)	Parents' involvement in child care or school Parents' involvement in community Parents' relationships with significant others (e.g., grandparents, care providers) Influences of religious community (e.g., church, synagogue, mosque) or parents and school	Community centers Local political influences Parents' work Parents' friends and activities Social services Health care Libraries	Cultural group membership Beliefs and values of group Political structure	Child's and parents' ages Period in historic time

TABLE 4–5 Nine Parameters of Personality

PARAMETER	DESCRIPTION	SCORING
1. Activity level	The degree of motion during eating, playing, sleeping, bathing	Scored as high, medium, or low
2. Rhythmicity	The regularity of schedule maintained for sleep, hunger, elimination	Scored as regular, variable, or irregular
3. Approach or withdrawal	The response to a new stimulus such as a food, activity, or person	Scored as approachable, variable, or withdrawn
4. Adaptability	The degree of adaptation to new situations	Scored as adaptive, variable, or nonadaptive
5. Threshold of responsiveness	The intensity of stimulation needed to elicit a response to sensory input, objects in the environment, or people	Scored as high, medium, or low
6. Intensity of reaction	The degree of response to situations	Scored as positive, variable, or negative
7. Quality of mood	The predominant mood during daily activity and in response to stimuli	Scored as positive, variable, or negative
8. Distractibility	The ability of environmental stimuli to interfere with the child's activity	Scored as distractible, variable, or nondistractible
9. Attention span and persistence	The amount of time devoted to activities (compared with other children of the same age) and the degree of ability to stick with an activity in spite of obstacles	Scored as persistent, variable, or nonpersistent

Source: Data from Chess, S., & Thomas, A. (1996). *Temperament: Theory and practice.* Philadelphia, PA: Brunner/Mazel, Publishers.

Many other researchers have expanded the work of Chess and Thomas, developing assessment tools for temperament types. The concept of "goodness of fit" is an outgrowth of this theory. *Goodness of fit* refers to whether parents' expectations of their child's behavior are consistent with the child's temperament type. There is a "good fit" when the properties of the environment are in accord with the child's capabilities, characteristics, and style of behavior, and when the people in the environment know how to best support the child (The Center for Parenting Education, 2014). For example, an infant who is very active and reacts strongly to verbal stimuli may be unable to sleep well when placed in a room with older siblings. A child who is slow to warm up may not perform well in the first few months at a new school, much to the parents' disappointment. When parents understand a child's temperament characteristics, they are better able to shape the environment to meet the child's needs.

NURSING APPLICATION

The concept of personality type or temperament is a useful one for nurses. Nurses can assess the temperament of young children and alter the environment to meet their needs. This may involve moving a hospitalized child to a single room to ensure adequate rest if the child is easily stimulated, or allowing a shy child time to become accustomed to new surroundings and equipment before beginning procedures or treatments.

Parents are often relieved to learn about temperament characteristics. They learn to appreciate their children's qualities and to adapt the environment to meet the children's needs. A burden of guilt can also be lifted from parents who feel that they are responsible for their child's actions. Parents may be taught ways to enhance goodness of fit between the child's personality and the environment (Chess & Thomas, 1999) (Table 4–7).

TABLE 4–6 Patterns of Temperament

PATTERN	DESCRIPTION	% OF N.Y. LONGITUDINAL STUDY PARTICIPANTS
The "easy" child	Generally moderate in activity Shows regularity in patterns of eating, sleeping, and elimination Usually positive in mood Adapts to new situations when subjected to new stimuli Able to accept rules Works well with others	Approximately 40%
The "difficult" child	Displays irregular schedules for eating, sleeping, and elimination Adapts slowly to new situations and persons Displays a predominantly negative mood Intense reactions to the environment common	Approximately 10%
The "slow-to-warm-up" child	Initial withdrawal, followed by gradual, quiet, slow interaction with the environment Adapts slowly to new situations Mild reactions to environment	Approximately 15%
Mixed	Some of each personality type's characteristics apparent	Approximately 35%

TABLE 4–7 Ways to Improve Goodness of Fit Between Parents and Child

CHILD'S BEHAVIOR	PARENTS' ADAPTATIONS
Extremely active	Plan periods of active play several times a day. Have restful periods before bedtime to foster sleep.
Shy	Allow time to adapt at own pace to new people and situations.
Easily stimulated	Have quiet room for sleeping for an infant. Have quiet room for homework for a school-age child.
Short attention span	Provide projects that can be completed in a short period. Gradually encourage longer periods at activities.

Resiliency Theory

THEORETICAL FRAMEWORK

Why do some children coming from similar backgrounds have such different behavioral outcomes? The resiliency theory examines the individual's characteristics as well as the interaction of these characteristics with the environment. **Resilience** is the ability to function with healthy responses even when faced with significant stress and adversity (Benard, 2014; Henderson, Benard, & Sharp-Light, 2007). In this model, the individual or family members experience a crisis that provides a source of stress, and the family interprets or deals with the crisis based on resources available. Families and individuals have **protective factors**, which are characteristics that provide strength and assistance in dealing with crises, and **risk factors**, which are characteristics that promote or contribute to their challenges (Cairns, Yap, Pilkington, et al., 2014). Risk and protective factors can be identified in children, in their families, and in their communities. (See Chapter 17 for further description of the interplay of social and environmental factors with individual characteristics.) A crisis for a young child might be a transfer to a new childcare provider. Protective factors could involve past positive experiences with new people, an "easy" temperament, and the new childcare provider's awareness of adaptation needs of young children to new experiences. Risk factors for a similar child might be repeated moves to new childcare providers, limited close relationships with adults, and a "slow-to-warm-up" temperament.

Once confronted by a stress or crisis, the child and family first experience the **adjustment phase**, characterized by disorganization and unsuccessful attempts at meeting the crisis. In the **adaptation phase**, the child and family meet the challenge and use resources to deal with the crisis. Adaptation may lead to increasing resilience as well when the child and family learn about new resources and inner strengths and develop the ability to deal more effectively with future crises. Components and examples are described in Table 4–8.

NURSING APPLICATION

Nurses gather information about the individual characteristics, prior life experiences, and environmental factors that act as protective and risk factors for children. Table 4–9 lists questions that can be helpful as the nurse gathers information from a child or family members. Nurses then use concepts of resiliency theory in planning interventions for children and families. Nursing strategies can target risk factors, such as encouraging gun safety in families with firearms, and by teaching about use of gun trigger locks and locked gun cabinets. In addition, protective factors can be emphasized, such as encouraging holding and verbalization to parents of infants to provide an environment that allows for trust establishment and speech development.

Influences on Development

Both nature and nurture are important in determining individual patterns of development. The interaction of these two forces can explain differences in time frames for acquisition of developmental skills, personality variations between identical twins, and other unique characteristics of individuals. Genetic

TABLE 4–8 Components of Intervention in the Resiliency Wheel

COMPONENT	EXAMPLE OF INTERVENTIONS
Provide caring and support.	Listen to concerns. Provide information based on developmental level.
Set and communicate high expectations.	Express confidence in child's ability to succeed. Provide youth and families with resources.
Provide opportunities for meaningful participation.	Facilitate the youth's problem solving about ways to improve situations.
Increase prosocial bonding.	Assist youth to work with others on positive, purposeful activities. Facilitate community participation.
Set and communicate high expectations.	Communicate rules and establish routines. Assist families in setting clear expectations for behaviors and consequences.
Teach life skills.	Encourage communication of thoughts and feelings. Facilitate critical thinking and problem solving skills.

TABLE 4–9 Assessment Questions to Determine Resilience Capability

CATEGORY	QUESTIONS
To determine risk factors, ask:	• Describe the event that occurred and what it has been like for your family. • What other stressors do you have in your family right now? • Are there financial worries? • Are there things you think and worry about late at night? • Describe your job, your friends. • What is a typical day like? • Describe your neighborhood. • Do you have friends, people to call in emergencies?
To determine protective factors, ask:	• What gives you strength? • How do you deal with this stress? • What do you think you do well in your family? • Who do you call when you need help? • Do you have a computer? Internet access? • Are you religious? Spiritual? • Do you exercise regularly? • How do you spend free time?

and environmental factors interact and contribute to individual differences in rates and outcomes of child development.

Genetic inheritance plays an important part in the child's potential and the unfolding of developmental milestones. See Chapter 3 for a description of chromosomes and genes. Every chromosome carries many genes that determine physical characteristics, intellectual potential, personality type, and other traits. Children are born with the potential for certain features; however, their interaction with the environment influences how and to what extent particular traits are manifested.

Some Asian cultures calculate age from the time of conception. This practice acknowledges the profound influence of the prenatal period. The mother's nutrition and general state of health play a part in pregnancy outcome. Poor nutrition can lead to small infants and infants with compromised neurologic performance, slow development, or impaired immune status with resultant high disease rates. Low maternal stores of iron can result in anemia in the infant (American Academy of Pediatrics, 2013). Maternal smoking is associated with low-birthweight infants. Ingestion of alcoholic beverages, including beer and wine, during pregnancy may lead to fetal alcohol syndrome (Figure 4–4). Illicit drug use by the mother may result in neonatal addiction, convulsions, hyperirritability, poor social responsiveness, and other neurologic disturbances.

Even prescription or over-the-counter drugs may adversely affect the fetus. This was brought to general attention with the drug thalidomide, which was commonly used in Europe to treat nausea during the 1950s. This drug resulted in the birth of infants with limb abnormalities to women who used the drug during pregnancy. Differences in physiology related to gastric emptying, renal clearance, drug distribution, and other factors contribute to variations in pharmacokinetics during pregnancy. Drugs can cause teratogenesis (abnormal development of the fetus) or mutagenesis (permanent changes in the fetus's genetic material). Certain drugs can cause bleeding, stained teeth, impaired hearing, or other developmental effects. The U.S. Food and Drug Administration (FDA) has established risk categories for drugs in pregnancy.

Some maternal illnesses are harmful to the developing fetus. An example is rubella (German measles), which is rarely a serious disease for adults but can cause deafness, vision defects, heart defects, and intellectual disability in the fetus if it is acquired by a pregnant woman. A fetus can also acquire diseases such as acquired immunodeficiency syndrome (AIDS)/human immunodeficiency virus (HIV) infection or hepatitis B from the mother.

Figure 4–4 **A child with fetal alcohol syndrome.**

SOURCE: Rick's Photography/Shutterstock.

Radiation, chemicals, and other environmental hazards may adversely affect a fetus when the mother is exposed to any of these influences during her pregnancy. The best outcomes for infants occur when mothers eat well; exercise regularly; seek early prenatal care; refrain from use of drugs, alcohol, tobacco, and excessive caffeine; and follow general principles of good health.

As we have seen, both nature and nurture are important in determining individual patterns of development. These two forces interact in unique ways in each individual, explaining differences in time frames for acquisition of developmental skills among children, personality variations between identical twins, and other unique characteristics of individuals. An environmental factor that is extremely important in the development of children is the profile of family characteristics. The family is an important component in the lives of all children and plays an essential role in fostering the development of youth. A significant concept in families is that of parenting. How children are parented interacts with their individual characteristics to influence risk and protective factors, personality characteristics, and developmental outcomes. The families into which children are born influence them profoundly. Children are supported in different ways and acquire different worldviews depending on such factors as whether one or both parents work, how many siblings are present, and whether an extended family is close by. Note should be made of variations in family structure such as single parent, homosexual parents, extended family, and stepparents. Foster parenting and movement of children into a number of foster homes during childhood influences children's self-esteem and the ability to perform at potential. How might a nontraditional "family" setting, such as an adoptive or foster home, influence a child's development?

Professionalism in Practice Foster Care

On a given day, about 400,000 U.S. children are in foster care, with the average time in such care being nearly 2 years (U.S. Department of Health and Human Services, 2013). Each state is responsible for establishing the standards of education, environmental provision, and other factors of foster homes. The Office of Data, Analysis, Research and Evaluation of the Administration on Children, Youth and Families (ACYF) maintains information about foster care in the United States through the Adoption and Foster Care Analysis and Reporting System (AFCARS). The Foster Care Independence Act of 1999 fosters youth who are becoming too old for the foster care system to achieve self-sufficiency. The U.S. Education and Training Voucher Program helps youth to obtain college or vocational training at a free or reduced cost.

Nurses should recognize that children who are in foster care may have experienced family situations that were challenging or traumatic, and can be dealing with new living situations. Carefully assess the stress, adaptation, and risk and protective factors in children who are living in foster homes. Evaluate proximity to siblings and other family members as well as expectations for return to the primary family or adoption options. Support foster families so that they can provide the care needed for their foster children.

Another factor that influences child development is that of culture. The traditional customs of the many cultural groups represented in North American society influence the development of the children in these groups. Foods commonly eaten vary among people with different cultural backgrounds and influence the incidence of health problems such as cardiovascular disease in these groups. The Native American practice of carrying infants on boards often delays walking when measured against the norm for walking on some developmental tests. Children who are carried by straddling the mother's hips or back for extended periods have a low incidence of developmental dysplasia of the hip since this keeps their hips in an abducted position. It is important for nurses to take cultural practices into account when performing developmental screening; some tests may not be culturally sensitive and can inaccurately label a child as delayed when the pattern of development is simply different in the group, perhaps due to childrearing practices in the family. In addition, certain ethnic or racial groups are more prone to develop certain diseases due to genetic variations. Examples include Hispanics, who have a high incidence of diabetes; African Americans, who more commonly have sickle cell disease; and Northern European Americans, who have a higher incidence of phenylketonuria.

All cultural groups have rules regarding patterns of social interaction. Schedules of language acquisition are determined by the number of languages spoken and the amount of speech in the home. The particular social roles assumed by men and women in the culture affect school activities and ultimately career choices. Attitudes toward touching and other methods of encouraging developmental skills vary among cultures.Chapter 10 includes further descriptions of other factors that influence child development such as school and child care, community services, and additional community and family factors.

Infant (Birth to 1 Year)

Imagine the experience of tripling body weight in 1 year, or becoming proficient in understanding fundamental words in a new language and even speaking a few. These and many more accomplishments take place in the first year of life. Starting the year as a mainly reflexive creature, the infant can walk and communicate by the year's end. Never again in life is development so rapid and profound.

Physical Growth and Development

The first year of life is one of rapid change for the infant. The birth weight usually doubles by about 5 months and triples by the end of the first year (Figure 4–5). Height increases by about a foot during this year. Teeth begin to erupt at about 6 months, and by the end of the first year, the infant has six to eight deciduous teeth (see Chapter 5). Physical growth is closely associated with type and quality of feeding. (See Chapter 14 for a discussion of nutrition in infancy.)

Body organs and systems, although not fully mature at age 1 year, function differently from what they did at birth. Kidney and liver maturation helps the 1-year-old excrete drugs or other toxic substances more readily than in the first weeks of life. The changing body proportions mirror changes in developing internal organs. Maturation of the nervous system is demonstrated by increased control over body movements with growing differentiation from general to specific skills, thus enabling the infant to sit, stand, and walk. Sensory function also increases as the infant begins to discriminate visual images, sounds, and tastes (Table 4–10).

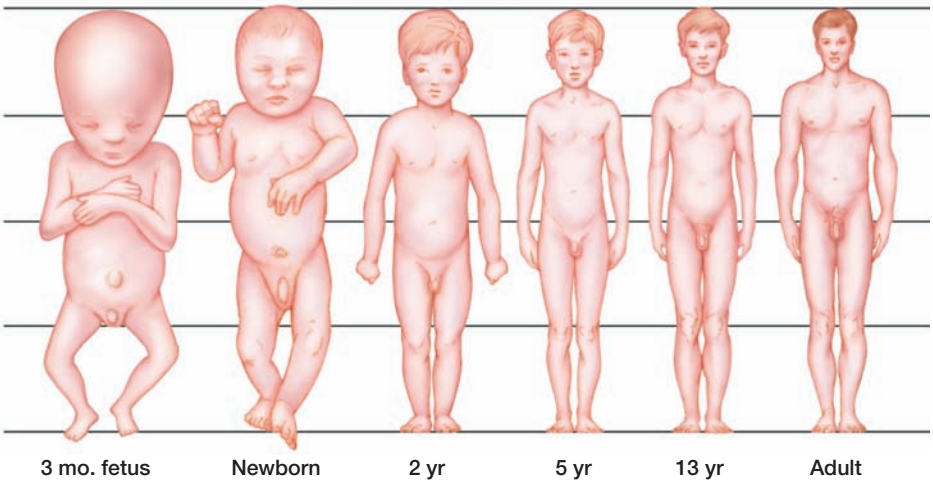

Figure 4–5 **Body proportions at various ages.**

Cognitive Development

The brain continues to increase in complexity during the first year. Most of the growth involves maturation of cells, with only a small increase in number of cells. This growth of the brain is accompanied by development of its functions. One only has to compare the behavior of an infant shortly after birth with that of a 1-year-old to understand the incredible maturation of brain function. The newborn's eyes widen in response to sound; the 1-year-old turns to the sound and recognizes its significance. The 2-month-old cries and coos; the 1-year-old says a few words and understands many more. The 6-week-old grasps a rattle for the first time; the 1-year-old reaches for toys and feeds self.

The infant's behaviors provide clues about thought processes. Piaget's work outlines the infant's actions in a set of

TABLE 4–10 Physical Growth and Development Milestones During Infancy

AGE	PHYSICAL GROWTH	FINE MOTOR ABILITY	GROSS MOTOR ABILITY	SENSORY ABILITY
Birth to 1 month	Gains 140–200 g (5–7 oz)/week Grows 1.5 cm (1/2 in.) in first month Head circumference increases 1.5 cm (1/2 in.)/month	Holds hand in fist (*A*) Draws arms and legs to body when crying	Inborn reflexes such as startle and rooting are predominant activity May lift head briefly if prone (*B*) Alerts to high-pitched voices Comforts with touch (*C*)	Prefers to look at faces and black-and-white geometric designs Follows objects in line of vision (*D*)

rapidly progressing changes in the first year of life. The infant receives stimulation through sight, sound, and feeling, which the maturing brain interprets. This input from the environment interacts with internal cognitive abilities to enhance cognitive functioning.

Psychosocial Development

PLAY

An 8-month-old infant is sitting on the floor, grasping blocks and banging them on the floor. Infants spend much of their time engaging in **solitary play**, or playing by themselves. When a parent walks by, the infant laughs and waves hands and feet wildly. Physical capabilities enable the infant to move toward and reach out for objects of interest. Cognitive ability is reflected in manipulation of blocks to create different sounds. Social interaction enhances play. The presence of a parent or other person increases interest in surroundings and teaches the infant different ways to play.

The play of infants begins in a reflexive manner. When an infant moves extremities or grasps objects, the foundations of play are established. The feel and sound of these activities give pleasure to the infant, who gradually performs them purposefully. For example, when a parent places a rattle in the hand of a 6-week-old infant, the infant grasps it reflexively. As the hands move randomly, the rattle makes an enjoyable sound. The infant learns to move the rattle to create the sound and then finally to grasp the rattle at will to play with it.

The next phase of infant play focuses on manipulative behavior. The infant examines toys closely, looking at them, touching them, and placing them in the mouth. The infant learns a great deal about texture, qualities of objects, and all aspects of the surroundings. At the same time, interaction with others becomes an important part of play. The social nature of play is obvious as the infant plays with other children and adults.

Toward the end of the first year, the infant's ability to move in space enlarges the sphere of play (Table 4–11). The infant who has begun crawling or walking can get to new places, find new toys, discover forgotten objects, or seek out other people for interaction. Play is a reflection of every aspect of development, as well as a method for enhancing learning and maturation.

PERSONALITY AND TEMPERAMENT

Why does one infant frequently awaken at night crying while another sleeps for 8 to 10 hours undisturbed? Why does one infant smile much of the time and react positively to interactions while another is withdrawn with unfamiliar people and frequently frowns and cries? Such differences in responses to the environment are believed to be inborn characteristics of temperament. Infants are born with a tendency to react in certain ways to noise and to interact differently with people. They may display varying degrees of regularity in activities of eating and sleeping, and manifest a capacity for concentrating on tasks for different amounts of time.

Nursing assessment identifies personality characteristics of the infant that the nurse can share with the parents. With this information the parents can appreciate more fully the uniqueness of their infant and design experiences to meet the infant's needs. Parents can learn to modify the environment to promote adaptation. For example, an infant who does not adapt easily to new situations may cry, withdraw, or develop another way of coping when adjusting to new people or places. Parents might be advised to use one or two babysitters rather than engaging new sitters frequently. If the infant is easily distracted when eating, parents can feed the infant in a quiet setting to encourage a focus on eating. Although the infant's temperament is unchanged, the ability to fit with the environment is enhanced. See Chapter 7 for further application of this information to health promotion of the infant.

TABLE 4–11 Psychosocial Development During Infancy

AGE	PLAY AND TOYS	COMMUNICATION
Birth–3 months	Prefers visual stimuli of mobiles, black-and-white patterns, mirrors Auditory stimuli are music boxes, tape players, soft voices Responds to rocking and cuddling Moves legs and arms while adult sings and talks Likes varying stimuli—different rooms, sounds, visual images	Coos Babbles Cries
3–6 months	Prefers noise-making objects that are easily grasped like rattles Enjoys stuffed animals and soft toys with contrasting colors	Vocalizes during play and with familiar people Laughs
6–9 months	Likes teething toys Increasingly desires social interaction with adults and other children Soft toys that can be manipulated and mouthed are favorites	Cries less Squeals and makes pleasure sounds Babbles multisyllabically (mamamamama) Increases vowel and consonant sounds Links syllables together Uses speechlike rhythm when vocalizing with others
9–12 months	Enjoys large blocks, toys that pop apart and go back together, nesting cups and other objects Laughs at surprise toys like jack-in-the-box Plays interactive games like peek-a-boo Uses push-and-pull toys	Understands “no” and other simple commands Says “dada” and “mama” to identify parents Learns one or two other words Receptive speech surpasses expressive speech

COMMUNICATION

Even at a few weeks of age, infants communicate and engage in two-way interaction. Comfort is expressed by soft sounds, cuddling, and eye contact. The infant displays discomfort by thrashing the extremities, arching the back, and crying vigorously. From these rudimentary skills, communication ability continues to develop until the infant speaks several words at the end of the first year of life (Table 4–11).

Nurses assess communication to identify possible abnormalities or developmental delays. Infants understand (receptive speech) more words than they can speak (expressive speech). Abnormalities may be caused by a hearing deficit, developmental delay, or lack of verbal stimulation from caretakers. Children in families with multiple languages speak in each language.

Nursing interventions focus on providing a stimulating environment. Encourage parents to speak to infants and teach words. Hospital nurses should include the infant’s known words when providing care.

Growth and Development

Strategies for communicating with infants include the following:

- Hold for feedings.
- Hold, rock, and talk to infant often.
- Talk and sing frequently during care.
- Tell names of objects.
- Use high-pitched voice with newborns.
- When the infant is upset, swaddle and hold securely.

Toddler (1 to 3 Years)

Toddlerhood is sometimes called the first adolescence. An infant only months before, the child from 1 to 3 years is now displaying independence and negativism. Pride in newfound accomplishments emerges.

Physical Growth and Development

The rate of growth slows during the second year of life. Parents may become concerned because the child has a limited food intake. They may need reassurance that this is normal. (See Chapter 14 for further discussion of nutrition in toddlerhood.) By age 2 years, the birth weight has usually quadrupled and the child is about one half of the adult height. Body proportions begin to change, with the legs longer and the head smaller in proportion to body size than during infancy (see Figure 4–5). The toddler has a pot-bellied appearance and stands with feet apart to provide a wide base of support. By approximately 33 months, eruption of deciduous teeth is complete, with 20 teeth being present.

Gross motor activity develops rapidly (Table 4–12) as the toddler progresses from walking to running, kicking, and riding a Big Wheel tricycle (Figure 4–6). As physical maturation occurs, the toddler develops the ability to control elimination patterns (see *Growth and Development* and *Developing Cultural Competence: Childrearing Practices*).

TABLE 4–12 Physical Growth and Development Milestones During Toddlerhood

AGE	PHYSICAL GROWTH	FINE MOTOR ABILITY	GROSS MOTOR ABILITY	SENSORY ABILITY
1–2 years	Gains 227 g (8 oz) or more per month Grows 9–12 cm (3.5–5 in.) during this year Anterior fontanelle closes	By end of second year, builds a tower of four blocks (*A*) Scribbles on paper (*B*) Can undress self (*C*) Throws a ball	Runs Shows growing ability to walk and finally walks with ease Walks up and down stairs a few months after learning to walk with ease (*E*) Likes push-and-pull toys (*F*)	Visual acuity 20/50
2–3 years	Gains 1.4–2.3 kg (3–5 lb)/year Grows 5–6.5 cm (2–2.5 in.)/year	Draws a circle and other rudimentary forms Learns to pour Learning to dress self (*D*)	Jumps Kicks ball Throws ball overhand

E Walks up and down stairs

F Likes push-and-pull toys

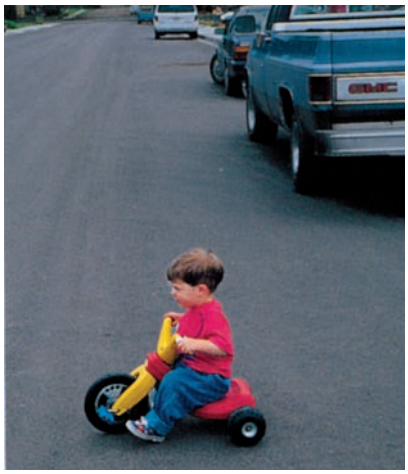

Figure 4–6 **Gross motor activity. This toddler has learned to ride a Big Wheel, which he is doing right into the street. Toddlers must be closely watched to prevent injury.**

Growth and Development

Strategies for toilet training include the following:

- When are children ready to learn toileting?
- Are parents responsible for the differences in ages at which toilet training is accomplished?
- Does toilet training provide clues to a child's intellectual ability?

We know that children are not ready for toilet training until several developmental capabilities exist: to stand and walk well, to pull pants up and down, to recognize the need to eliminate and then to be able to wait until they are in the bathroom. Once this readiness is apparent, the child can be given a small potty chair and the procedure explained.

Children often prefer their own chairs on the floor to using a large toilet. The child should be placed on the chair at regular intervals for a few moments and can be given a reward or praise for successes. If the child seems not to understand or does not wish to cooperate, it is best to wait a few weeks and then try again. Just as all of development is subject to individual timetables, toilet training occurs with considerable variability from one child to another. Identify for parents the developmental characteristics of their child and encourage them to appreciate without anxiety the unfolding of skills. These timetables are not predictive of future development.

The child who is ill or hospitalized or has other stress often regresses in toilet-training activities. It is best to quietly reinstitute attempts at training after the trauma. Potty chairs should be available on pediatric units and toileting habits identified during initial assessment so that regular routines can be followed and the child's usual words for elimination can be used.

Developing Cultural Competence Childrearing Practices

In traditional Native American families, children are allowed to unfold and develop naturally at their own pace. Children thus wean and toilet train themselves with little interference or pressure from parents. In other groups, toilet training is accomplished at an early age. The nurse should be sensitive to the childrearing practices of the family and support them in these culturally accepted practices, rather than imposing a more structured approach to toilet training.

Cognitive Development

During the toddler years, the child moves from the sensorimotor to the preoperational stage of development. The early use of language awakens in the 1-year-old the ability to think about objects or people when they are absent. Object permanence is well developed.

At about 2 years of age, the increasing use of words as symbols enables the toddler to use preoperational thought. Rudimentary problem solving, creative thought, and an understanding of cause-and-effect relationships are now possible.

Psychosocial Development

PLAY

Many changes in play patterns occur between infancy and toddlerhood. For example, developing motor skills enable toddlers to bang pegs into a pounding board with a hammer. The social nature of toddler play is also readily seen. Toddlers find the company of other children pleasurable, even though socially interactive play may not occur. Two toddlers tend to play with similar objects side by side, occasionally trading toys and words. This is called **parallel play**. This playtime with other children helps toddlers develop social skills. Toddlers engage in play activities they have seen at home, such as pounding with a hammer and talking on the phone. This imitative behavior teaches them new actions and skills.

Physical skills are manifested in play as toddlers push and pull objects, climb in and out and up and down, run, ride a Big Wheel, turn the pages of books, and scribble with a pen. Both gross motor and fine motor abilities are enhanced during this age period.

Cognitive understanding enables the toddler to manipulate objects and learn about their qualities. Stacking blocks and placing rings on a building tower teach spatial relationships and other lessons that provide a foundation for future learning. Various kinds of play objects should be provided for the toddler to meet play needs. These play needs can easily be met whether the child is hospitalized or at home (Table 4–13).

PERSONALITY AND TEMPERAMENT

The toddler retains most of the temperamental characteristics identified during infancy but may demonstrate some changes. The normal developmental progression of toddlerhood also plays a part in responses. For example, the infant who previously responded positively to stimuli, such as a new babysitter, may appear more negative in toddlerhood. The increasing independence characteristic of this age is shown by the toddler's use of the word "no." The parent and child constantly adapt their responses to each other and learn anew how to communicate with each other.

COMMUNICATION

Because of the phenomenal growth of language skills during the toddler period, adults should communicate frequently with

TABLE 4–13 Psychosocial Development During Toddlerhood

AGE	PLAY AND TOYS	COMMUNICATION
1–3 years	Refines fine motor skills by use of cloth books, large pencil and paper, wooden puzzles Facilitates imitative behavior by playing kitchen, grocery shopping, toy telephone Learns gross motor activities by riding Big Wheel tricycle, playing with soft ball and bat, molding water and sand, tossing ball or bean bag Cognitive skills develop with exposure to educational television shows, music, stories, and books	Increasingly enjoys talking Exponential growth of vocabulary, especially when spoken and read to Needs to release stress by pounding board, frequent gross motor activities, and occasional temper tantrums Likes contact with other children and learns interpersonal skills

children in this age group. Toddlers imitate words and speech intonations, as well as the social interactions they observe.

At the beginning of toddlerhood, the child may use four to six words in addition to "mama" and "dada." Receptive speech (the ability to understand words) far outpaces expressive speech. By the end of toddlerhood, however, the 3-year-old has a vocabulary of almost 1000 words and uses short sentences.

Communication occurs in many ways, some of which are nonverbal. Toddler communication includes pointing, pulling an adult over to a room or object, and speaking in expressive jargon. **Expressive jargon** is using unintelligible words with normal speech intonations as if truly communicating in words. Another communication method occurs when the toddler cries, pounds feet, displays a temper tantrum, or uses other means to illustrate dismay. These powerful communication methods can upset parents, who often need suggestions for handling them. It is best to verbalize the feelings shown by the toddler, for example, by saying, "You must be very upset that you cannot have that candy. When you stop crying you can come out of your room," and then ignore further negative behavior. The toddler's search for autonomy and independence creates a need for such behavior. Sometimes an upset toddler responds well to holding, rocking, and stroking.

Growth and Development

Strategies for communicating with toddlers include the following:

- Give short, clear instructions.
- Do not give choices if none exist. For example, do not ask "Do you want to take your medicine now?" but rather say "What juice do you want after you take your medicine—apple or orange?"
- Offer a choice of two alternatives when possible.
- Approach positively and slowly, allowing time for the toddler to adjust.
- Tell the toddler what you are doing, and say the names of objects.

Parents and nurses can promote a toddler's communication by speaking frequently, naming objects, explaining procedures in simple terms, expressing feelings that the toddler seems to be displaying, and encouraging speech. The toddler from a bilingual home is at an optimal age to learn two languages. If the parents do not speak English, the toddler will benefit from a daycare experience in which the providers do, so that the child can learn both languages.

The nurse who understands the communication skills of toddlers is able to assess expressive and receptive language and communicate effectively, thereby promoting positive healthcare experiences for these children (Table 4–14).

TABLE 4–14 Communicating With a Toddler

Procedures such as drawing blood can be frightening for a toddler. Effective communication minimizes the trauma caused by such procedures:

- Avoid telling toddlers about the procedure too far in advance. They do not have an understanding of time and can become quite anxious.
- Use simple terminology. "We need to get a little blood from your arm. It will help us find out if you are getting better." If the parent is willing, say, "Your mom will hold your arm still so we can do it quickly."
- Allow the toddler to cry. Acknowledge that it must be frightening and that you understand.
- Perform the procedure in a treatment room so that the toddler's bed and room are a safe haven.
- Be sure the toddler is restrained, with the joints above and below the procedure immobilized.
- Use a Band-Aid to cover up the site. This can reassure the toddler that the body is still intact.
- Allow the toddler to choose a reward such as a sticker after the procedure.
- Praise the toddler for cooperation and acknowledge that you know this was difficult.
- Comfort the toddler by rocking, offering a favorite drink, playing music, and holding. If parents are present, they can offer the comfort needed.

Preschool Child (3 to 6 Years)

The preschool years are a time of new initiative and independence. Most children are in a childcare center or school for part of the day and learn a great deal from this social contact. Language skills are well developed, and the child is able to understand and speak clearly. Endless projects characterize the world of busy preschoolers. They may work with play dough to form animals, then cut out and paste paper, then draw and color.

Physical Growth and Development

Preschoolers grow slowly and steadily, with most growth taking place in the long bones of the arms and legs. The short, chubby toddler gradually gives way to a slender, long-legged preschooler (Table 4–15).

TABLE 4–15 Physical Growth and Development Milestones During the Preschool Years

PHYSICAL GROWTH

Gains 1.5–2.5 kg (3–5 lb)/year

Grows 4–6 cm (1 1/2–2 1/2 in.)/year

A Uses scissors

B Draws circle, square, cross

FINE MOTOR ABILITY

Uses scissors (*A*)
Draws circle, square, cross (*B*)
Draws at least a six-part person
Enjoys art projects such as pasting, stringing beads, using clay
Learns to tie shoes at end of preschool years (*C*)
Buttons clothes (*D*)
Brushes teeth (*E*)
Uses spoon, fork, knife
Eats three meals with snacks

C Ties shoes

D Buttons clothes

E Brushes teeth

GROSS MOTOR ABILITY

Throws a ball overhand
Climbs well (*F*)
Rides bicycle (*G*)

SENSORY ABILITY

Visual acuity continues to improve
Can focus on and learn letters and numbers (*H*)

F Climbs well

G Rides bicycle or bicycle with training wheels

H Learns letters and numbers

Figure 4–7 **Development of physical skills in preschoolers. Preschoolers continue to develop advanced skills such as kicking a ball without falling down.**

Physical skills continue to develop (Figure 4–7). The preschooler runs with ease, holds a bat, and throws balls of various types. Writing ability increases, and the preschooler enjoys drawing and learning to write a few letters.

The preschool period is a good time to encourage good dental habits. Children can begin to brush their own teeth with parental supervision and help to reach all tooth surfaces. Parents should floss children's teeth, give fluoride as prescribed if the water supply is not fluoridated, and schedule the first dental visit so the child can become accustomed to the routine of periodic dental care.

Cognitive Development

The preschooler exhibits characteristics of preoperational thought. Symbols or words are used to represent objects and people, enabling the young child to think about them. This is a milestone in intellectual development; however, the preschooler still has some limitations in thought (Table 4–16).

Psychosocial Development

PLAY

The preschooler has begun playing in a new way. Toddlers simply play side by side with friends, engaging in their own activities, but preschoolers interact with others during play. For example, one child cuts out colored paper while her friend glues it on paper in a design. This new type of interaction is called **associative play** (Figure 4–8). The child-life therapist in hospital settings recognizes the therapeutic value of play in planning activities for children that enable them to work through feelings about procedures and separation, as well as facilitating the normal developmental need for interaction with other children.

In addition to this social dimension of play, other aspects of play also differ. The preschooler enjoys large motor activities such as swinging, riding a tricycle, and throwing a ball. Increasing manual dexterity is demonstrated in greater complexity of drawings and manipulation of blocks and modeling. These changes necessitate planning of playtime to include appropriate activities. Preschool programs and child-life departments in hospitals help meet this important need.

Materials provided for play can be simple but should guide activities in which the child engages. Since fine motor activities are popular, paper, pens, scissors, glue, and a variety of other such objects should be available. The child can use them to create important images such as pictures of people, hospital beds, or friends. A collection of dolls, furniture, and clothing can be manipulated to represent parents and children, nurses and physicians, teachers, or other significant people. Because fantasy life

Figure 4–8 **These preschoolers are participating in associative play, which means they can interact. One child is cutting out shapes, and the other is gluing them in place.**

TABLE 4–16 Characteristics of Preoperational Thought

CHARACTERISTIC	DEFINITION	EXAMPLE
Egocentrism	Ability to see things only from one's own point of view	The child who cannot understand why parents may need to leave the hospital for work when the child wishes them to be present
Transductive reasoning	Connecting two events in a cause-and-effect relationship simply because they occur together in time	A child who, awakening after surgery and feeling pain, notices the intravenous infusion and believes that it is causing the pain
Centration	Focusing on only one particular aspect of a situation	The child who is concerned about breathing through an anesthesia mask and will not listen to any other aspects of preoperative teaching
Animism	Giving lifelike qualities to nonliving things	The child who views a monitoring machine as alive because it beeps

Figure 4–9 **Jasmine is participating in dramatic play with a nurse while her mother looks on. In dramatic play, the child uses props to play out the drama of human life. It can be an excellent way for a nurse to assess the developmental level of children while talking to them. Notice that the child and the nurse are on the floor at the same level and the atmosphere is informal. Why is it important to be at the same level as the child?**

is so powerful at this age, the preschooler readily uses props to engage in **dramatic play**—that is, the living out of the drama of human life (Figure 4–9).

The nurse can use playtime to assess the preschool child's developmental level, knowledge about health care, and emotions related to healthcare experiences. Observations about objects chosen for play, content of dramatic play, and pictures drawn can provide important assessment data. The nurse can also use play periods to teach the child about healthcare procedures and offer an outlet for expression of emotions (Table 4–17).

PERSONALITY AND TEMPERAMENT

Characteristics of personality observed in infancy tend to persist over time. The preschooler may need assistance as these characteristics are expressed in the new situations of preschool or nursery school. An excessively active child, for example, will need gentle, consistent handling to adjust to the structure of a classroom. Encourage parents to visit preschool programs to choose the one that would best foster growth in their child. Some preschoolers enjoy the structured learning of a program that focuses on cognitive skills, whereas others are happier and more open to learning in a small group that provides much time for free play. Nurses can help parents identify their child's personality or temperament characteristics and find the best environment for growth.

COMMUNICATION

Language skills blossom during the preschool years. The vocabulary grows to over 2000 words, and children speak in complete sentences of several words and use all parts of speech. They practice these newfound language skills by endlessly talking and asking questions.

Growth and Development

Strategies for communicating with preschoolers include the following:

- Allow time for child to integrate explanations.
- Verbalize frequently to the child.
- Use drawings and stories to explain care.
- Use accurate names for body functions.
- Allow choices.

The sophisticated speech of preschoolers mirrors the development occurring in their minds and helps them to learn about the world around them. However, this speech can be quite deceptive. Although preschoolers use many words, their grasp of meaning is usually literal and may not match that of adults. These literal interpretations have important implications for healthcare providers. For example, the preschooler who is told she will be "put to sleep" for surgery may think of a pet recently euthanized; the child who is told that a dye will be injected for a diagnostic test may think he is going to die; mention of "a little stick" in the arm can cause images of tree branches rather than of a simple immunization.

The child may also have difficulty focusing on the content of a conversation. The preschooler is egocentric and may be unable to move from individual thoughts to those the nurse is proposing in a teaching situation.

TABLE 4–17 Psychosocial Development During the Preschool Years

AGE	PLAY AND TOYS	COMMUNICATION
3–6 years 	Associative play is facilitated by simple games, puzzles, nursery rhymes, songs Dramatic play is fostered by dolls and doll clothes, play houses and hospitals, dress-up clothes, puppets Stress is relieved by pens, paper, glue, scissors Cognitive growth is fostered by educational television shows, music, stories, and books	All parts of speech are developed and used, occasionally incorrectly Communicates with a widening array of people Play with other children is a favorite activity Health professionals can: • Verbalize and explain procedures to children • Use drawings and stories to explain care • Use accurate names for body functions • Allow the child to talk, ask questions, and make choices

Concrete visual aids such as pictures of a child undergoing the same procedure or a book to read together enhance teaching by meeting the child's developmental needs. Handling medical equipment such as intravenous bags and stethoscopes increases interest and helps the child to focus. Teaching may have to be done in several short sessions rather than one long session.

School-Age Child (6 to 12 Years)

Errol, 10 years old, arrives home from school shortly after 3 P.M. each day. He immediately calls his friends and goes to visit one of them. They are building models of cars and collecting baseball cards. Endless hours are spent on these projects and on discussions of events at school that day (Figure 4–10).

A

B

Figure 4–10 *A*, **School-age children may take part in activities that require practice. This is a consideration when children are hospitalized and unable to practice or perform. Why?** *B*, **School-age children enjoy spending time with others the same age on projects and discussing the activities of the day. This is an important consideration when they are in an acute care setting. When you are in the clinical setting, look for examples of this type of interaction taking place.**

Nine-year-old Karen practices soccer two afternoons a week and plays in games each weekend. She also is learning to play the flute and spends her free time at home practicing. Although practice time is not her favorite part of music, Karen enjoys the performances and wants to play well in front of her friends and teacher. Her parents now allow her to ride her bike unaccompanied to the store or to a friend's house.

These two school-age children demonstrate common characteristics of their age group. They are in a stage of industry in which it is important to the child to perform useful work. Meaningful activities take on great importance and are usually carried out in the company of peers. A sense of achievement in these activities is important in developing self-esteem and preventing a sense of inferiority or poor self-worth.

Physical Growth and Development

School age is the last period in which girls and boys are close in size and body proportions. As the long bones continue to grow, leg length increases (see Figure 4–5). Fat gives way to muscle, and the child appears leaner. Jaw proportions change as the first deciduous tooth is lost at 6 years and permanent teeth begin to erupt. Body organs and the immune system mature, resulting in fewer illnesses among school-age children. Medications are less likely to cause serious side effects, since they can be metabolized more easily. The urinary system can adjust to changes in fluid status. Physical skills are also refined as children begin to play sports, and fine motor skills are well developed through school activities (Table 4–18 and Figure 4–11).

Although it is commonly believed that the start of adolescence (age 12 years) heralds a growth spurt, the rapid increases in size commonly occur during the school-age period. Girls may begin a growth spurt by 9 or 10 years and boys a year or so later. Nutritional needs increase dramatically with this spurt.

The loss of the first deciduous teeth and the eruption of permanent teeth usually occur at about age 6 years, or at the beginning of the school-age period. Of the 30 permanent teeth, 22 to 26 erupt by age 12 years and the remaining molars follow during the teenage years. The school-age child should be closely monitored to ensure that brushing and flossing are adequate, that fluoride is taken if the water supply is not fluoridated, that dental care is obtained to provide for examination of teeth and alignment, and that loose teeth are identified before surgery or other events that may lead to loss of a tooth.

Cognitive Development

The child enters the stage of concrete operational thought at about age 7 years. This stage enables school-age children to consider alternative solutions and solve problems. However, school-age children continue to rely on concrete experiences and materials to form their thought content.

During the school-age years, the child learns the concept of **conservation** (that matter is not changed when its form is altered). At earlier ages a child believes that when water is poured from a short, wide glass into a tall, thin glass, there is more water in the taller glass. The school-age child recognizes that although it may look like the taller glass holds more water, the quantity is the same. The concept of conservation is helpful when the nurse explains medical treatments. The school-age child understands that an incision will heal, that a cast will be removed, and that an arm will look the same as before once the intravenous infusion is removed.

TABLE 4–18 Physical Growth and Development Milestones During the School-Age Years

PHYSICAL GROWTH	FINE MOTOR ABILITY	GROSS MOTOR ABILITY	SENSORY ABILITY
Gains 1.4–2.2 kg (3–5 lb)/year Grows 4–6 cm (1 1/2–2 1/2 in.)/year	Enjoys craft projects Plays card and board games	Rides two-wheeler (*A*) Jumps rope (*B*) Roller skates or ice skates	Can read Able to concentrate for longer periods on activities by filtering out surrounding sounds (*C*)

A Rides two-wheeler

B Jumps rope

C Concentrates on activities for longer periods

Shutterstock

Psychosocial Development

PLAY

When the preschool teacher tries to organize a game of baseball, both the teacher and the children become frustrated. Not only are the children physically unable to hold a bat and hit a ball, but they seem to have no understanding of the rules of the game and do not want to wait for their turn at bat. By 6 years of age, however, children have acquired the physical ability to hold the bat properly and may occasionally hit the ball. School-age children also understand that everyone has a role—the pitcher, the catcher, the batter, the outfielders. They cooperate with one another to form a team, are eager to learn the rules of the game, and want to ensure that these rules are followed exactly (Table 4–19).

The characteristics of play exhibited by the school-age child are cooperation with others and the ability to play a part in order to contribute to a unified whole. This type of play is called **cooperative play**. The concrete nature of cognitive thought leads to a reliance on rules to provide structure and security. Children have an increasing desire to spend much of playtime with friends, which demonstrates the social component of play. Play is an extremely important method of learning and living for the school-age child. Active physical play has decreased in recent years as television viewing and playing of computer games have increased, leading to poor nutritional status and a high rate of overweight among children. See Chapters 14 and 17 for further discussion of nutrition and physical activity in children.

Figure 4–11 **School-age children's physical development. Left, Front teeth are lost around age 6 years. The family may have rituals associated with the loss of teeth that could affect the child's behavior if he loses a tooth while in the hospital. Right, School-age girls and boys enjoy participating in sports. They begin to lose fat while developing their muscles, so they appear leaner than at earlier ages.**

TABLE 4–19 Psychosocial Development During the School-Age Years

AGE	ACTIVITIES	COMMUNICATION
6–12 years 	Gross motor development is fostered by ball sports, skating, dance lessons, water and snow skiing/boarding, biking A sense of industry is fostered by playing a musical instrument, gathering collections, starting hobbies, playing board and video games Cognitive growth is facilitated by reading, crafts, word puzzles, schoolwork	Mature use of language Ability to converse and discuss topics for increasing lengths of time Spends many hours at school and with friends in sports or other activities Health professionals can: • Assess child's knowledge before teaching • Allow the child to select rewards following procedures • Teach techniques such as counting or visualization to manage difficult situations • Include both parent and child in health-care decisions

When a child is hospitalized, the separation from playmates can lead to feelings of sadness and purposelessness. School-age children often feel better when placed in multibed units with other children. Games can be devised even when children are wheelchair bound (Figure 4–12). Normal, rewarding parts of play should be integrated into care. Friends should be encouraged to visit or call a hospitalized child. Discharge planning for the child who has had a cast or brace applied should address the activities the child can engage in and those the child must avoid. Reinforce the importance of playing games with friends.

PERSONALITY AND TEMPERAMENT

The enduring aspects of temperament continue to be manifested during the school years. The child classified as "difficult" at an earlier age may now have trouble in the classroom. Advise parents to provide a quiet setting for homework and to reward the child for concentration. For example, after homework is completed, the child can watch a television show. Creative efforts and alternative methods of learning should be valued. Encourage parents to see their children as individuals who may not all learn in the same way. The "slow-to-warm-up" child may need encouragement to try new activities and to share experiences with others, while the "easy" child will readily adapt to new schools, people, and experiences.

Figure 4–12 **The nurse can help the hospitalized school-age child and family accept and adjust to new circumstances. Encouraging the child in a wheelchair to participate in group activities can help build confidence in physical skills. Good self-esteem, goal attainment, personal satisfaction, and general health are the continued benefits.**

COMMUNICATION

During the school-age years, the child should learn how to correct any lingering pronunciation or grammatical errors. Vocabulary increases, and the child is taught about parts of speech in school. School-age children enjoy writing and can be encouraged to keep a journal of their experiences while in the hospital as a method of dealing with anxiety. It is uncommon for school-age children to understand words as literally as preschoolers.

Growth and Development

Strategies for communicating with school-age children include the following:

- Provide concrete examples of pictures or materials to accompany verbal descriptions.
- Assess knowledge before planning teaching.
- Allow child to select rewards following procedures.
- Teach techniques such as counting or visualization to manage difficult situations.
- Include child in discussions and history with parent.
- Be honest in explanations and all communications.

SEXUALITY

Children become aware of sexual differences between genders during preschool years, but they deal much more consciously with sexuality as school-age children. As children mature physically, they need information about their body changes so that they can develop a healthy self-image and an understanding of the relationships between their bodies and sexuality. Children become interested in sexual issues and are often exposed to erroneous information on television shows, in magazines, or from friends and siblings. Schools and families need to find opportunities to teach school-age children factual information about sex and to foster healthy concepts of self and others. It is advisable to ask occasional questions about sexual issues to learn how

much the child knows and to provide correct information when answers demonstrate confusion. Both friends and the media are common sources of erroneous ideas. Appropriate and inappropriate touch should be discussed, with lists of trusted people who can be approached (teachers, clergy, school counselors, family members, neighbors) to discuss any episodes with which the child feels uncomfortable. Even these trusted people can be implicated in inappropriate episodes, so encourage the child to go to more than one person, an important approach if the child is uncomfortable about a relationship with any individual.

Adolescent (12 to 18 Years)

Adolescence is a time of passage signaling the end of childhood and the beginning of adulthood. Although adolescents differ in behaviors and accomplishments, they are in a period of identity formation. If a healthy identity and sense of self-worth are not developed in this period, role confusion and purposeless struggling will ensue. The adolescents encountered in nursing practice represent various degrees of identity formation, and each will offer unique challenges.

Physical Growth and Development

The physical changes ending in **puberty**, or sexual maturity, begin near the end of the school-age period. The prepubescent period is marked by a growth spurt at an average age of 10 years for girls and 13 years for boys. The increase in height and weight is generally remarkable and is completed in 2 to 3 years (Table 4–20). The growth spurt in girls is accompanied by an increase in breast size and growth of pubic hair. Menstruation occurs last and signals achievement of puberty. In boys, the growth spurt is accompanied by growth in size of the penis and testes and by growth of pubic hair. Deepening of the voice and growth of facial hair occur later, at the time of puberty. See Chapter 5 for a description of the pubertal stages.

During adolescence children grow stronger and more muscular and establish characteristic male and female patterns of fat distribution. The apocrine and eccrine glands mature, leading to increased sweating and a distinct odor to perspiration. All body organs are now fully mature, enabling the adolescent to take adult doses of medications.

The adolescent must adapt to a rapidly changing body for several years. Height, weight, and body proportions increase. Such changes occur with great variability so an adolescent may be at different points of maturation than peers. These physical changes, hormonal variations, and differences in timing offer challenges to identity formation. The adolescent must incorporate the new body, its functions, and retain a healthy sense of self in relationship to peers. The formation of self-identity is a psychologic process but is necessarily closely connected with the bodily changes occurring.

Cognitive Development

Adolescence marks the beginning of Piaget's last stage of cognitive development, the stage of formal operational thought. The adolescent no longer depends on concrete experiences as the basis of thought but develops the ability to reason abstractly. Such concepts as justice, truth, beauty, and power can be understood. The adolescent revels in this newfound ability and spends a great deal of time thinking, reading, and talking about abstract concepts.

The ability to think and act independently leads many adolescents to rebel against parental authority and experiment with risky behaviors. Through these actions, adolescents seek to establish their own identity and values.

Psychosocial Development

ACTIVITIES

Maturity leads to new activities. Adolescents may drive, ride buses, or bike independently. They are less dependent on parents for transportation and spend more time with friends.

TABLE 4–20 Physical Growth and Development Milestones During Adolescence

PHYSICAL GROWTH	FINE MOTOR ABILITY	GROSS MOTOR ABILITY	SENSORY ABILITY
Variation in age of growth spurt During growth spurt, girls gain 7–25 kg (15–55 lb) and grow 2.5–20 cm (2–8 in.); boys gain approximately 7–29.5 kg (15–65 lb) and grow 11–30 cm (4 1/2–12 in.)	Skills are well developed (*A*)	New sports activities attempted and muscle development continues (*B*) Some lack of coordination common during growth spurt	Fully developed

A Fine motor skills are well developed

B New sports activities attempted

TABLE 4–21 Psychosocial Development During Adolescence

AGE	ACTIVITIES	COMMUNICATION
12–18 years 	Sports—ball games, gymnastics, water and snow skiing/boarding, swimming, school sports School activities—drama, yearbook, class office, club participation Quiet activities—reading, schoolwork, television, computer, video games, music	Increasing communication and time with peer group—movies, dances, driving, eating out, attending sports events Applying abstract thought and analysis in conversations at home and school

Activities include participation in sports and extracurricular school activities, as well as "hanging out" and attending movies or concerts with friends (Table 4–21). The peer group becomes the focus of activities (Figure 4–13), regardless of the teen's interests. Peers are important in establishing identity and providing meaning. Although same-sex interactions dominate, boy–girl relationships are more common than at earlier stages. Adolescents thus participate in and learn from social interactions fundamental to adult relationships.

A

B

Figure 4–13 **Peer group activities in adolescence. Social interaction between children of same and opposite sex is as important inside the acute care setting as it is outside.** ***A,*** **Teenagers enjoy playing together.** ***B,*** **Emotional relationships form during adolescence.**

PERSONALITY AND TEMPERAMENT

Characteristics of temperament manifested during childhood usually remain stable in the teenage years. For instance, the adolescent who was a calm, scheduled infant and child often demonstrates initiative to regulate study times and other routines. Similarly, the adolescent who was an easily stimulated infant may now have a messy room, a harried schedule with assignments always completed late, and an interest in many activities. It is also common for an adolescent who was an easy child to become more difficult because of the psychologic changes of adolescence and the need to assert independence.

As during the child's earlier ages, the nurse's role may be to inform parents of different personality types and to help them support the teen's uniqueness while providing necessary structure and feedback. Nurses can help parents understand their teen's personality type and work with the adolescent to meet expectations set by teachers and others in authority.

COMMUNICATION

The adolescent uses and understands all parts of speech. Colloquialisms and slang are commonly used with the peer group. The adolescent often studies a foreign language in school, having the ability to understand and analyze grammar and sentence structure.

The adolescent increasingly leaves the home base and establishes close ties with peers. These relationships become the basis for identity formation. There is generally a period of stress or crisis before a strong identity can emerge. The adolescent may try out new roles by learning a new sport or other skills, experimenting with drugs or alcohol, wearing different styles of clothing, or trying other activities. It is important to provide positive role models and a variety of experiences to help the adolescent make wise choices.

Adolescents also have a need to leave the past, to be different, and to change from former patterns to establish their own identities. Rules that are repeated constantly and dogmatically will probably be broken in the adolescent's quest for self-identity. This poses difficulties when the adolescent has a health problem, such as diabetes, or a heart problem that requires ongoing care. Introducing the adolescent to other teens who manage the same problem appropriately is usually more successful than telling the adolescent what to do.

Ensure privacy during the taking of health histories or interventions with teens. Even if a parent is present for part of a history or examination, the adolescent should be given the opportunity to relay information or ask questions alone with the healthcare provider. Give the adolescent a choice of whether to have a parent present during an examination or while care is provided. Most information shared by an adolescent is confidential. Some states mandate disclosure of certain information to parents, such as an adolescent's desire for an abortion. In these cases, the adolescent should be informed of what will be disclosed to the parent.

Setting up teen rooms (recreation rooms for use only by adolescents) or separate adolescent units in hospitals can provide necessary peer support during hospitalization. Most adolescents are not pleased when placed on a unit or in a room with young children. Choices should be allowed whenever possible. These might include preference for evening or morning bathing, the type of clothes to wear while hospitalized, timing of treatments, and who should be allowed to visit and for how long. Use of negotiations and agreements with adolescents may increase compliance. Firmness, gentleness, choices, and respect must all be balanced during care of adolescent clients.

Growth and Development

Strategies for communicating with adolescents include the following:

- Provide written as well as verbal explanations.
- Direct history and explanations to teen alone; then include parent.
- Allow for safe exploration of topics by suggesting that the teen is similar to other teens. ("Many teens with diabetes have questions about how to eat foods they and their friends like and still stay within their diet needs. How about you?")
- Arrange meetings for discussions with other teens.

SEXUALITY

With maturation of the body and increased secretion of hormones, the adolescent achieves sexual maturity. This complex process involves a growing interest in sexuality and romantic or sexual relationships, an interplay of the forces of society and family, and identity formation. The early adolescent progresses from dances and other social events with members of the opposite sex; the late adolescent is mature sexually and may have regular sexual encounters. Nearly one half of all high-school students in the United States have had intercourse, and 34% had intercourse in the previous 3 months. However, 59% of youth did not use a condom at their last sexual encounter, putting this age group at high risk of acquiring sexually transmitted infections (Kann et al., 2014).

Teenagers need information about their bodies and emerging sexuality. To make informed decisions about their behavior, teenagers should understand the interests and forces they experience. Including sex education in school classes and healthcare encounters is important. Information on how to prevent sexually transmitted infections (STIs) is given, with most school districts now providing some teaching on AIDS. Far more common risks to teens, however, are diseases such as gonorrhea and herpes. Health histories should include questions on sexual activity, STIs, and birth control use and understanding. Most hospitals routinely perform pregnancy screening on adolescent girls before elective procedures.

Adolescents benefit from clear information about sexuality, an opportunity to develop relationships with adolescents in various settings, an open atmosphere at home and school where problems and issues can be discussed, and previous experience in problem solving and self-decision making. Sexual issues should be among topics that adolescents can discuss openly in a variety of settings. Alternatives and support for their decisions should be available.

Some adolescents identify with a sexual minority group such as lesbian, gay, bisexual, or transgender. They are at particular risk of being stigmatized and harassed by other youth or adults. They are more likely to suffer a variety of problems, such as isolation, rejection by family and friends, violence, and suicide, and to take sexual risks (Steever, Francis, Gordon, et al., 2014). Nurses are instrumental in helping these youth by providing information for them and their parents, integrating sexual minority content into school sexual curricula, and providing referrals for health care and social care when needed. See Chapter 17 for further information about the health issues related to homosexuality and other sexual minority practices.

Chapter Highlights

- Development unfolds in a predictable pattern, but at different rates dependent on the particular characteristics and experiences of each child.
- Major theories of development encompass the psychosexual (Freud), psychosocial (Erikson), cognitive (Piaget), moral (Kohlberg), social learning (Bandura), and behavioral (Skinner and Watson) components of individuals.
- The ecologic theory of Bronfenbrenner and the temperament theory of Chess and Thomas emphasize the interactions of the individual with the environment.
- Resiliency theory examines risk and protective factors that hinder or help children and families when dealing with developmental and life crises.
- The newborn period begins at birth and ends at about 1 month of age and is characterized by adaptation to extrauterine life. Infancy spans 1 month to 1 year and is marked by rapid physical growth, mastery of basic fine and gross motor skills, and emerging cognitive and language skills.
- Toddlers range in age from 1 to 3 years and become increasingly mobile and communicative. Preschool years range from

ages 3 to 6 and are marked by increasing social skills, coordination, and language mastery.

- School age spans the years from ages 6 to 12, and puberty occurs from ages 9 to 12 years, marked by a growth spurt and sexual maturation. Adolescence begins at 12 years of age and lasts through the teen years, with physical, emotional, cognitive, and social maturation.
- The nurse assesses development at each stage and provides anticipatory guidance and other interventions to foster optimal development.

Clinical Reasoning in Action

You encounter a 12-month-old child, Julia, while working in the developmental clinic. Her mother tells you that their family practice physician had concerns that Julia might have a developmental delay. She was a full-term baby and there were no complications throughout her mother's pregnancy or delivery. Julia's mother tells you that Julia has a generally shy and slow-to-warm-up temperament. She makes little eye contact with you and prefers to sit on her mother's lap and cling to her arms if a stranger gets close. She is able to pick up small objects, babble, crawl, and use her pincer grasp. She is not able to walk, hold a crayon, or speak any words. Julia clearly has a developmental delay.

1. What are some examples of toys you can suggest to Julia's parents based on her developmental level (not based on her age)?
2. What are some examples of hazards you can advise Julia's parents about avoiding based on her developmental level?
3. What is a suggestion you can give the parents about dealing with a child like Julia who has a shy or slow-to-warm-up temperament?

Chapter 5
Pediatric Assessment

Ryan McVay/Getty Images

I was scared when we brought Colby to the hospital. He looked helpless, afraid, and sick. The nurses and doctors took over when we got to the hospital, and I felt better because they seemed to know what to do.

—Father of Colby, age 6 months

Learning Outcomes

5.1 Describe the elements of a health history for infants and children of different ages.

5.2 Apply communication strategies to improve the quality of historical data collected.

5.3 Demonstrate strategies to gain cooperation of a young child for assessment.

5.4 Describe the differences in sequence of the physical assessment for infants, children, and adolescents.

5.5 Modify physical assessment techniques for the age and developmental stage of the child.

5.6 List five normal variations in pediatric physical findings (such as breast budding in a girl) found during a physical assessment.

5.7 Evaluate the growth pattern of an infant or child.

5.8 Distinguish between expected and unexpected physical signs to identify at least five signs that require urgent nursing intervention.

How do examination techniques vary by the age of the child? How does the nurse encourage infants and toddlers to cooperate with the examination? This chapter provides an overview of pediatric assessment, including history taking and examination techniques geared to the unique needs of pediatric clients. Strategies for obtaining the child's history are presented first. The remainder of the chapter then outlines a systematic process for physical examination of children and adolescents.

Anatomic and Physiologic Characteristics of Infants and Children

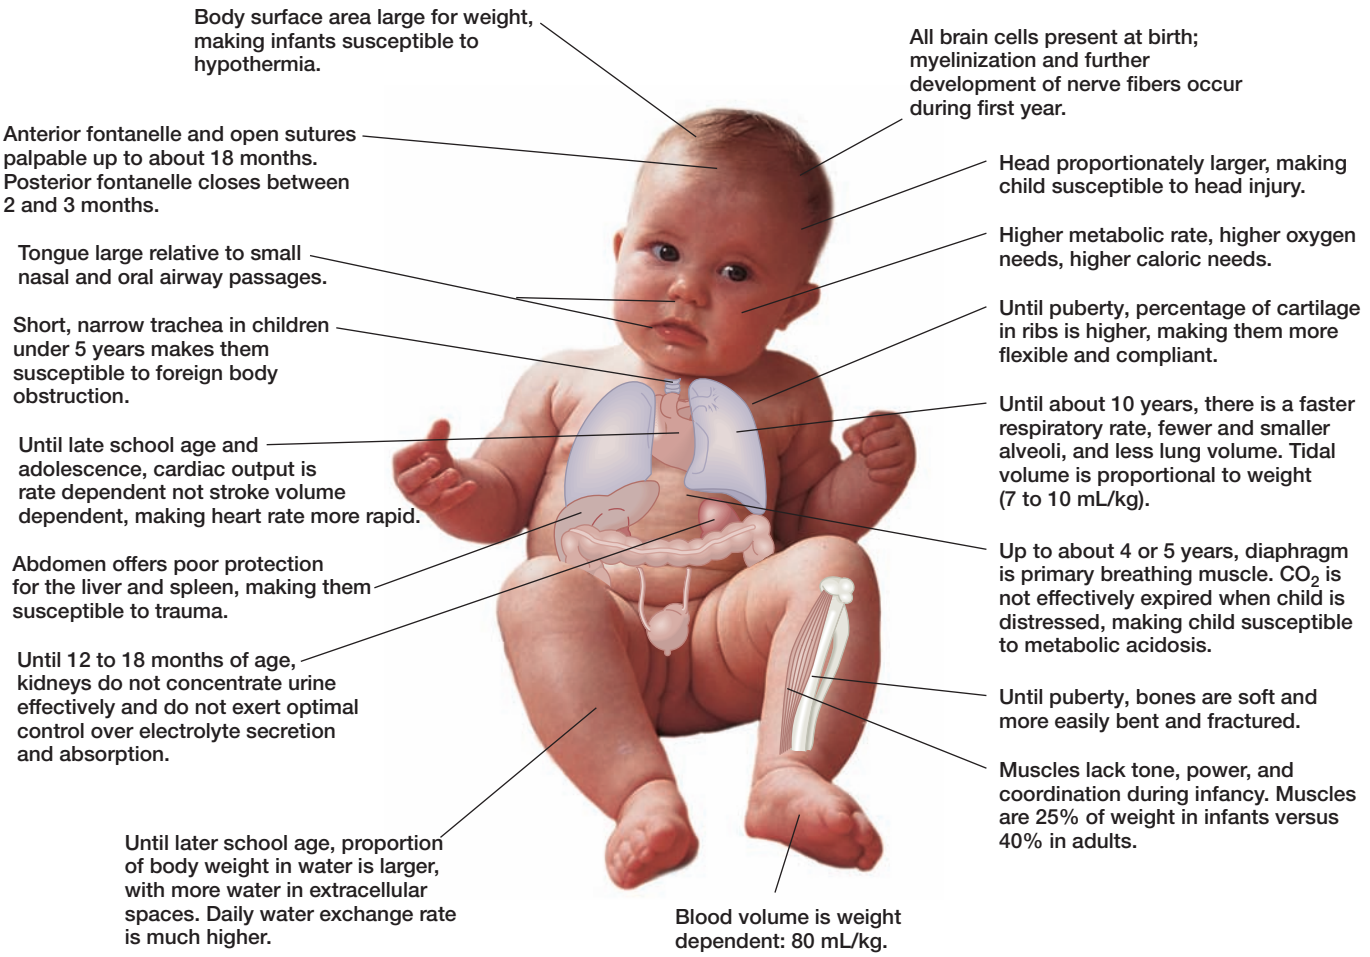
Children and infants are not only smaller than adults; they also have very different physiology. Knowledge of pediatric anatomic and physiologic differences will aid in recognizing normal variations found during the physical examination. It also assists with understanding the different physiologic responses children have to illness and injury. The illustration in *As Children Grow: Children Are Not Just Small Adults* provides an overview of important anatomic and physiologic differences between children and adults.

Obtaining the Child's History

Communication Strategies

The health history interview is a very personal conversation with a parent, caregiver, or adolescent during which private concerns and feelings are shared. Try to ensure that both parties clearly understand the information exchange and use effective communication with the parent or the child. Effective communication is difficult to accomplish because parents and children may not always correctly interpret what the nurse says, just as the nurse

As Children Grow: **Children Are Not Just Small Adults**



Children are not just small adults. There are important anatomic and physiologic differences between children and adults that will change based on a child's growth and development.

may not understand completely what the parent or child says. People's interpretation of information is based on their life experiences, culture, and education.

STRATEGIES TO BUILD RAPPORT WITH THE FAMILY

When obtaining the client history, make sure the parents understand the purpose of the interview and how the information will be used for the child's benefit. To develop rapport, demonstrate interest in and concern for the child and family during the interview. This rapport forms the foundation for the collaborative relationship between the nurse and parent that will lead to the best nursing care for the child. The following strategies help to establish rapport with the child's family during the nursing history:

- *Introduce yourself* (name, title or position, and role in caring for the child). To demonstrate respect, ask all family members present what name they prefer you to use when talking with them.
- *Explain the purpose of the interview* and why the nursing history is different from the information collected by other health professionals. For example, "Nurses use this information to plan nursing care best suited for your child."
- *Provide privacy* and remove as many distractions as possible during the interview. If the client's room does not offer privacy, attempt to find a vacant room or lounge to interview the child and family. Assure the parents and the child that the information provided is protected under the Health Insurance Portability and Accountability Act (HIPAA), a federal law that requires written consent before personal health information can be shared with healthcare providers outside the facility.
- *Direct the focus of the interview* with open-ended questions. Open-ended questions are useful to initiate the interview, develop rapport, and understand the parents' perceptions of the child's problem. For example, "What problems led to Roberto's admission to the hospital?" Use close-ended questions or directing statements to clarify information or to obtain detailed information. For example, "How high was Tommy's fever this morning?"
- *Ask one question at a time* so that the parent or child understands what piece of information is desired and so that it is clear which question the parent is answering. "Does any member of your family have diabetes, heart disease, or sickle cell disease?" is a multiple question. Ask about each disease separately to ensure the most accurate response.

- *Involve the child in the interview* by asking age-appropriate questions. Young children can be asked, "What is your doll's name?" or "Where does it hurt?" Demonstrating an interest in the child initiates development of rapport with both child and parents. Ask older children and teens questions about their illness or injury. Offer them an opportunity to discuss their major concerns privately without parents present.
- *Be honest with the child* when answering questions or when giving information about what will happen. Children need to learn that they can trust their nurse.
- *Choose the language style best understood by the parent and child.* Commonly used phrases or medical terms may have different meanings to different people. To improve communication, ask the parents or child questions to ensure that their understanding of a phrase or term is correct. For example, "You used the term *hyperactivity*. Tell me what this behavior means to you."
- *Use an interpreter to improve communication when not fluent in the family's primary language.* Avoid using a family member or friend for history taking to ensure client and family confidentiality.

Developing Cultural Competence Phrasing Your Questions

Some cultural groups, particularly Asians, try to anticipate the answers you want to hear, or say yes even if they do not understand the question. This is done in an effort to please you or as an expression of politeness. Remember to use open-ended questions or phrase your questions in a neutral manner.

CAREFUL LISTENING

Complete attention is necessary to "hear" and accurately interpret information the parents and child give during the nursing history. While carefully listening to the information provided, pay attention to how it is expressed, and observe behavior during the interaction.

- Does the parent hesitate or avoid answering certain questions?
- Pay attention to the parent's attitude or tone of voice when the child's problems are discussed. Determine if it is consistent with the seriousness of the child's problem. The tone of voice can reveal anxiety, anger, or lack of concern.
- Be alert to any underlying themes. For example, the parent who talks about the child's diagnosis, but repeatedly refers to the impact of the illness on the family's finances or on meeting the needs of other family members, is requesting that these issues be addressed.
- Observe the parent's *nonverbal* behavior (posture, gestures, body movements, eye contact, and facial expression) for consistency with the words and tone of voice used. Is the parent interested in and appropriately concerned about the child's condition? Behaviors such as sitting up straight, making eye contact, and appearing apprehensive reflect appropriate concern for the child. Physical withdrawal, failure to make eye contact, or a happy expression could be inconsistent with the child's serious condition.

Subtle nonverbal and verbal cues may indicate that the parent has not provided complete information about the child's problem. Observe for behaviors such as avoiding eye contact, change in voice pitch, or hesitation when responding to a question. Be supportive and ask clarifying questions to encourage further description or the expression of information that is difficult for the parent or child to share. For example, "It sounds like that was a very difficult experience. How did Lily react?"

Developing Cultural Competence Interaction Patterns

Prolonged eye contact may be avoided by some cultural groups, such as persons of Native American, African American, Hindu, Japanese, and Chinese heritage, because it is considered impolite, aggressive, or a sign of disrespect. Other cultures, such as persons of Arabic, European, and Russian heritage, seek eye contact, and some may look for a response or impact regarding what is said (Purnell, 2014).

Encourage parents to share information, even if it is private or sensitive, especially when it influences nursing care planning. Often parents avoid sharing some information because they want to make a good impression, or they do not understand the value of the missing information. If parents hesitate to share information, briefly explain why the question was asked—for example, to make their child's hospital experience more pleasant or to begin planning for the child's discharge and home care. Silence is common in some Asian and Native American groups as they attempt to form responses to questions.

In some cases, the parent may become too agitated, upset, or angry to continue responding to questions. When the information is not needed immediately, move on to another portion of the history to determine whether the parent is able to respond to other questions. Depending on the emotional status of the parent, it may be appropriate to collect the remaining information later.

Data to Be Collected

Nurses collect and organize health, medical, and personal-social history to plan a child's nursing care. The health status, psychosocial, and developmental data are organized to help develop the nursing diagnoses and the nursing care plan.

CLIENT INFORMATION

Obtain the child's name and nickname, age, sex, and ethnic origin. The child's birth date, race, religion, address, and phone number can be obtained from the admission form. Ask the parent for an emergency contact address and phone number, as well as a work phone number. Record the name of the person providing the client history and that person's relationship to the child.

PHYSIOLOGIC DATA

Collect information about the child's health problems and diseases chronologically using categories specified by the electronic health record, such as the following.

Chief Concern. Identify the child's primary problem or reason for hospital admission or visit to a healthcare setting, and document it using the parent's or child's exact words.

TABLE 5–1 History of Present Illness or Injury

CHARACTERISTIC	DEFINING VARIABLES
Onset	Sudden or gradual, previous episodes, date and time began
Type of symptom	Pain, itching, cough, vomiting, runny nose, diarrhea, rash, etc.
Location	Generalized or localized—be anatomically precise
Duration	Continuous or episodic symptoms, length of episodes
Severity	Effect on daily activities (e.g., interrupted sleep, decreased appetite, unable to attend school)
Influencing factors	What relieves or worsens symptoms, what precipitated the problem, recent exposure to infection or allergen
Past evaluation for the problem	Laboratory studies and diagnostic procedures, physician's office or hospital where done, results of past examinations
Previous and current treatment	Prescribed and over-the-counter drugs used, complementary therapies (e.g., heat, ice, rest), response to treatments

Present Illness or Injury. Obtain a detailed description of the current health problem that includes the characteristics in Table 5–1. Each problem is described separately.

Past History. This more detailed description of the child's prior health problems includes all major past illnesses and injuries. Identify all major illnesses, including common communicable diseases. Identify major injuries, their cause or mechanism, and their severity. Obtain information about each prior surgery, its purpose, and if the surgery required overnight hospitalization. For all hospitalizations, identify the reason and length of stay. Identify the circumstances for any prior transfusion, its type (blood, blood products, or immune globulin), and any reaction. Obtain information about each specific diagnosis, treatment, outcome, complication or residual problem, and the child's reaction to the event. Use the guidelines in Table 5–2 to obtain a *birth history* when the child's present problem may be related to problems during the pregnancy, birth, and newborn care.

Current Health Status. Obtain a detailed description of each aspect of the child's typical health status.

- *Health maintenance*—child's primary healthcare provider, dentist, and other specialty healthcare providers, timing of last visit to each.
- *Medications*—prescribed and over-the-counter medications (oral, topical, injectable) used daily or frequently for fever, colds, coughs, and rashes. Ask about the use of herbs, plants, teas, or other complementary therapies.
- *Allergies*—to food, medication, animals, insect bites, or other exposures, and the type of reaction (e.g., respiratory difficulty, rash, hives, itching).
- *Immunizations*—review dates immunizations were received. Ask about any unexpected reactions. Inquire about the reason if not up-to-date. (See Chapter 16 for the recommended immunization schedule.)

TABLE 5–2 Birth History

Prenatal condition	• Mother's age, health during pregnancy, prenatal care, weight gained, special diet, use of alcohol or drugs, expected date of birth • Details of illnesses, radiograph or sonogram findings, hospitalizations, medications, complications, and their timing during pregnancy • Prior obstetric history
Intrapartum—description of birth	• Site of birth (hospital, home, birthing center) • Labor induced or spontaneous, time of rupture of membranes, length of labor, color of amniotic fluid, complications • Vaginal or cesarean birth, forceps or suction used, vertex or breech position • Length of pregnancy (weeks), single or multiple birth
Condition of baby at birth	• Birth weight, Apgar score, cried immediately • Need for incubator, resuscitation, oxygen, ventilator • Any abnormalities detected, meconium staining
Postnatal condition	• Difficulties in the nursery—feeding, respiratory problems, jaundice, cyanosis, rashes, seizures • Length of hospital stay, special nursery, home with mother • Breastfed or bottlefed, weight lost/gained in hospital • Medical care needed in first week—readmission to hospital

- *Safety measures used*—car restraint system, window guards, medication storage, sports protective gear, smoke detectors, bicycle helmet, firearm storage, water safety, and others.
- *Activities and exercise*—usual play and/or sports activities; physical mobility and limitations, adaptive equipment used.
- *Nutrition*—formula-fed or breastfed; if breastfed, for how long, type and amount of daily formula and other liquid intake; when solid foods were introduced; enrollment in the Special Supplemental Nutrition Program for Women, Infants, and Children (WIC). Contrast the child's food intake to the appropriate amount for age and weight (see Chapter 14).
- *Sleep*—infant sleep position, length and timing of naps and nighttime sleep; nightmares or night terrors, snoring, other sleep disturbances; where the child sleeps; bedtime rituals.

TABLE 5–3 Familial or Hereditary Diseases

Infectious diseases	Tuberculosis, HIV, hepatitis, herpes
Heart disease	Heart defects, myocardial infarctions, hypertension, dyslipidemia, sudden childhood deaths
Allergic disorders	Eczema, hay fever
Eye disorders	Glaucoma, cataracts, vision loss
Ear disorders	Hearing loss, unusual shape or position of ears
Hematologic disorders	Sickle cell disease, thalassemia, glucose-6-phosphate dehydrogenase (G6PD) deficiency, hemophilia
Respiratory disorders	Cystic fibrosis, asthma
Cancer	Retinoblastoma, cancer with early age of onset
Endocrine disorders	Diabetes mellitus types 1 and 2, hypothyroidism, hyperthyroidism, Turner syndrome
Brain disorders	Intellectual disability, epilepsy, psychiatric disorders
Musculoskeletal disorders	Muscular dystrophy, scoliosis, spina bifida
Gastrointestinal disorders	Pyloric stenosis, ulcers, colitis, celiac disease, polycystic kidneys
Metabolic disorders	Phenylketonuria, galactosemia, maple syrup urine disease, Tay-Sachs disease, Gaucher disease
Problem pregnancies	Repeated miscarriages, stillbirths
Learning problems	Attention deficit disorder, Down syndrome, fragile X syndrome

Familial and Hereditary Diseases. Collect data about hereditary diseases and other significant health conditions for three generations of family members, including the parents, grandparents, aunts, uncles, cousins, child, and siblings, using information listed in Table 5–3. Collect information about the health status of each parent. Record information in either a family genogram or pedigree (see Chapter 3) or a narrative format.

Review of Systems. Collect a comprehensive overview of the child's health during the review of systems using the guidelines from Table 5–4. Additional signs and symptoms associated with the child's condition may be identified, as well as other problems with no direct relationship to the child's health problem that could potentially impact nursing care or home care. For example, asking about allergies may reveal a latex allergy that requires the use of nonlatex supplies and preparation for allergic reactions. For each problem, obtain the treatment, outcomes, residual problems, and age at time of onset.

PSYCHOSOCIAL DATA

Obtain information about family composition to establish a socioeconomic and sociologic context for planning the child's care in the hospital, community, and at home.

- *Family composition*—family members living in the home, their relationship to the child, marital status of parents or other family structure, and people helping to care for the child
- *Financial resources*—household members employed, family income, healthcare resources (e.g., private insurance, Medicaid, Child Health Insurance Program [CHIP]), and other resources (Supplemental Nutrition Assistance Program [SNAP], Temporary Assistance for Needy Families [TANF], or WIC)
- *Home environment*—housing description (condition, potential lead exposure, safe play area); city or well water; sanitation; and availability of electricity, heat, and refrigeration
- *Community environment*—neighborhood description; safety, playgrounds, transportation, and access to shopping; school or childcare arrangements
- *Family or lifestyle changes*—for example, recent unemployment, relocations, or divorce; how the child and family members have coped

Newborns. The psychosocial history for parents of newborns should focus on readiness to care for the newborn at home. Inquire about support for the parent in the initial postpartum period, safe transport, and a home environment that provides heat, refrigeration, and safe water supplies.

Children. Information about the child's daily routines, psychosocial data, and other living patterns should focus on issues that have an impact on the quality of daily living (Table 5–5).

Adolescents. The psychosocial history for adolescents should focus on critical areas in their lives that may contribute to a less than optimal environment for normal growth and development. Key topics that should be addressed are included in the HEEADSSS screening tool (Brown, 2011):

- **H**ome environment
- **E**ducation and employment
- **E**ating
- **A**ctivities
- **D**rugs (substance abuse)
- **S**exuality
- **S**uicidal thoughts
- **S**afety, savagery (exposure to violence)

DEVELOPMENTAL STATUS

Information about the child's motor, cognitive, language, and social development will help to plan nursing care. Ask the parent about the child's developmental milestones and current fine and gross motor skills. Obtain the age at which the child first used words appropriately and the current words used or language ability. Actual assessment of the child with a parent questionnaire may also be used to collect this information. For children in school, ask about academic performance to assess cognitive development. Ask the parent about the child's manner of interaction with other children, family members, and strangers. For adolescents, ask about school performance and activities indicating development of independence and autonomy. (See Chapter 4 for developmental assessment guidelines.)

TABLE 5–4 Review of Systems

BODY SYSTEMS	SAMPLES OF ISSUES TO IDENTIFY
General	General growth pattern, overall health status, ability to keep up with other children or tires easily with feeding or activity, fever, sleep patterns Allergies, type of reaction (hives, rash, respiratory difficulty, swelling, nausea), seasonal or with each exposure
Skin and lymph	Rashes, dry skin, itching, changes in skin color or texture, new lesions, tendency for bruising, swollen or tender lymph glands
Hair and nails	Hair loss, changes in color or texture, use of dye or chemicals on hair Abnormalities of nail growth or color
Head	Headaches, concern about size of head
Eyes	Vision problems, squinting, crossed eyes, lazy eye, wears glasses; eye infections, redness, tearing, burning, rubbing, swelling eyelids
Ears	Ear infections, frequent discharge from ears, or tubes in ears Hearing loss (no response to loud noises or questions, inattentiveness, date of last hearing test), hearing aids, or cochlear implant
Nose and sinuses	Nosebleeds, nasal congestion, colds with runny nose, seasonal symptoms, sinus pain or infections Nasal obstruction, difficulty breathing, snoring at night
Mouth and throat	Mouth breathing, difficulty swallowing, lesions, sore throats, streptococcal infections, mouth odor Tooth eruption, cavities, braces, orthodontic devices Voice change, hoarseness, speech problems
Cardiac and hematologic	Heart murmur, anemia, hypertension, cyanosis, edema, rheumatic fever, chest pain, bruises easily, easily tires with exercise
Chest and respiratory	Trouble breathing, choking episodes, cough, wheezing, cyanosis; exposure to tuberculosis, bronchiolitis, bronchitis, other infections
Gastrointestinal	Bowel movements, frequency, color, consistency, discomfort; constipation or diarrhea; abdominal pain; bleeding from rectum; flatulence Usual appetite, nausea or vomiting
Urinary	Frequency, urgency, dysuria, foul-smelling urine, dribbling, strength of urinary stream, undescended testicles Toilet trained—age when day and night dryness attained, enuresis
Reproductive Female Male Both	For pubescent children Menses onset, amount, duration, frequency, discomfort, problems; vaginal discharge, breast development Puberty onset, emissions, erections, pain or discharge from penis, swelling or pain in testicles Sexual activity, use of contraception, sexually transmitted infections
Musculoskeletal	Weakness, clumsiness, poor coordination, balance, tremors, abnormal gait, painful muscles or joints, swelling or redness of joints, fractures
Neurologic	Seizures, fainting spells, dizziness, numbness, brain injury or concussion; problems with articulation Memory or learning problems, attention span, hyperactivity

Developmental Approach to the Examination

The sequence and approach to the examination vary by age, but the techniques are the same for all ages (Table 5–6). Provide a comfortable atmosphere for the examination with privacy so that modesty is respected. Explain the procedures as you begin to perform them. In young children, a foot-to-head sequence is often used so that the least distressing parts of the examination are completed first. In older cooperative children, the head-to-toe approach is generally used. Experienced examiners often vary the sequence, such as by auscultating the lungs, heart, and abdomen when an infant or toddler is asleep or quiet.

NEWBORNS AND INFANTS UNDER 6 MONTHS OF AGE

Infants are among the easiest children to examine because they do not resist the examination procedure. Keep the parent present

TABLE 5–5 Daily Living Patterns

Role relationships	• Family relationships/alterations in family process • Social and peer relationships and interactions, child care, preschool, school, clubs, sports groups
Self-perception/ self-concept	• Personal identity and role identity • Self-esteem, body image, presence of nonvisible disorder such as a brain injury
Coping/stress tolerance	• Temperament, coping behaviors • Discipline methods used • Any substance abuse
Values and beliefs	• Part of a spiritual group or faith community • Any foods, drinks, or medical interventions prohibited according to spiritual beliefs, special food preparation • Personal values/beliefs
Home care provided for child's condition	• Resources needed/available, respite care available • Knowledge and skills of parents, other family members
Sensory/perceptual problems	• Adaptations to daily living for any sensory loss (vision, hearing, cognitive, or motor)

TABLE 5–6 Examination Techniques

TECHNIQUE	DESCRIPTION
Inspection	Purposeful observation of the child's physical features and behaviors during the entire physical examination. Physical feature characteristics include size, shape, color, movement, position, and location. Adequate lighting is essential. Detection of odors is also a part of the inspection.
Palpation	Use of touch to identify characteristics of the skin, internal organs, and masses. Characteristics include texture, moistness, tenderness, temperature, position, shape, consistency, and mobility of masses and organs. The palmar surface of the fingers and the fingertip pads are used for determining position, size, consistency, and masses. The ulnar surface of the hand is best for detecting vibrations.
Auscultation	Listening to sounds produced by the airway, lungs, stomach, heart, and blood vessels to identify their characteristics. Auscultation is usually performed with a stethoscope to enhance the sounds heard in the chest and abdomen. Speech is also assessed during auscultation.
Percussion	Striking the surface of the body, either directly or indirectly, to set up vibrations that reveal the density of underlying tissues and borders of internal organs in the chest and abdomen. As the density of the tissue increases, the percussion tone becomes quieter. The tone over air is the loudest, and the tone over solid areas is soft.

Note: Standard precautions are used during the physical examination. Perform good hand hygiene before contact with the child and wear gloves for any contact with mucous membranes and body fluids.

to provide comfort and security for the infant during the examination by feeding, using a pacifier, cuddling, or changing the diaper to keep the infant calm and quiet. Distraction such as rocking or clicking noises may help when the infant begins to get distressed. Observe the infant for general level of activity, overall mood, and responsiveness to handling.

Be flexible with the sequence of the examination, taking advantage of times when the infant is quiet or asleep to auscultate lung, heart, and abdominal sounds. If the infant continues to be quiet or can be quieted with a pacifier, palpate the abdomen while the muscles are relaxed. The remainder of the examination can proceed in a head-to-toe sequence. Portions of the examination that may disturb the infant, such as the examination of the hips, should be performed last.

INFANTS OVER 6 MONTHS OF AGE

Because of developing separation and stranger anxiety, it is often best to examine the infant and toddler on the parent's lap and then held against the parent's chest for some steps, such as the ear examination (Figure 5–1). The infant will not object to having clothing removed, but make sure the room is warm for the infant's comfort. Observe the infant's general level of activity, mood, and responsiveness to handling by the parent.

Smile and talk soothingly to the infant during the procedure. Use toys to distract the older infant. Use a pacifier or bottle to quiet the child when necessary. Because the infant may be fearful of being touched by a stranger, begin with the feet and hands before moving to the trunk. However, take advantage of opportunities to listen to heart, lung, and abdominal sounds when the infant is sleeping or quiet.

Figure 5–1 Infants and toddlers are often fearful of separation from the parent. With the legs of the nurse and mother put together knee-to-knee, this infant has a surface to lie on that facilitates cooperation for the abdominal examination.

TODDLERS

Toddlers may be active, curious, shy, cautious, or slow to warm up. Because of stranger anxiety, keep toddlers with their parents, often examining them on the parent's lap. For invasive procedures (ear and mouth examination) the parent can hold the child close to the chest with legs between the parent's legs. Attempt to reduce the child's anxiety by demonstrating the use of instruments on the parent or security object. The cranial nerve assessment or developmental assessment can be used as a method to gain cooperation for other procedures.

Avoid asking the child if you can perform a part of the examination because the typical response will be "No." Rather, tell the child what you will do at each step of the examination, using a confident voice that expects cooperation. When a choice is possible, let the child have some control. For example, let the toddler choose which ear to examine first or to stand or sit for a certain part of the examination. Much of the neurologic and musculoskeletal assessment is performed by observing the child play and walk around in the examining room. Begin the examination by touching the feet and then moving gradually toward the body and head. Use instruments to examine the ears, eyes, and mouth last as they often cause anxiety.

PRESCHOOLERS

Assess the willingness of the child to be separated from the parent. Younger children may prefer to be examined on the parent's lap, whereas older children will be comfortable on the examining table with the parent close by. Most children are willing to undress, but leave the underpants on until conducting the genital examination. Most preschoolers are cooperative during the physical examination. Some children will prefer to have the head, eyes, ears, and mouth examined first while others will prefer to postpone them to the end.

Allow the child to touch and play with the equipment. Give simple explanations about the assessment procedures, and offer choice when there is one during the examination. Use distraction to gain cooperation during the examination, such as asking the child to count, name colors, or talk about a favorite activity. Give positive feedback when the child cooperates.

SCHOOL-AGE CHILDREN

School-age children willingly cooperate and want to be helpful during the examination, so have them sit on the examining table. Anticipate the development of modesty in school-age children and offer a gown to cover the underwear. Let the older school-age child determine if the examination will be conducted in privacy or with the parent or siblings present.

A head-to-toe sequence can be used in this age group. Demonstrate how the instruments are used and let the child handle them if they wish. During the examination, explain what you are doing and why. Offer as many choices as possible to help the child feel empowered. The examination is a good opportunity to teach the child about how the body works, such as letting the child listen to heart and breath sounds.

ADOLESCENTS

Protect the adolescent's modesty by providing a private place to undress and put on the gown, and then during the examination by covering the parts of the body not being assessed. Examine the adolescent in the head-to-toe sequence as used for adults. Perform the examination without parent or siblings unless the adolescent specifically requests the parent's presence, but provide a chaperone (preferably the same gender as the client) when the parent or accompanying adult is not present. See *Professionalism in Practice: Using Chaperones to Examine Adolescents*.

Adolescents often have a lot of concerns regarding their developing bodies. When appropriate, provide reassurance about the normal progression of secondary sexual characteristic development and what further changes to expect.

Professionalism in Practice **Using Chaperones to Examine Adolescents**

A chaperone (same gender as the client), such as a nurse or patient-care technician rather than a family member, should be provided when examining a female adolescent's breasts and during the anorectal and genital examination of both boys and girls. However, the use of a chaperone should be a shared decision between the examiner and the adolescent client (American Academy of Pediatrics Committee on Practice and Ambulatory Medicine, 2011). Hospitals and health clinics often have policies regarding the use of chaperones for physical examinations as well as diagnostic or treatment procedures to guide nurses on when a chaperone should be used and how this should be documented.

General Appraisal

The examination begins upon first meeting the child. Observe the child's general appearance and behavior. The child should appear well nourished and well developed. Infants and young children are often fearful and seek reassurance from their parents. Is the child encouraged to speak? Is the child appropriately reassured or supported by the parent? The child should feel secure with the parent and perceive permission to interact with the nurse.

Measure the infant's weight, length, and head circumference. (See the *Clinical Skills Manual* SKILLS.) After the child is 2 years of age and can stand, measure the child's height rather than length. Accurate measurement is important as medication dosages and fluids are based on weight. Growth measurements are then plotted on growth charts throughout childhood to assure health or to identify the impact of disease on the child. (See the growth charts for all ages of boys and girls in Appendix A.)

Once the weight and height of children have been measured, calculate the body mass index (BMI) (see Chapter 14). The BMI is a formula used to assess total body fat and nutritional status. For children, it helps determine if their height and weight are proportional for their age. Visit the Centers for Disease Control and Prevention website and enter the child's height and weight for an automatic calculation of the BMI. A BMI for age under the 5th percentile indicates the child is underweight. The child is at risk for overweight when the BMI for age is greater than the 85th percentile, and the child is overweight when the BMI is greater than the 95th percentile.

Take the child's temperature, heart rate, respiratory rate, and blood pressure (see the *Clinical Skills Manual* SKILLS.)

Assessing Skin and Hair Characteristics

Examination of the skin requires good lighting to detect variations in skin color and to identify lesions. Daylight is preferred when available. Rather than inspecting the entire skin surface

of the child at one time, examine the skin simultaneously with other body systems as each region of the body is exposed. Follow standard precautions by wearing gloves when palpating mucous membranes, open wounds, and lesions.

Inspection of the Skin

SKIN COLOR

The color of the child's skin usually has an even distribution. Check for color variations—such as increased or decreased pigmentation, pallor, mottling, bruises, erythema, cyanosis, or jaundice—that may be associated with local or generalized conditions. Some variations in skin color are common and normal, such as freckles found in the White population and hyperpigmented patches (Mongolian spots) usually found on the sacral region in infants with dark skin (Figure 5–2).

Ecchymosis or bruising is common on the forehead, knees, shins, and lower arms as children stumble and fall. Bruises are uncommon in infants who are not yet walking, unless they have a bleeding disorder condition (Anderst, Carpenter, Abshire, et al., 2013). Bruises found on other parts of the child's body, especially in various stages of healing, should raise a suspicion of child abuse (see Chapter 17). Bruises go through several skin color changes (red, purple, black, blue, yellow, green, and brown) as the body breaks down hemoglobin and blood cells over several days before returning to normal skin color. Note any tattoos or body piercings.

Developing Cultural Competence **Skin Tone Differences**

The palms of the hands and soles of the feet are often lighter than the rest of the skin surface in children with darker skin. In addition, their lips may appear slightly bluish.

Figure 5–2 **Hyperpigmented patches are bluish-colored skin with an irregular shape often seen over the buttocks and back. They are a normal occurrence in a large majority of Native American, Asian, Black, and Hispanic infants. These patches usually fade during the first few years of life and disappear by puberty.**

When a skin color abnormality is suspected, inspect the buccal mucosa and tongue to confirm the color change. This is important in darker-skinned children because the mucous membranes are usually pink, regardless of skin color. Press the gums lightly for 1 to 2 seconds. Any residual color, such as that seen in jaundice or cyanosis, is more easily detected in blanched skin. Generalized cyanosis is associated with respiratory and cardiac disorders. Jaundice is associated with liver disorders.

Palpation of the Skin

Lightly touch or stroke the skin surface to palpate the skin and to evaluate the following characteristics:

- *Temperature*—normally feels cool to the touch when the wrist or dorsum of the hand is placed against the child's skin. Excessively warm skin may indicate the presence of fever or inflammation, whereas abnormally cool skin may be a sign of shock or cold exposure.
- *Texture*—expect soft, smooth skin over the entire body. Identify any areas of roughness, thickening, or **induration** (area of extra firmness with a distinct border). Abnormalities in texture are associated with endocrine disorders, chronic irritation, and inflammation.
- *Moistness*—normally dry to the touch, but may feel slightly damp when the child has been exercising or crying. Excessive sweating without exertion is associated with a fever or with an uncorrected congenital heart defect.
- *Resilience*—taut, elastic, and mobile because of the balanced distribution of intracellular and extracellular fluids. To evaluate skin turgor, pinch a small amount of skin on the abdomen between the thumb and forefinger, release the skin, and watch the speed of recoil (Figure 5–3). Skin that is elastic rapidly returns to its previous contour and is expected. Skin that tents or feels doughy takes longer to resume its original contour and is commonly associated with dehydration.

If **edema**, an accumulation of excess fluid in the interstitial spaces, is present, the skin feels doughy or boggy. To test for the degree of edema present, press for 5 seconds against a bone beneath the area of puffy skin, release the pressure, and observe how rapidly the indentation disappears. If the indentation disappears rapidly, the edema is "nonpitting." Slow disappearance of

Figure 5–3 **Tenting of the skin is associated with poor skin turgor. Assess skin turgor on the abdomen, forearm, or thigh. Skin with elasticity and normal turgor will return to a flat position quickly.**

A

B

Figure 5–4 Capillary refill technique. ***A,*** **Press against the palmar tip of a finger, toe, or over a bony surface (e.g., jaw) for 2 to 3 seconds until the skin is blanched.** ***B,*** **Quickly release the pressure and count the number of seconds it takes for the color or blood to return to the veins. A capillary refill time of greater than 2 seconds could be related to dehydration, shock, or constriction around a limb such as a tight bandage or cast.**

the indentation indicates "pitting" edema, which is commonly associated with kidney or heart disorders.

Capillary Refill Time

One technique to evaluate the adequacy of tissue *perfusion* (oxygen circulating to the tissues) is the capillary refill time (Figure 5–4*A* and Figure 5–4*B*). The capillary refill time is normally less than 2 seconds. When the time is prolonged, assess the child for dehydration, hypovolemic shock, or a physical constriction such as a cast or bandage that is too tight.

Skin Lesions

Skin lesions usually indicate an abnormal skin condition. Characteristics such as location, size, type of lesion, pattern, and discharge, if present, provide clues about the cause of the condition. Inspect and palpate the isolated or generalized skin color abnormalities, elevations, lesions, or injuries to describe all characteristics present.

Primary lesions (such as macules, papules, and vesicles) are often the skin's initial response to injury or infection. Hyperpigmented patches (Mongolian spots) and freckles are normal findings also classified as primary lesions (see the illustrations in *Pathophysiology Illustrated: Common Primary Skin Lesions and Associated Conditions*). Secondary lesions (such as scars, ulcers, and fissures) are the result of irritation, infection, and delayed healing of primary lesions (see Table 31–1).

Primary lesions often appear in common patterns that help distinguish between lesions.

- *Annular*—circular, begins in center and spreads to periphery (e.g., ringworm); when annular lesions run together they are polycyclic
- *Linear*—in a row or stripe (e.g., poison ivy)
- *Herpetiform*—grouped or clustered (e.g., herpes, chickenpox)
- *Reticulated*—networked or lacelike (e.g., parvovirus B19)

Inspection of the Hair

Inspect the scalp hair for color, distribution, and cleanliness. The hair shafts should be evenly colored, shiny, and either curly or straight. Variation in hair color not caused by bleaching or coloring may be associated with a nutritional deficiency. Normally, hair is distributed evenly over the scalp. Investigate areas of hair loss. Hair loss in a child may result from tight braids or skin lesions such as ringworm. (See Chapter 31 for information about fungal infections.) Notice any unusual hair growth patterns. An unusually low hairline on the neck or forehead may be associated with a congenital disorder such as hypothyroidism.

Children are frequently exposed to head lice. Inspect the individual hair shafts for small nits (lice eggs) that adhere to the hair (see Chapter 31). None should be present.

Observe the distribution of body hair as other skin surfaces are exposed during examination. Fine hair covers most areas of the body. Body hair in unexpected places should be noted. For example, a tuft of hair at the base of the spine often indicates a spinal defect.

Note the age at which pubic and axillary hair develops in the child. Pubic hair begins to develop in children between 8 and 12 years of age, and axillary hair develops about 6 months later (see Figures 5–29 and 5–30). Facial hair is noted in boys shortly after axillary hair develops. Development at an unusually young age is associated with precocious puberty.

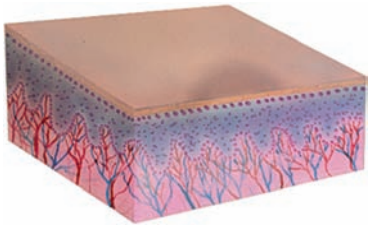
Palpation of the Hair

Palpate the hair shafts for texture. Hair should feel soft or silky with fine or thick shafts. Endocrine conditions such as hypothyroidism may result in coarse, brittle hair. Part the hair in various spots over the head to inspect and palpate the scalp for crusting or other lesions. If lesions are present, describe them using the characteristics presented in *Pathophysiology Illustrated*.

Developing Cultural Competence Hair Characteristics

Hair varies by genetic origin. Children of African origin often have curly, wavy, or coiled hair that breaks easily. Children of Asian origin have hair that is coarse and straight. White children have hair with fine to medium coarseness that is straight or wavy.

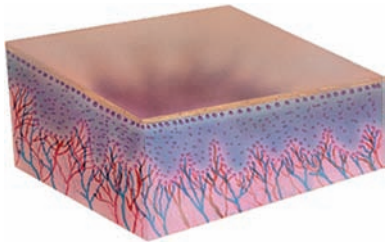
Pathophysiology Illustrated: Common Primary Skin Lesions and Associated Conditions



Lesion name: Macule

Description: Flat, nonpalpable, diameter less than 1 cm (½ in.)

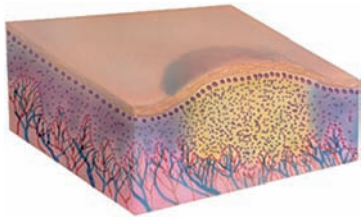
Example: Freckle, rubella, rubeola, petechiae



Lesion name: Patch

Description: Macule, diameter greater than 1 cm (½ in.)

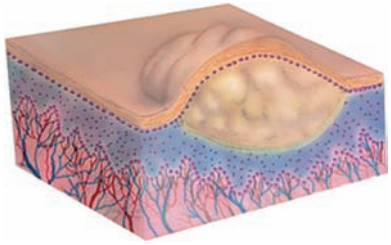
Example: Vitiligo, hyperpigmented patch (Mongolian spot)



Lesion name: Papule

Description: Elevated, firm, diameter less than1 cm (½ in.)

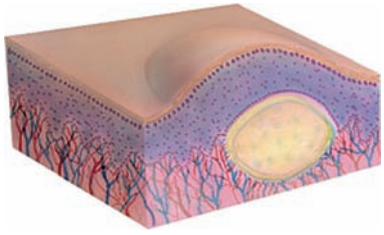
Example: Warts, pigmented nevi



Lesion name: Tumor

Description: Elevated, solid, diameter greater than 2 cm (1 in.)

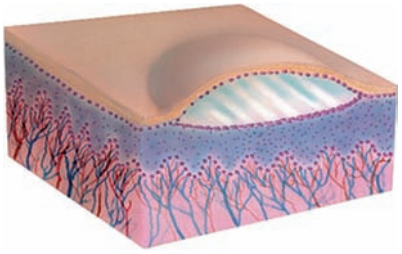
Example: Neoplasm, hemangioma



Lesion name: Nodule

Description: Elevated, firm, deeper in dermis than papule, diameter 1 to 2 cm (½ to 1in.)

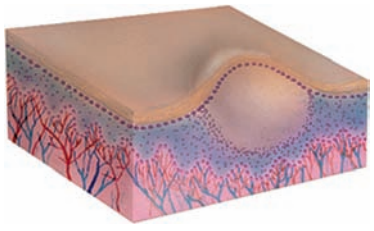
Example: Erythema nodosum



Lesion name: Vesicle

Description: Elevated, filled with fluid, diameter less than 1 cm (½ in.)

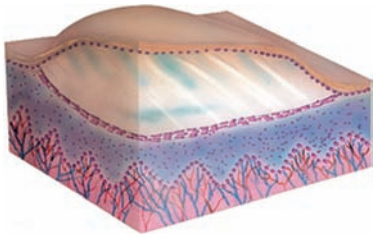
Example: Early chickenpox, herpes simplex



Lesion name: Pustule

Description: Vesicle filled with purulent fluid

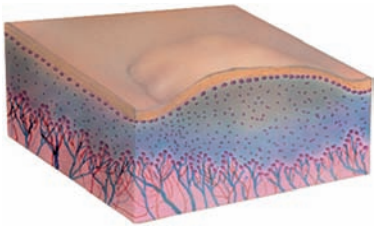
Example: Impetigo, acne



Lesion name: Bulla

Description: Vesicle diameter greater than 1 cm (½ in.)

Example: Burn blister



Lesion name: Wheal

Description: Irregular elevated solid area of edematous skin

Example: Urticaria, insect bite

Assessing the Head for Skull Characteristics and Facial Features

Inspection of the Head and Face

During early childhood the skull's sutures expand to allow for brain growth. Infants and young children normally have a rounded skull with a prominent occipital area. The shape of the head changes during childhood, and the occipital area becomes less prominent. An abnormal skull shape can result from premature closure of the sutures.

Clinical Tip

Children who were low-birth-weight infants often have a flat, elongated skull because the soft skull bones were flattened by the weight of the head early in infancy. Head flattening is also associated with the back-lying sleep positions in infants.

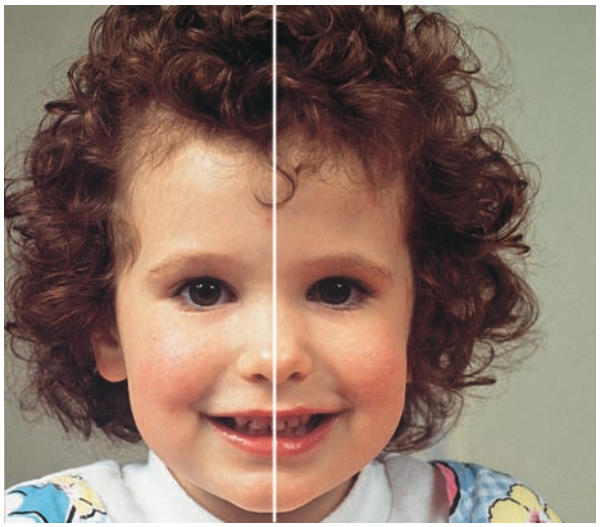


Figure 5–5 **To inspect the face for symmetry, draw an imaginary line down the middle of the face over the nose and compare the features on each side. Significant asymmetry may be caused by paralysis of cranial nerve V or VII, in utero positioning, or swelling from infection, allergy, or trauma.**

The head circumference of infants and young children is routinely measured until 2 years of age to ensure that adequate growth for brain development has occurred. The *Clinical Skills Manual* SKILLS describes the proper technique. A larger-than-normal head is associated with hydrocephalus, and a smaller-than-normal head suggests microcephaly.

Inspect the child's face for symmetry when the child is resting, smiling, talking, and crying (Figure 5–5). Significant asymmetry may result from paralysis of trigeminal or facial nerves (cranial nerves V or VII), in utero positioning, and swelling from infection, allergy, or trauma.

Next inspect the face for unusual facial features such as coarseness, wide eye spacing, or disproportionate size. Tremors, tics, and twitching of facial muscles are often associated with seizures.

Palpation of the Skull

Palpate the skull in infants and young children to assess the sutures and fontanelles and to detect soft bones (see *As Children Grow: Sutures*).

SUTURES

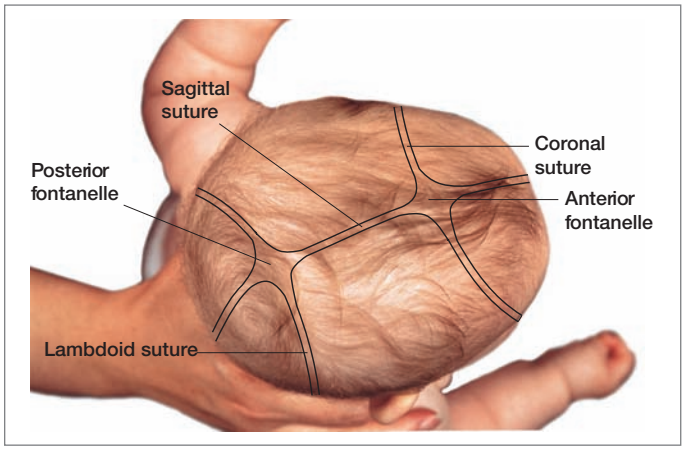
Use your fingerpads to palpate each suture line. The edge of each bone in the suture line can be felt, but normally there is no separation of the two bones. If additional bone edges are felt, a skull fracture may be present.

FONTANELLES

At the intersection of the sutures, palpate the anterior and posterior fontanelles. The fontanelle should feel flat and firm inside the bony edges. The anterior fontanelle is normally smaller than 5 cm (2 in.) in diameter at 6 months of age and then becomes progressively smaller. It closes between 12 and 18 months of age. The posterior fontanelle closes between 2 and 3 months of age.

A tense fontanelle, bulging above the margin of the skull when the child is sitting quietly, is an indication of increased intracranial pressure. A soft fontanelle, sunken below the margin of the skull, is associated with dehydration.

As Children Grow: **Sutures**



The sutures are fibrous connections between bones of the skull that have not yet ossified. The fontanelles are formed at the intersection of these sutures where bone has not yet formed. Fontanelles are covered by tough membranous tissue that protects the brain. The posterior fontanelle closes between 2 and 3 months. The anterior fontanelle and sutures are palpable up to the age of 18 months. The suture lines of the skull are seldom palpated after 2 years of age. After that time the sutures rarely separate.

Developing Cultural Competence **Touching the Head**

The head is a sacred part of the body to some Southeast Asians. Ask for permission before touching the infant's head to palpate the sutures and fontanelles (Purnell, 2014, p. 412). When a Hispanic child is examined, however, many families consider not touching the head bad luck.

Assessing Eye Structures, Function, and Vision

Equipment needed for this examination includes an ophthalmoscope, vision chart, penlight, small toy, and an index card or paper cup.

Inspection of the External Eye Structures

Inspect the external eye structures, including the eyeballs, eyelids, and eye muscles. Test the function of cranial nerves II, III, IV, and VI, which innervate the eye structures.

EYE SIZE AND SPACING

Inspect the eyes and surrounding tissues simultaneously when examining facial features (Figure 5–6). The eyes should be the same size but not unusually large or small. Observe for eye

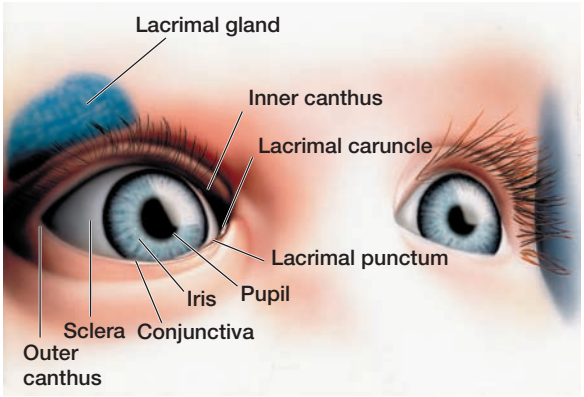


Figure 5–6 External structures of the eye. Notice that the light reflex is at the same location on each eye.

bulging, which can be identified by retracted eyelids, or for a sunken appearance. Bulging may be associated with a tumor, and a sunken appearance may reflect dehydration.

Next inspect the eyes to see if they are appropriately distanced from each other. The distance between the inner canthi of the eyes should equal the distance between the inner and outer canthi of the child's eye (Hummel, 2011). **Hypertelorism**, or widely spaced eyes, can be a normal variation in children.

EYELIDS AND EYELASHES

Inspect the eyelids for color, size, position, mobility, and condition of the eyelashes. Eyelids should be the same color as surrounding facial skin and free of swelling or inflammation along the edges. Sebaceous glands that look like yellow striations are often present near the hair follicles. Eyelashes curl away from the eye to prevent irritation of the conjunctivae.

Inspect the conjunctivae lining the eyelids by pulling down the lower lid. Everting (rolling upward) the upper lid is rarely required. The conjunctivae should be pink and glossy. No redness or excess tearing should be present.

When the eyes are open, inspect the level at which the upper and lower lids cross the eye. Each lid normally covers part of the iris but not any portion of the pupil. The lids should also close completely over the iris and cornea. *Ptosis*, drooping of the lid over the pupil, is often associated with injury to the oculomotor nerve, cranial nerve III. *Sunset sign*, in which the sclera is seen persistently between the upper lid and the iris, may indicate hydrocephalus or increased intracranial pressure.

Inspect the eyes for the palpebral slant (Figure 5–7). The eyelids of most people open horizontally. An upward slant is a normal finding in Asian children; however, children with Down syndrome also often have an upward slant (Figure 5–8). A downward slant is seen in some children as a normal variation. Children of Asian descent often have an extra fold of skin, known as the **epicanthal fold**, covering all or part of the lacrimal caruncle on the nasal side of the eye.

EYE COLOR

Inspect the color of each sclera, iris, and bulbar conjunctiva. The sclera is normally white or ivory in darker-skinned children. Sclerae of another color suggest the presence of an underlying disease. For example, yellow sclerae indicate jaundice. Typically, the iris is blue or light colored at birth and becomes pigmented within 6 months. Different colored irises are rare and may be associated with a tumor, injury, or genetic syndrome

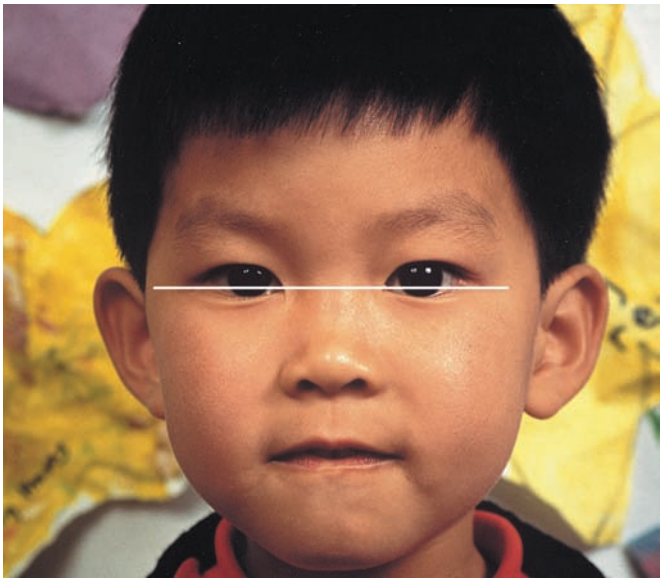

Figure 5–7 To identify the palpebral slant, draw an imaginary line across the medial canthi and extend it to each side of the face. When the imaginary line crosses the lateral canthi, the palpebral fissures are horizontal and no slant is present. When the lateral canthi fall above the line, the eyes have an upward slant. A downward slant is present when the lateral canthi fall below the line. Look at Figures 5–6, 5–8, and 5–10. Which type of eye slant do these children have? Are epicanthal folds present?

(Olitsky, Hug, Plummer, et al., 2016). Inspect the iris for the presence of *Brushfield spots*, white specks in a linear pattern around the iris circumference, which are often associated with Down syndrome. The bulbar conjunctivae, which cover the

Figure 5–8 The eyes of this boy with Down syndrome show an upward slant.

sclera to the edge of the cornea, are normally clear. Redness can indicate eyestrain, allergies, or irritation.

PUPILS

Inspect the size and shape of the pupils. Normally, the pupils are round, clear, and equal in size. Some children have a **coloboma**, which is a keyhole-shaped pupil caused by a notch in the iris. This sign can indicate that the child has other congenital anomalies.

To test the pupillary response to light, shine a bright light into one eye. A brisk constriction of both the pupil exposed to direct light and the other pupil (consensual response) is a normal finding.

To test pupillary response to accommodation, ask the child to look first at a near object (e.g., a toy) and then at a distant object (e.g., a picture on the wall). The expected response is pupil constriction with near objects and pupil dilation with distant objects. These procedures test cranial nerve II.

ASSESSMENT OF THE EYE MUSCLES

It is important to detect *strabismus*, a muscle imbalance that makes the eyes look crossed, which can cause vision impairment if uncorrected. Use the following procedures to detect a muscle imbalance:

- *Extraocular movements.* Seat the child at eye level to evaluate the extraocular movements. Hold a toy or penlight 30 cm (12 in.) from the child's eyes and move it through the six cardinal fields of gaze. Make sure the child's eyes move rather than the head. Both eyes should move together, tracking the object. This procedure tests the oculomotor, trochlear, and abducens nerves (cranial nerves III, IV, and VI, respectively) (Figure 5–9).
- *Corneal light reflex.* To test the corneal light reflex, shine a light on the child's nose, midway between the eyes. Identify the location where the light is reflected on the cornea of each eye. The light reflection is normally symmetric, at the same spot on each cornea (see Figure 5–6). An asymmetric corneal light reflex after 6 months of age indicates a muscle imbalance.
- *Cover–uncover test.* This test can be used only for older, cooperative children, starting at about 5 years of age. See Figure 5–10 for the technique. Perform the procedure for both eyes. Because the eyes work together, no obvious movement of either eye is expected. Eye movement indicates a muscle imbalance.

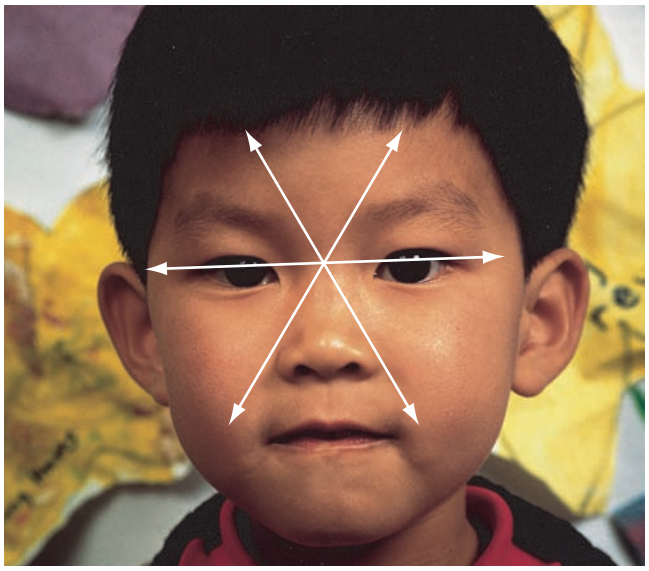

Figure 5–9 To assess extraocular movements have the child sit at your eye level. Hold a toy or penlight about 30 cm (12 in.) from the child's eyes and move it through the six cardinal fields of gaze. Both eyes should move together, tracking the object. This procedure tests cranial nerves III, IV, and VI.

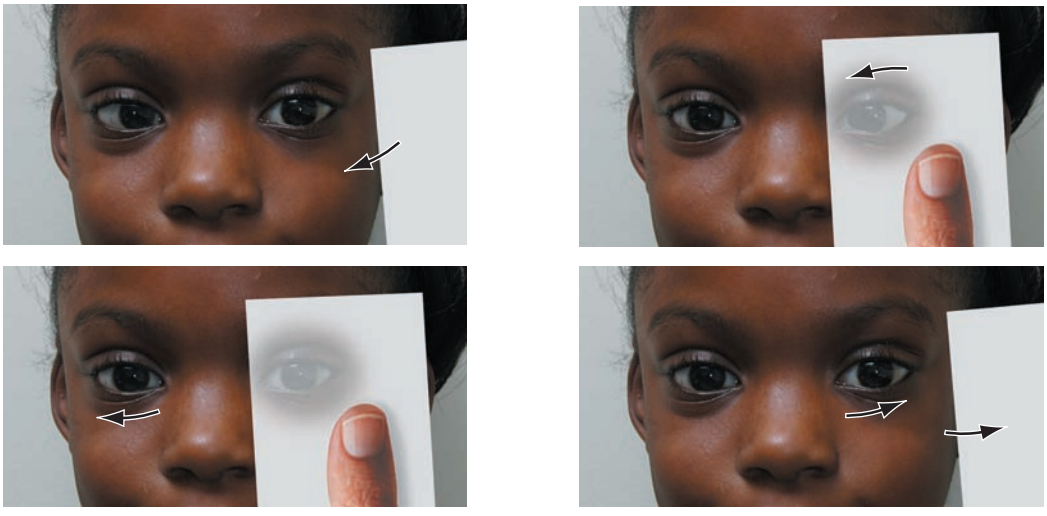

A Right, uncovered eye is weaker.

B Left, covered eye is weaker.

Figure 5–10 Cover–uncover test. With the child at your eye level, ask the child to look at a picture on the wall. *A*, Cover one eye with an index card or paper cup and simultaneously watch for any movement of the uncovered eye. If the uncovered eye jumps to fixate on the picture, it has a muscle weakness. *B*, Remove the cover from the eye and simultaneously watch the eye that was covered for any movement to fixate on the picture. If the eye has a muscle weakness, it drifts to a relaxed position once covered.

Vision Assessment

Because vision is such an important sense for learning, assessment is essential to detect any serious problems. Vision is evaluated using an age-appropriate vision test, but no simple method exists. Photo screening or an autorefractor may be used to assess vision in some preschool and school-age children. See the *Clinical Skills Manual* SKILLS.

INFANTS AND TODDLERS

When the infant's eyes are open, test the blink reflex by moving your hand quickly toward the infant's eyes. A quick blink is the normal response. An absent blink reflex can indicate that the infant is blind.

To test an infant's ability to visually track an object, hold a light or toy about 15 cm (6 in.) from the infant's eyes. When the infant has fixated on or is staring at the object, move it slowly to each side. Refer the infant who does not follow the object with the eyes and by moving the head. Once an infant has developed skills to reach for and then pick up objects, observe play behavior to evaluate vision. Children under 3 years of age should be able to easily find and pick up small pieces of food.

STANDARDIZED VISION CHARTS

Standardized vision charts can be used to test vision when the child can understand directions and cooperate, usually at about 3 or 4 years of age. The HOTV, Snellen E, and Picture charts are used to test visual acuity of preschool-age children just as the Snellen Letter chart is used for school-age children and adolescents. For all screening tools used to test far vision, make sure the child is the appropriate distance from the chart, usually 10 or 20 feet. Cover one eye so each eye is evaluated separately before testing them together. See the *Clinical Skills Manual* SKILLS for the use of these charts. Vision develops during early childhood. Refer children who fail photoscreening and those who do not correctly identify most images with each eye on the standardized vision chart 20/50 line for 3-year-olds, 20/40 line for 4-year-olds, and 20/32 line for 5-year-olds (American Association for Pediatric Ophthalmology and Strabismus, 2014).

Inspection of the Internal Eye Structures

The funduscopic examination with an ophthalmoscope allows the structures of the internal eye—the retina, optic disc, arteries and veins, and macula—to be examined. This examination is most often performed by experienced examiners. To assist the examiner, darken the room so the child's pupils dilate. Encourage cooperation by explaining the procedure to the child. Have a picture on the wall or have the parent or assistant hold a toy for the child to stare at so that the child's eye will remain open.

RED REFLEX

A penlight or the light of an ophthalmoscope can be used to assess the **red reflex**, the orange-red glow of the vascular retina as the light travels through the cornea, aqueous humor, lens, and vitreous humor to the retina. Shine the light at both eyes from a distance of 45 cm (18 in.). The red reflexes should be an orange-red glow that is symmetric and uniform in shape and color. Black spots or opacities within the red reflex are abnormal and may indicate congenital cataracts, hemorrhage, or corneal scars. A white reflex is associated with a tumor or retinoblastoma (see Chapter 24).

Assessing the Ear Structures and Hearing

Equipment needed for this examination includes an otoscope, noisemakers (bell, rattle, tissue paper), and a 500- to 1000-Hz tuning fork.

Inspection of the External Ear Structures

The position and characteristics of the *pinna*, the external ear, are inspected as a continuation of the head and eye examination. See Figure 5–11 to determine if the pinna is considered "low set," which is often associated with congenital renal disorders.

Inspect the pinna for any malformation. The pinna should be completely formed, with an open auditory canal. Next, inspect the tissue around the pinna for abnormalities. A pit or hole in front of the auditory canal may indicate the presence of a sinus. If the one pinna protrudes outward, there may be swelling behind the ear, a sign of infection in the mastoid process of the temporal bone of the skull.

Inspect the external auditory canal for any discharge. A foul-smelling, purulent discharge may indicate the presence of a foreign body or an infection in the external canal. Clear fluid or a blood-tinged discharge may indicate a cerebrospinal fluid leak associated with a basilar skull fracture.

Inspection of the Tympanic Membrane

Examination of the tympanic membrane is important in infants and young children because they are prone to otitis media, a middle ear infection. To examine the auditory canal and tympanic membrane, use an otoscope, an instrument with a magnifying lens, bright light, and speculum. Choose the largest ear speculum that fits into the auditory canal to form a seal for testing the movement of the tympanic membrane and to reduce the risk for injury to the auditory canal if the child moves suddenly.

Figure 5–11 **To evaluate the placement of the external ears, draw an imaginary line through the medial and lateral canthi of the eye toward the ear. This line normally passes through the upper portion of the pinna. The pinna is considered "low set" when the top lies completely below the imaginary line. Low-set ears are often associated with renal disorders.**

Figure 5–12 **Inspecting the tympanic membrane. To restrain an uncooperative child, place the child on the parent's lap with the child's head and chest held firmly against the parent's chest. Keep your hands free to hold the otoscope and position the external ear.**

Toddlers and young children often resist having their ears inspected with the otoscope because of past painful experiences, so postpone this until the end of the assessment for this age group. Use simple explanations to prepare the child. Let the child play with the otoscope or demonstrate how it is used on the parent or a doll. Figure 5–12 illustrates one method of human restraint for an uncooperative toddler or preschool child. See the *Clinical Skills Manual* SKILLS.

To begin using the otoscope, hold the handle in the palm of your hand closest to the child's face. If using a pneumatic squeeze bulb, hold it between your index finger and the otoscope handle. When the child is cooperative, rest the back of your hand holding the otoscope against the child's head to stabilize it. Your other hand is used to pull the pinna back and either up or down, whichever position straightens the auditory canal and provides the best view of the tympanic membrane (Figure 5–13).

Slowly insert the speculum into the auditory canal, inspecting the walls for signs of irritation, discharge, or a foreign body. The walls of the auditory canal are normally pink, and some cerumen is present. Children often put beads, peas, or other small objects into their ears. If the auditory canal is obstructed by cerumen or a foreign body, warm water irrigation can be used to clean the canal.

SAFETY ALERT!

Never irrigate the ear canal if any discharge is present in the auditory canal, as the tympanic membrane may be ruptured. Water could enter the middle ear and potentially worsen the infection.

The tympanic membrane, which separates the outer ear from the middle ear, is usually pearly gray and translucent. It reflects light, and the bones (ossicles) in the middle ear are normally visible (Figure 5–14). When the auditory canal is sealed and the pneumatic attachment is squeezed and released, the tympanic membrane normally moves in and out in response to the positive and negative pressure applied. Table 5–7 lists the abnormal findings during examination of the tympanic membranes. See Figures 19–4 and 19–5 for the tympanic membrane appearance when acute otitis media and otitis media with effusion are present.

Figure 5–13 **To straighten the auditory canal, pull the pinna back and up for children over 3 years of age. Pull the pinna down and back for children under 3 years of age.**

Hearing Assessment

Hearing evaluation is important in children of all ages because hearing is essential for normal speech development and learning. Hearing loss may occur at any time during early childhood as the result of birth trauma, frequent otitis media, meningitis, or antibiotics that damage cranial nerve VIII. Hearing loss may also be associated with congenital anomalies and genetic syndromes. The hearing of newborns is evaluated at birth and periodically throughout childhood.

Evaluate hearing by observing the child's responses to various auditory stimuli using age-appropriate methods. Use hearing and speech articulation milestones as an initial hearing screen.

When a hearing deficiency is suspected as a result of screening, refer the child for audiometry or tympanometry. *Audiometry* is a screening procedure using air conduction that measures hearing for pure-tone frequencies and loudness. The high- and low-pitch sounds are presented through earphones and are used to test different sound frequencies and the loudness needed to hear each sound. Hearing loss is determined when the child needs

Growth and Development **Indicators of Hearing Loss**

Infant:

- No startle reaction to loud noises.
- Does not turn toward sounds by 4 months of age.
- Babbles as a young infant but does not keep babbling or develop speech sounds after 6 months of age.

Young child:

- No speech by 2 years of age.
- Inability to follow age-appropriate directions, such as "Bring me the block."
- Speech sounds are not distinct at appropriate ages.

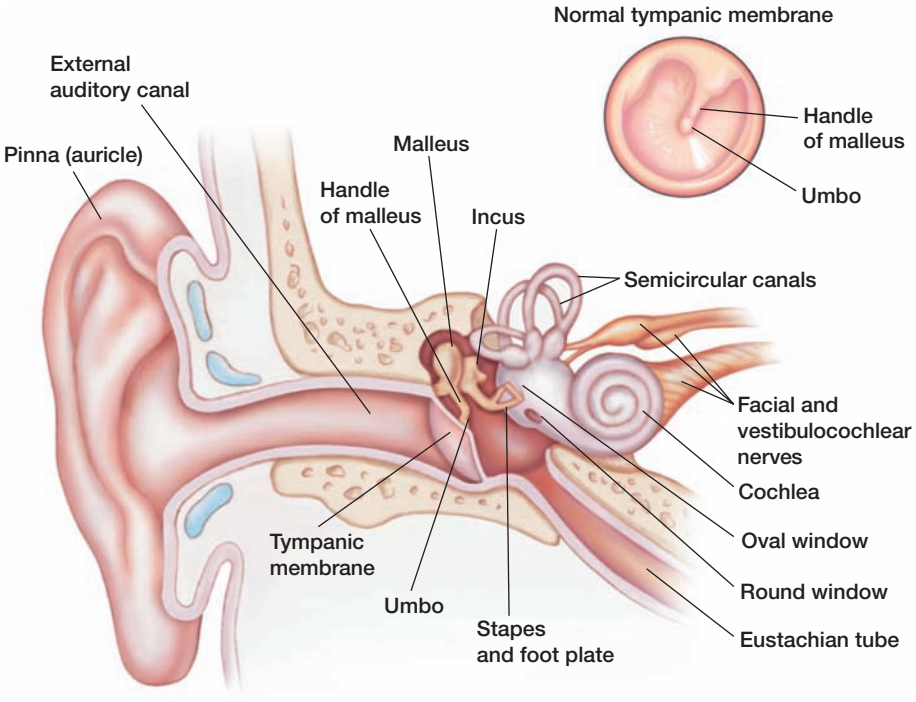

Figure 5–14 **The tympanic membrane normally has a triangular light reflex with the base on the nasal side pointing toward the center. The bony landmarks, the umbo and handle of malleus, are seen through the tympanic membrane.**

higher-than-normal decibels (louder sound) to hear a tone. *Tympanometry* is a test to estimate the pressure in the middle ear, and it is an indirect measure of tympanic membrane movement. See the *Clinical Skills Manual* SKILLS.

INFANTS AND TODDLERS

Select noisemakers with different frequencies that will attract the child's attention, such as a rattle, bell, and tissue paper. Ask the parent or an assistant to entertain the infant with a quiet toy, such as a teddy bear. Stand behind the infant, about 60 cm (2 feet) away from the infant's ear but outside the infant's field of vision, and make a soft sound with the noisemaker. Have the parent or assistant observe the child for any of the following responses when the noisemaker is used: widening the eyes, briefly stopping all activity to listen, or turning the head toward the sound. Repeat the test in the other ear and with the other noisemakers.

PRESCHOOL AND OLDER CHILDREN

Use whispered words to evaluate the hearing of children over 3 years of age. Position your head about 30 cm (12 in.) away from the child's ear, but out of the range of vision so the child cannot read your lips. Use words easily recognized by the child, such as *Mickey Mouse*, *hot dog*, and *popsicle*, and ask the child to repeat the words. Repeat the test with different words in the opposite ear. The child should correctly repeat the whispered words. If the child will not repeat the whispered words, use a whisper to ask the child to point to different body parts or objects. Remember to stay out of the child's line of sight so lip reading is not possible. The child should point to the correct body part each time.

BONE AND AIR CONDUCTION OF SOUND

A tuning fork may be used to evaluate the hearing of school-age children who can follow directions. Hold the stem and lightly tap

TABLE 5–7 Unexpected Findings on Examination of the Tympanic Membrane and Their Associated Conditions

CHARACTERISTICS	TYMPANIC MEMBRANE UNEXPECTED FINDINGS	ASSOCIATED CONDITIONS
Color	Redness	Infection in middle ear
	Slight redness	Prolonged crying
	Amber	Serous fluid in middle ear
	Deep red or blue	Blood in middle ear
Light reflex	Absent	Bulging tympanic membrane, infection in middle ear
	Distorted, loss of triangular shape	Retracted tympanic membrane, serous fluid in middle ear
Bony landmarks	Extra prominent	Retracted tympanic membrane, serous fluid in middle ear
Movement	No movement	Infection or fluid in middle ear
	Excessive movement	Healed perforation

A B C

Figure 5–15 **Testing bone and air conduction.** ***A,*** **Weber test. Place vibrating tuning fork on midline of the child's head.** ***B,*** **Rinne test, step 1. Place vibrating tuning fork on mastoid process.** ***C,*** **Rinne test, step 2. Reposition still vibrating tines between 2.5 and 5.0 cm (1 and 2 in.) from ear.**

the tines of the tuning fork to begin the vibration. Avoid touching the vibrating tines, which will dampen the sound. Test bone conduction by placing the handle of the tuning fork on the child's skull. Test air conduction by holding the vibrating tines close to the child's ear (Figure 5–15).

- *Weber test:* Place the vibrating tuning fork on top of the child's skull in the midline. Ask the child if the sound is heard better in one ear or in both ears equally. The sound should be heard equally in both ears. If the sound is heard better in one ear (lateralized to affected ear), conductive hearing loss may be present.
- *Rinne test:* Place the vibrating tuning fork handle on the mastoid process behind an ear. Ask the child to say when the sound is no longer heard. Immediately move the tuning fork, holding the vibrating tines about 2.5 to 5 cm (1 to 2 in.) from the same ear. Again, ask the child to say when the sound is no longer heard. The child normally hears the air-conducted sound twice as long as the bone-conducted sound. Repeat the Rinne test on the other ear. When the sound is heard longer by bone conduction than air conduction, the affected ear may have conductive hearing loss. When sound is heard longer by air conduction than bone conduction, but less than twice as long, the affected ear may have sensorineural hearing loss.

Assessing the Nose and Sinuses for Airway Patency and Discharge

An otoscope with a nasal speculum or a penlight is needed for this examination.

Inspection of the External Nose

Examine the external nose characteristics and placement on the face during the assessment of the facial features. Inspect the external nose for size, shape, symmetry, midline placement on the face, and for the presence of unusual characteristics. For example, a crease across the nose between the cartilage and bone is often caused when an allergic child uses a hand to rub an itchy nose upward. **Nasal flaring**, widening of the nares with breathing, is a sign of respiratory distress and should not be present.

The nose should be proportional in size to other facial features, have symmetric nasolabial folds, and be positioned in the middle of the face. Asymmetry of the nasolabial folds may be associated with injury to the facial nerve (cranial nerve VII). A flattened nasal bridge is the expected finding in Asian and Black children but may also be seen in children with Down syndrome. A saddle-shaped nose is associated with congenital defects such as cleft palate.

Palpation of the External Nose

When a deformity is noted, gently palpate the nose to detect any pain or break in contour. No tenderness or masses are expected. Pain and a contour deviation are usually the result of trauma.

NASAL PATENCY

The child's airway must be patent to ensure adequate oxygenation. To test for nasal patency, occlude one nostril and observe the child's effort to breathe through the open nostril with the mouth closed. Repeat on the other nostril. Breathing should be noiseless and effortless.

If the child struggles to breathe, a nasal obstruction may be present. Nasal obstruction may be caused by a foreign body, congenital defect, dry mucus, discharge, polyp, or trauma. Young children commonly place objects up their noses, and unilateral nasal flaring is a sign of such an obstruction.

Growth and Development

Newborns and infants under 6 months of age will not automatically open their mouths to breathe when their nose is occluded, such as by mucus.

Assessment of Smell

The olfactory nerve (cranial nerve I) can be tested in school-age children and adolescents, but it is rarely done. When testing smell, choose scents the child will easily recognize such as orange, chocolate, peanut butter, and mint. When the child's eyes are closed, occlude one nostril and hold the scent under the nose. Ask the child to take a deep sniff and identify the

Figure 5–16 **Technique for examining the nose. For infants and young children, push the tip of the nose upward and shine the light at the end of the nose. The nasal speculum of the otoscope can be used in older children. Avoid touching the septum of the nose with the speculum to prevent injury.**

scent. Alternate odors between the nares. The child can normally identify common scents.

Inspection of the Internal Nose

Inspect the internal nose for color of the mucous membranes and the presence of any discharge, swelling, lesions, or other abnormalities. Use a bright light, such as an otoscope light or penlight. See Figure 5–16.

TABLE 5–8 Nasal Discharge Characteristics and Associated Conditions

DISCHARGE DESCRIPTION	ASSOCIATED CONDITION
Watery	
Clear, bilateral	Allergy
Serous, unilateral	Spinal fluid from a basilar skull fracture
Mucoid or purulent	
Bilateral	Upper respiratory infection
Unilateral	Foreign body
Bloody	Nosebleed, trauma

MUCOUS MEMBRANES AND NASAL SEPTUM

The mucous membranes should be dark pink and glistening. A film of clear discharge may also be present. Turbinates, if visible, should be the same color as the mucous membranes and have a firm consistency. When the turbinates are pale or bluish gray, the child may have allergies. A polyp, a rounded mass projecting from the turbinate, is also associated with allergies.

The nasal septum should be straight without perforations, bleeding, or crusting. Crusting will be noted over the site of a nosebleed.

DISCHARGE

Observe for the presence of nasal discharge, noting if it is unilateral or bilateral. Nasal discharge is not a normal finding unless the child is crying. Discharge may be watery, mucoid, purulent, or bloody. Table 5–8 lists conditions associated with nasal discharge.

Inspection of the Sinuses

The sinuses are air-filled spaces that develop during childhood. See the illustration in *As Children Grow: Sinus Development*.

As Children Grow: **Sinus Development**

The ethmoid sinuses are present at birth and air filled. The maxillary sinuses are present at birth and become air filled by 4 years of age. The sphenoid sinuses are present by 5 years of age. The frontal sinuses form at about 7 to 8 years of age and are completely developed by adolescence (Pappas & Hendly, 2016).

Inspect the face for any puffiness and swelling around one or both eyes; normally, neither is present. To palpate over the maxillary sinuses, press up under both zygomatic arches with the thumbs. To palpate the ethmoid sinuses, press up against the bone above both eyes with the thumbs. No swelling or tenderness is expected. Tenderness may indicate sinusitis. Sinus infections can occasionally occur in young children.

Assessing the Mouth and Throat for Color, Function, and Signs of Abnormal Conditions

Equipment needed to examine the mouth and throat includes a tongue blade and penlight. Wear gloves when examining the mouth.

Inspection of the Mouth

Young children often need coaxing and simple explanations before they will cooperate with the mouth and throat examination. Most children readily show their teeth. If the child resists by clenching the teeth, gently separate them with a tongue blade. Mouth structures for inspection are illustrated in Figure 5–17.

LIPS

Inspect the lips for color, shape, symmetry, moisture, and lesions. The lips are normally symmetric without drying, cracking, or other lesions. Lip color is normally pink in White children and more bluish in darker-skinned children. Pale, cyanotic, or cherry-red lips indicate poor tissue perfusion caused by various conditions. Note any clefts or edema.

SAFETY ALERT!

Avoid examining the mouth if there are signs of respiratory distress, high fever, drooling, and intense apprehension. These may be signs of epiglottitis. Inspecting the mouth may trigger a total airway obstruction. (See Table 20–3 for more information.)

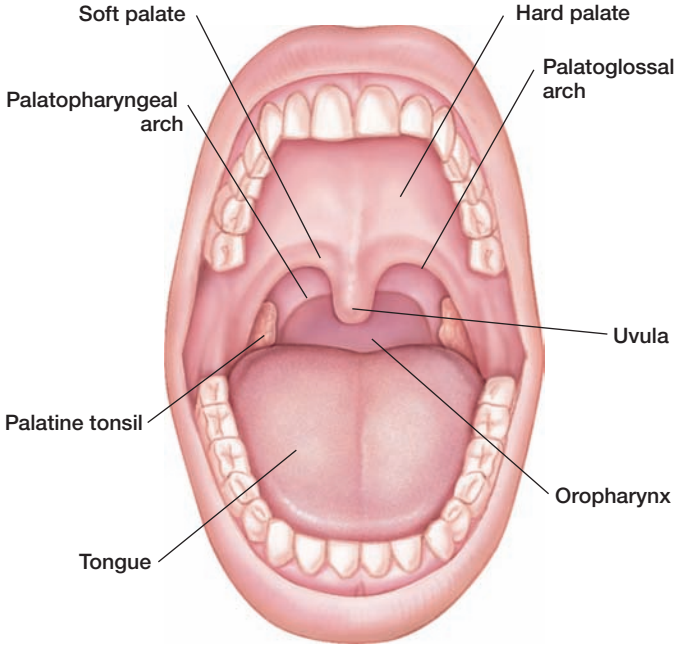

Figure 5–17 The structures of the mouth.

TEETH

Inspect and count the child's teeth. The timing of tooth eruption is often genetically determined, but it occurs in a regular sequence. See Figure 5–18 for the typical sequence of tooth eruption for both deciduous and permanent teeth.

Inspect the condition of the teeth, look for loose teeth, and note any spaces where teeth are missing. Note any dental care, braces, or orthodontic appliances. Compare empty tooth spaces with the child's developmental stage of tooth eruption. Once the permanent teeth have erupted, none should be missing. Teeth are normally white, without a flattened, mottled, or pitted appearance. Discolorations on the crown of a tooth may indicate caries. Discolorations on the tooth surface may be associated with some medications or excessive fluoride intake.

MOUTH ODORS

During inspection of the teeth, be alert to any abnormal odors that may indicate problems such as diabetic ketoacidosis, infection, or poor hygiene. Be alert for alcohol odors in older children that could signal substance abuse.

GUMS AND BUCCAL MUCOSA

Inspect the gums for color and adherence to the teeth. The gums are normally pink, with a stippled or dotted appearance. Use a tongue blade to help visualize the gums around the upper and lower molars. No raised or receding gum areas should be apparent around the teeth. When inflammation, swelling, or bleeding is observed, palpate the gums to detect tenderness. Inflammation and tenderness are associated with infection and poor nutrition. Hyperplasia may be associated with some medications, such as phenytoin.

Inspect the mucous membrane lining of the cheeks for color and moisture. The mucous membrane is usually pink, but patches of hyperpigmentation are commonly seen in darker-skinned children. The *Stensen duct*, the parotid gland opening, is opposite the upper second molar bilaterally. Normally pink, the duct opening becomes red when the child is infected with mumps. Small pink sucking pads can be present in infants. No areas of redness, swelling, or ulcerative lesions should be present.

TONGUE

Inspect the tongue for color, moistness, size, tremors, and lesions. The child's tongue is normally pink and moist, without a coating, and it fits easily into the mouth. A protuberant tongue is associated with various genetic conditions, such as Down syndrome. A pattern of gray, irregular borders that form a design (geographic tongue) is often normal, but it may be associated with fever, allergies, or drug reactions. Tremors are abnormal. A white adherent coating on an infant's tongue may be caused by thrush, a *Candida* infection (see Chapter 31).

Observe the mobility of the tongue by asking the child to touch the gums above the upper teeth with the tongue. This tongue movement is adequate to enunciate all speech sounds clearly. Ask the child to stick out the tongue and lift it so the underside of the tongue and the floor of the mouth can be inspected.

PALATE

Inspect the hard and soft palates to detect any clefts or masses or an unusually high arch. The palate is normally pink, dome shaped, and has no cleft. The uvula hangs freely from the soft palate. A high-arched palate can be associated with sucking difficulties in young infants.

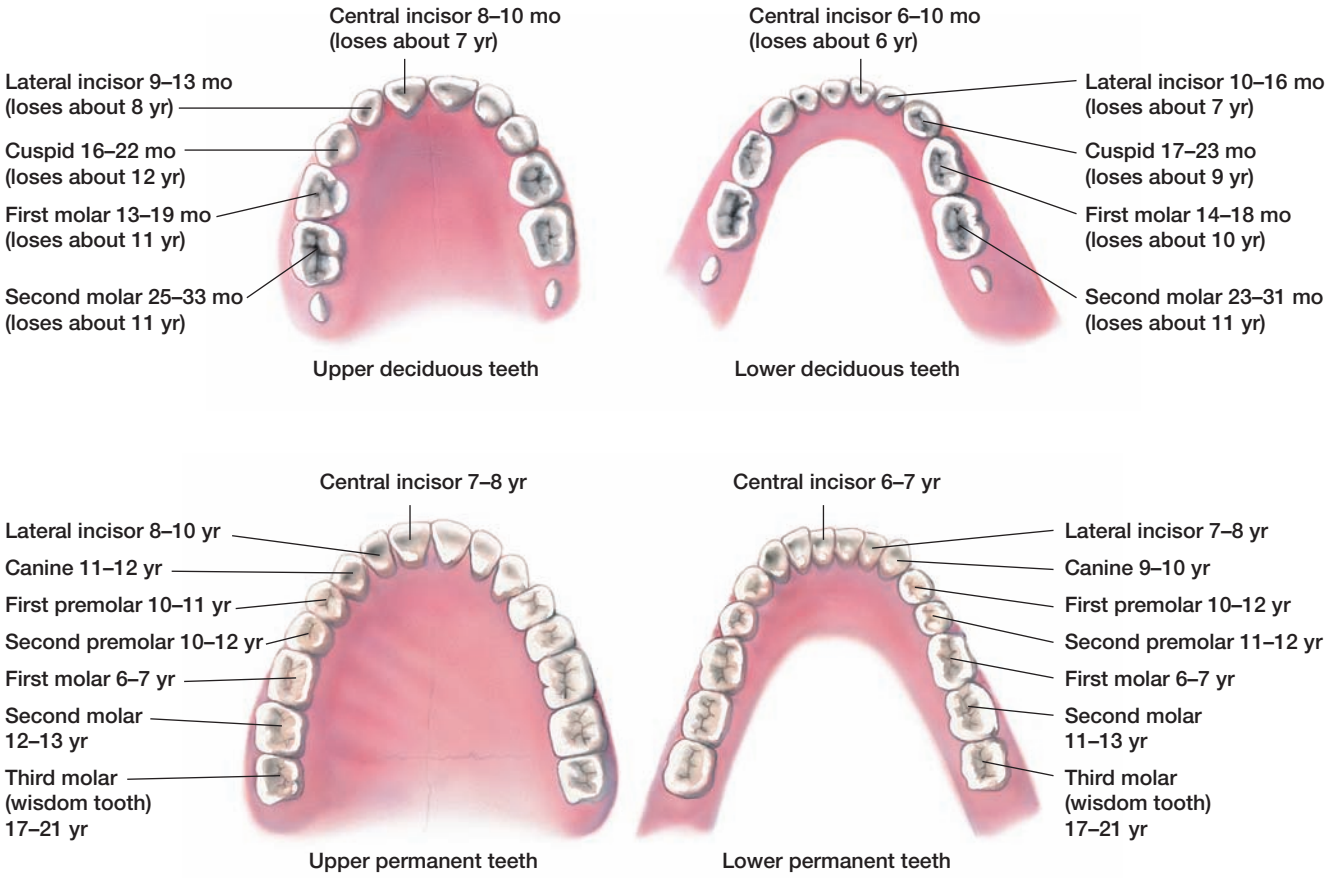

Figure 5–18 **Usual ages and sequence of tooth eruption for both deciduous and permanent teeth. The bottom deciduous teeth are shed before upper teeth, and bottom permanent teeth erupt first as well.**

Palpation of the Mouth Structures

Using gloves, palpate any masses seen in the mouth to determine their characteristics, such as size, shape, firmness, and tenderness. No masses should be found.

To assess the tongue's strength, while simultaneously testing the hypoglossal nerve (cranial nerve XII), place your index finger against the child's cheek and ask the child to push against your finger with the tongue. Some pressure against the finger is normally felt.

To palpate the palate, insert your gloved little finger, with the finger pad upward, into the mouth. While the infant sucks against your finger, palpate the entire palate. This procedure also tests the strength of the sucking reflex, innervated by the hypoglossal nerve (cranial nerve XII). No clefts should be palpated.

Inspection of the Throat

Use a flashlight to inspect the throat for color, swelling, lesions, and the condition of the tonsils. Ask the child to open the mouth wide and stick out the tongue. Use a tongue blade, if needed, to visualize the posterior pharynx. Moistening the tongue blade may decrease the child's tendency to gag. The throat is normally pink without lesions, drainage, or swelling. The epiglottis lies behind the tongue and is normally pink like the rest of the buccal mucosa. Swelling or bulging in the posterior pharynx may be associated with a peritonsillar abscess (see Chapter 19).

During childhood the tonsils are large in proportion to the size of the pharynx because lymphoid tissue grows fastest in early childhood. The tonsils should be pink without exudate, but crypts (fissures) may be present as a result of prior infections. The size of the tonsils can be graded as indicated in the *Pathophysiology Illustrated: Tonsil Size With Infection* diagram.

When using a tongue blade to see the throat and tonsils, the gag reflex may be triggered. A symmetric rising movement of the uvula should be observed as the child gags. The gag reflex is not often specifically tested in children.

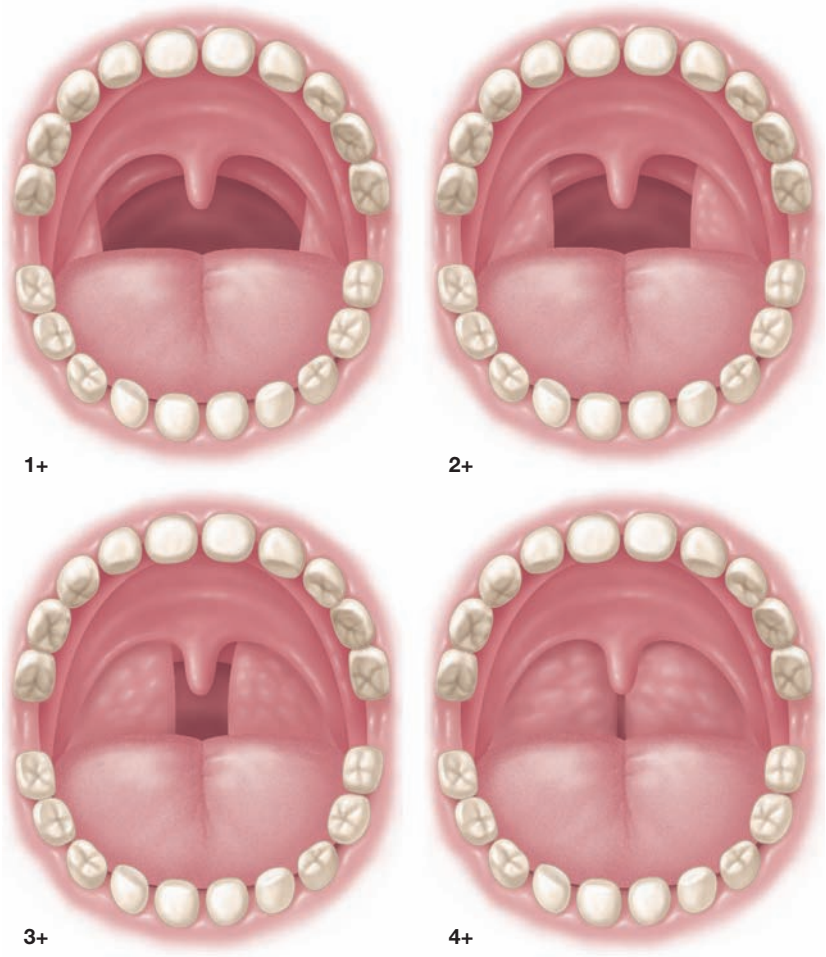
Assessing the Neck for Characteristics, Range of Motion, and Lymph Nodes

Inspection of the Neck

Inspect the neck for size, symmetry, swelling, and any abnormalities such as *webbing*, an extra fold of skin on each side of the neck. A short neck with skinfolds is normal for infants. The neck is normally symmetric without swelling. Swelling may be caused by local infections such as mumps or a congenital defect. The neck lengthens between 3 and 4 years of age. Webbing is commonly associated with Turner syndrome (see Chapter 30).

Infants develop head control by 2 months of age when the infant has enough neck strength to lift the head up and look around when lying on the stomach. A lack of head control can result from neurologic injury, such as an anoxic episode.

Pathophysiology Illustrated: **Tonsil Size With Infection**



Tonsil size can be graded from 1+ to 4+ in relation to how much of the airway is obstructed. Tonsil size of 1+ and 2+ is normal. Tonsil size of 3+ is common with infections such as strep throat. Tonsils that "kiss" or nearly touch each other (4+) significantly reduce the size of the airway.

Palpation of the Neck

Face the child and use your finger pads to simultaneously palpate both sides of the neck for lymph nodes, as well as the trachea and thyroid.

LYMPH NODES

To palpate the lymph nodes, slide your finger pads gently over the lymph node chains in the head and neck. One sequence is to palpate the lymph nodes in the occipital area, around the ears, under the jaw, and then the cervical chain in the neck (Figure 5–19). Firm, clearly defined, nontender, movable lymph nodes up to 1 cm (½ in.) in diameter are common in young children. Enlarged, firm, warm, tender lymph nodes indicate a local infection.

TRACHEA

To palpate the trachea, place your thumb and forefinger on each side of the trachea near the chin and slowly slide down the trachea to determine its position and to detect the presence of any masses. The trachea is normally in the midline of the neck. It is difficult to palpate in children less than 3 years of age because of their short necks. Any shift to the right or left of midline may indicate a tumor or a collapsed lung.

THYROID

As the fingers slide over the trachea in the lower neck, attempt to feel the isthmus of the thyroid, a band of glandular tissue crossing over the trachea. The lobes of the thyroid wrap behind the trachea and are normally covered by the sternocleidomastoid muscle. Because of the anatomic position of the thyroid, its lobes are not usually palpable in the child unless they are enlarged.

Range of Motion Assessment

To test the neck's range of motion, ask the child to touch the chin to each shoulder and to the chest and then to look at the ceiling. Move a light or toy in all four directions when assessing infants. Children should freely move the neck and head in all four directions without pain.

When the child is unable to move the head voluntarily in all directions, passively move the child's neck through the expected range of motion. Limited horizontal range of motion may be a sign of **torticollis**, persistent head tilting. Torticollis results from a birth injury to the sternocleidomastoid muscle or from unilateral vision or hearing impairment. Pain with flexion of the neck toward the chest (Brudzinski sign) may indicate meningitis (see Chapter 27).

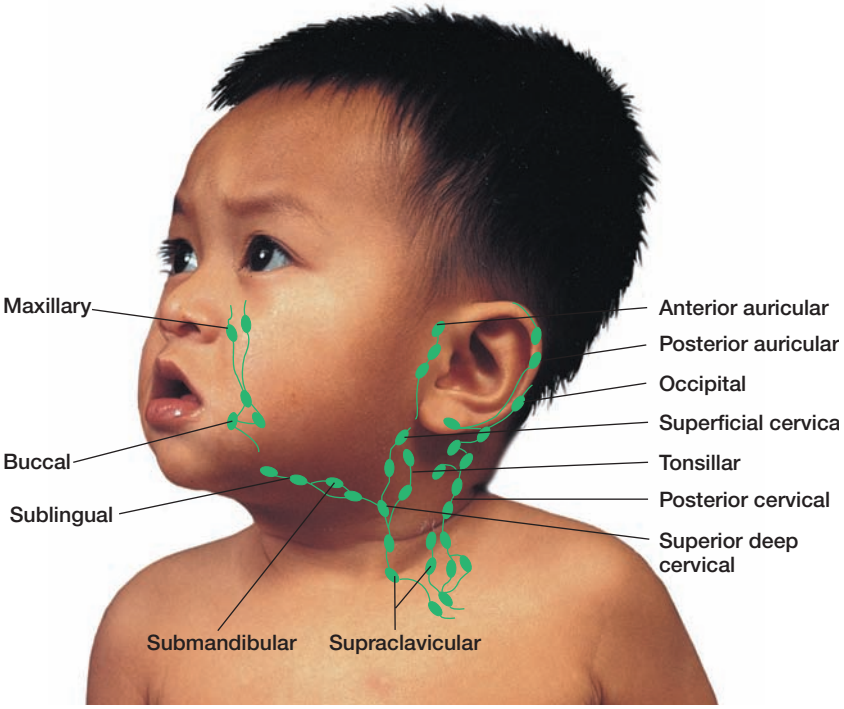


Figure 5–19 Palpate for enlarged lymph nodes in front of and behind the ears, under the jaw, in the occipital area, and in the cervical chain of the neck.

Assessing the Chest for Shape, Movement, Respiratory Effort, and Lung Function

Examination of the chest includes the following procedures: inspecting the size and shape of the chest, palpating chest movement that occurs during respiration, observing the effort of breathing, and auscultating breath sounds. A stethoscope is needed.

Inspection of the Chest

The chest skeleton provides most of the landmarks used to describe the location of findings during examination of the chest, lungs, and heart. The intercostal spaces are the horizontal markers. The sternum and spine are the vertical landmarks. When both a horizontal and a vertical landmark are used, the location of findings can be precisely described on the right or left side of the child's chest (Figures 5–20 and 5–21). The distance between the finding and the center of the sternum (midsternal line) or the midspinal line can be measured with a ruler.

Figure 5–20 Ribs and intercostal spaces are the horizontal landmarks used to describe the location of chest findings. *A,* To determine the rib number on the anterior chest, palpate down from the top of the sternum until a horizontal ridge, the angle of Louis, is felt. Directly to the right and left of that ridge is the second rib. The second intercostal space is immediately below the second rib. Ribs 3–12 and the corresponding intercostal spaces can be counted as the fingers move toward the abdomen. *B,* To determine the rib number on the posterior chest, find the protruding spinal process of the seventh cervical vertebra at the shoulder level. The next spinal process belongs to the first thoracic vertebra, which attaches to the first rib.

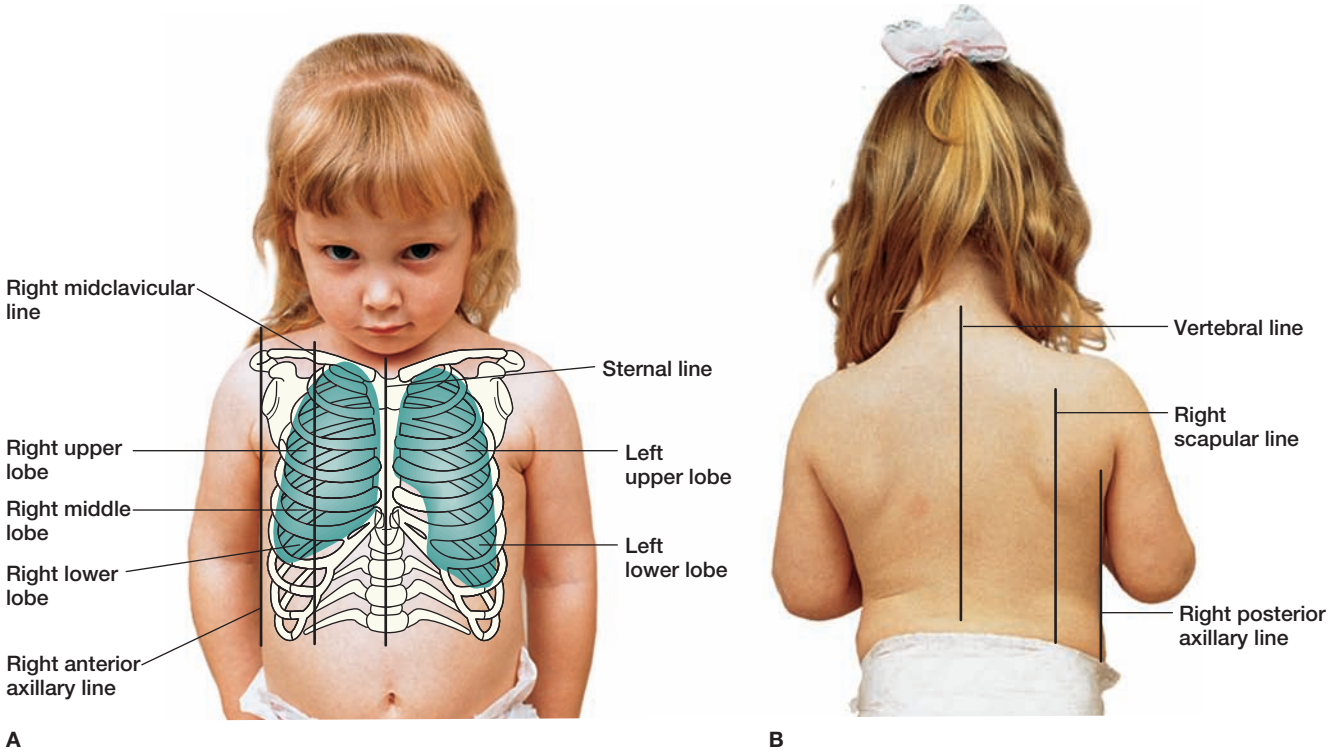

Figure 5–21 **The sternum and spine are the vertical landmarks used to describe the anatomic location of findings. Imaginary vertical lines, parallel to the midsternal and spinal lines, are used to further describe the location of findings. The midclavicular line is through the middle of the clavicle. The midaxillary line is through the middle of the axilla. The scapular line is through the bottom angle of the scapula. *A,* Anterior vertical landmarks. *B,* Posterior vertical landmarks.**

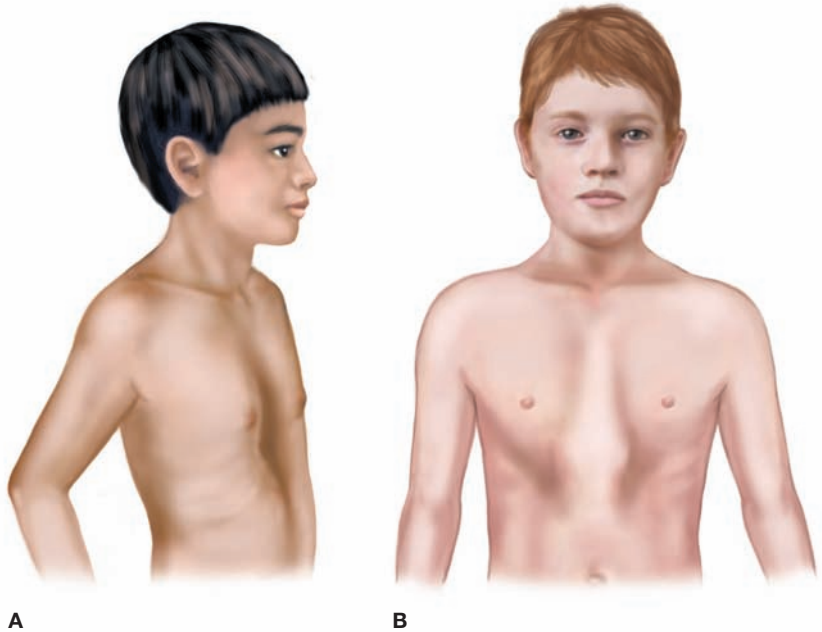

Figure 5–22 **Abnormal chest shape. *A,* Pectus carinatum (funnel chest) in which the lower portion of the sternum is depressed, decreasing the anteroposterior diameter. *B,* Pectus excavatum (pigeon chest) in which the sternum protrudes, increasing the anteroposterior diameter.**

Position the child on the parent's lap or on the examining table with all clothing above the waist removed to inspect the chest. The thoracic muscles and subcutaneous tissue are less developed in children than in adolescents and adults, so the chest wall is thinner and the rib cage is more prominent unless obesity is present.

SHAPE OF THE CHEST

Inspect the chest for any irregularities in shape. In infants, the chest is rounded with the anteroposterior diameter approximately equal to the lateral diameter. By 2 years of age, the chest becomes more oval with growth, and the lateral diameter is greater than the anteroposterior diameter. If a child over 2 years of age has a rounded chest, a chronic obstructive lung condition such as asthma or cystic fibrosis may be present.

An abnormal chest shape may result from structural deformities, such as pectus carinatum and pectus excavatum (Figure 5–22). Scoliosis, curvature of the spine, causes a lateral deviation of the chest (see Chapter 29). A shield-shaped chest, unusually broad with widely spaced nipples, may be associated with Turner syndrome (see Chapter 30).

CHEST MOVEMENT AND RESPIRATORY EFFORT

The diaphragm is the primary muscle used for ventilation by infants and young children. As the thoracic muscles develop, they become the primary ventilation muscles. Chest movement with breathing is normally symmetric bilaterally. On inspiration, the chest and abdomen should rise simultaneously and fall on expiration. The chest movement of infants and young children is less pronounced than the abdominal movement. Asymmetric chest rise is associated with a collapsed lung.

The thoracic muscles serve as accessory respiratory muscles in infants and young children. When the child has a condition that causes a partial airway obstruction, the accessory muscles are used for inspiration and retractions are seen. **Retractions**, visible depression of tissue between the ribs of the chest wall with each inspiration, indicate an increased work of breathing and often respiratory distress (see *Pathophysiology Illustrated: Retraction Sites* in Chapter 20).

RESPIRATORY RATE

Because infants and young children use the diaphragm as the primary breathing muscle, observe or feel the rise and fall of the abdomen to count the respiratory rate in children under age 6 years. Table 5–9 gives the normal respiratory rates for each age group.

Growth and Development **Respiratory Rate**

Infants and children have a faster respiratory rate than adults because of their higher metabolic rate and oxygen requirement. Young children are also unable to increase the depth of respirations because the intercostal muscles are inadequately developed to lift the chest wall and increase intrathoracic volume (Chameides, Samson, Schexnayder, et al., 2011, p. 42).

To get the most accurate reading of a young infant's respiratory rate, wait until the baby is sleeping or resting quietly. Use the stethoscope to auscultate the rate or place your hand on the abdomen. Count the number of breaths for an entire minute because newborns and young infants can have irregular respirations.

Tachypnea, an increased respiratory rate, occurs in response to excitement, fear, respiratory distress, fever, and other conditions that increase oxygen needs. A sustained respiratory rate higher than normal for age is an important sign of respiratory distress. The child is at risk for developing hypoxemia if treatment is not started. An abnormally slow respiratory rate occurs in response to respiratory failure.

TABLE 5–9 Normal Respiratory Rate Ranges by Age

AGE	RESPIRATORY RATE PER MINUTE
Newborn	30–55
1 year	25–40
3 years	20–30
6 years	16–22
10 years	16–20
17 years	12–20

Palpation of the Chest

Palpation is used to evaluate chest movement, respiratory effort, deformities of the chest wall, and tactile fremitus.

CHEST WALL

To palpate the chest motion with respiration, place your palms and outspread fingers on each side of the child's chest. Confirm the bilateral symmetry of chest motion. Use your finger pads to palpate any depressions, bulges, or unusual chest wall shape that might indicate abnormal findings such as tenderness, cysts, other growths, crepitus, or fractures. None should be found. **Crepitus**, a crinkly sensation palpated on the chest surface, is caused by air escaping into the subcutaneous tissues. It often indicates a serious injury to the upper or lower airway.

TACTILE FREMITUS

To palpate **tactile fremitus**, vibrations produced by crying and talking, place the palms of your hands on each side of the chest. Ask the child to repeat a series of words or numbers, such as *puppy dog*, *kitty cat*, or *ice cream*. As the child repeats the words, move your hands systematically over the anterior and posterior chest, comparing the quality of vibrations side to side. The vibration or tingling sensation is normally palpated over the entire chest. Decreased sensations indicate that air is trapped in the lungs, as occurs with asthma.

Auscultation of the Chest

Auscultate the chest with a stethoscope to assess the quality and characteristics of breath sounds, to identify abnormal breath sounds, and to evaluate vocal resonance. Use an infant or pediatric stethoscope when available to help localize any unexpected breath sounds. Use the stethoscope diaphragm because it transmits the high-pitched breath sounds better.

BREATH SOUNDS

Evaluate the quality and characteristics of breath sounds over the entire chest, comparing sounds between the sides. Select a routine sequence for auscultating the entire chest so assessment of all lobes of the lungs will be consistently performed. Figure 5–23 shows one suggested chest auscultation sequence. Listen to an entire inspiratory and expiratory phase at each spot on the chest before moving to the next site.

Growth and Development **Auscultating Breath Sounds**

Auscultation of breath sounds is difficult when an infant is crying. If the infant continues to cry after giving a pacifier, bottle, or toy, all is not lost. At the end of each cry the infant takes a deep breath, which you can use to assess breath sounds, vocal resonance, and tactile fremitus.

Encourage toddlers and preschoolers to take deep breaths by blowing a pinwheel or a piece of tissue off your hand. This may enhance auscultation of subtle wheezes that occur at the end of expiration.

When trying to encourage the child to breathe normally while auscultating the chest, use suggestive language to increase cooperation: "You certainly are good at breathing slowly. Have you been practicing?" The child will often deepen and slow the breathing pattern as you praise the effort.

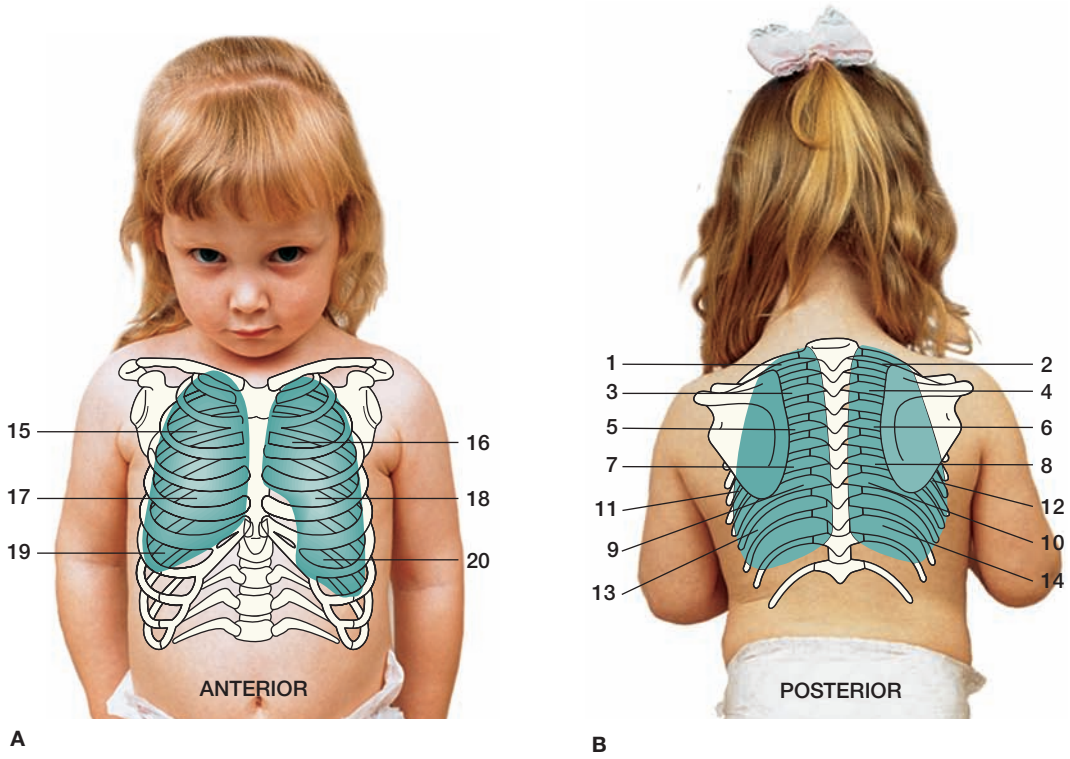

Figure 5–23 One sequence for auscultation of the chest.

Three types of normal breath sounds are usually heard when the chest is auscultated.

- *Vesicular breath sounds* are low-pitched, swishing, soft, short expiratory sounds usually heard in older children but not in infants and young children.
- *Bronchovesicular breath sounds* are medium-pitched, hollow, blowing sounds heard equally on inspiration and expiration in all age groups.
- *Bronchial/tracheal breath sounds* are hollow and higher pitched than vesicular breath sounds.

Breath sounds normally have equal intensity, pitch, and rhythm bilaterally. Absent or diminished breath sounds may indicate a pneumothorax or airway obstruction.

Clinical Tip

Infants and young children have a thin chest wall because of immature muscle development. The breath sounds of one lung are heard over the entire chest. It takes practice to accurately identify absent or diminished breath sounds in infants and young children. Because the distance between the lungs is greatest at the apices and midaxillary areas in young children, these sites are best for identifying absent or diminished breath sounds. Carefully auscultate, comparing the quality of breath sounds heard bilaterally.

VOCAL RESONANCE

Auscultate to evaluate **vocal resonance**, the transmission of voice sounds through the chest. Have the child repeat a series of words, such as *apple*, *banana*, and *cereal*. Use the stethoscope to auscultate the chest, comparing the quality of sounds from side to side and over the entire chest. Voice sounds, with words and syllables muffled and indistinct, are normally heard throughout the chest.

If voice sounds are absent or more muffled than usual, an airway obstruction condition such as asthma may be present. If voice sounds are more distinct, louder, or clearer, a lung consolidation condition such as pneumonia may be present.

ABNORMAL BREATH SOUNDS

Abnormal breath sounds, also called adventitious sounds, generally indicate disease. Examples of abnormal breath sounds are crackles, rhonchi (sonorous wheezing), and sibilant **wheezing** (a noise resulting from the passage of air through mucus or fluids in a narrowed lower airway). To further assess abnormal breath sounds, identify the following:

- Location—for example, side of body and lung lobe(s)
- Presence during part or entire phase of inspiration or expiration
- Change in character or disappearance when the child coughs or changes position

It takes practice to routinely identify these adventitious sounds. Table 5–10 describes adventitious sounds.

ABNORMAL VOICE SOUNDS

Observe the quality of the voice and other audible sounds. A cough is a reflexive clearing of the airway associated with a respiratory infection. Hoarseness is associated with inflammation of the larynx.

Percussion of the Chest

Percussion of the chest may be performed by an experienced examiner to assess the resonance of the lungs and size of underlying organs, such as the heart. Radiographic examination is commonly used for this evaluation.

TABLE 5–10 Description of Selected Adventitious Sounds and Their Cause

TYPE	DESCRIPTION	CAUSE
Fine crackles	High-pitched, discrete, noncontinuous sound heard at end of inspiration; does not clear with coughing *(Rub pieces of hair together beside your ear to duplicate the sound.)*	Air passing through watery secretions in the smaller airways (alveoli and bronchioles)
Coarse crackles	Loud, lower pitched, more moist or bubbly sound heard during inspiration; does not clear by coughing	Air passing through thicker secretions in the airway
Sibilant wheezing	Higher pitched, musical, squeaking, or hissing noise usually heard continuously during inspiration or expiration, but generally louder on expiration; does not clear with coughing	Air passing through mucus or fluids in a narrowed lower airway (bronchioles) as with asthma
Rhonchi (sonorous wheezing)	Coarse, low-pitched sound like a snore, heard during inspiration or expiration; may clear with coughing	Air passing through thick secretions that partially obstruct the larger bronchi and trachea
Stridor	High-pitched, piercing sound most often heard during inspiration without a stethoscope	Whistling sound as air passes through a narrowed trachea and larynx, associated with croup

Clinical Reasoning **Assessing a Child With Bronchiolitis**

Aliyah, 6 months old, is brought by her mother and father to the emergency department. She is an emergency admission from the local pediatrician's office with a diagnosis of bronchiolitis. As Aliyah's nurse, you are responsible for assessing her condition after she arrives on the pediatric nursing unit.

What procedures are used to perform a physical examination on a 6-month-old? Identify all the components of the physical assessment used to detect signs of respiratory difficulty.

Assessing the Breasts

Inspection of the Breasts

The nipples of prepubertal boys and girls are symmetrically located near the midclavicular line at the fourth to sixth ribs. The areolae are normally round and more darkly pigmented than the surrounding skin. Inspect the anterior chest for other dark spots that may indicate *supernumerary nipples*, small, undeveloped nipples and areolae that may be mistaken for moles. Their presence may be associated with congenital renal or cardiac anomalies.

See the section later in this chapter for a discussion of breast development with puberty.

Palpation of the Breasts

Boys and girls have no palpable breast tissue before puberty. Palpate the developing breasts of female adolescents for abnormal masses or hard nodules. With the girl lying down, use a concentric or vertical stripe pattern covering all areas of each breast, including the axilla, areola, and the nipple. Gently squeeze the nipples for discharge. Breast tissue normally feels dense, firm, and elastic. Any mass needs further evaluation.

During adolescence, the majority of boys have *gynecomastia*, unilateral or bilateral breast enlargement. It is often most noticeable around 14 years of age and commonly disappears by the time of full sexual maturity. Palpate the tissue to differentiate actual breast tissue from fatty tissue in the pectoral area, and to detect any masses.

Assessing the Heart for Heart Sounds and Function

A stethoscope and sphygmomanometer are needed to assess the heart.

Inspection of the Precordium

Begin the heart examination by inspecting the anterior chest (precordium). Place the child in a reclining or semi-Fowler position, either on the parent's lap or on the examining table. Inspect the shape and symmetry of the anterior chest from the front and side views. Asymmetry and bulging of the left side of the chest wall may indicate an enlarged heart. Observe for any chest movement associated with the heart's contraction. A *heave*, an obvious lifting of the chest wall during contraction, may indicate an enlarged heart.

Palpation of the Precordium

Lightly place the surface of your fingers together on the chest wall to systematically palpate the precordium for any pulsations, heaves, or vibrations. Palpating with minimal pressure increases the chance of detecting abnormal findings.

The **apical impulse**, the point of maximum intensity, is located where the left ventricle taps the chest wall during contraction. The apical impulse is sometimes seen on the anterior chest wall of thin children, but it is normally felt as a slight tap against one fingertip. Use the topographic landmarks of the chest to describe its location (see Figures 5–20 and 5–21).

Growth and Development

The location of the apical impulse changes as the child's rib cage grows. In children under 7 years old, it is located in the fourth intercostal space just medial to the left midclavicular line. In children over 7 years old, it is located in the fifth intercostal space at the left midclavicular line.

TABLE 5–11 Normal Heart Rates for Children of Different Ages

AGE	HEART RATE RANGE (BEATS/MIN)	AVERAGE HEART RATE (BEATS/MIN)
Newborns	100–170	120
Infants to 2 years	80–130	110
2–6 years	70–120	100
6–10 years	70–110	90
10–16 years	60–100	85

Any other sensation palpated is usually abnormal. A *lift* is the sensation of the heart lifting up against the chest wall. It may be associated with an enlarged heart or a heart contracting with extra force. A **thrill** is a vibration that may feel like a cat's purr. It is caused by turbulent blood flow from a defective heart valve and a heart murmur. If present, the thrill is palpated in the right or left second intercostal space. To describe the thrill location, use the topographic landmarks of the chest (see Figures 5–20 and 5–21) and estimate the diameter of the thrill palpated.

Heart Rate and Rhythm

The apical heart rate can be counted at the site of the apical impulse either by palpation or by auscultation. Count the apical rate for 1 minute in infants and in children who have an irregular rhythm. The brachial or radial pulse rate should be the same as the auscultated apical heart rate. Table 5–11 gives normal heart rates in children of different ages.

Clinical Tip

The child's heart rate varies with age, decreasing as the child grows older. The heart rate increases in response to exercise, excitement, anxiety, and fever. Such stresses increase the child's metabolic rate, creating a simultaneous need for more oxygen. Children respond to the need for more oxygen by increasing their heart rate, a response called *sinus tachycardia.*

Listen carefully to the heart rate rhythm. Children often have a normal cycle of irregular rhythm associated with respiration called *sinus arrhythmia* in which the child's heart rate is faster on inspiration and slower on expiration. When any rhythm irregularity is detected, ask the child to take a breath and hold it while you listen to the heart rate. The rhythm should become regular during inspiration and expiration. Other rhythm irregularities are abnormal (see Chapter 21).

Auscultation of the Heart

Auscultation is also used to assess the characteristics of the heart sounds and to detect abnormal heart sounds. Use the bell of the stethoscope to detect these lower-pitched sounds.

Auscultate the heart with the child first when sitting and then reclining. This will help detect differences in heart sounds caused by a change in the child's position or by a change in the position of the heart near the chest wall. If differences in heart sounds are detected with a position change, place the child in the left lateral recumbent position and auscultate again.

IDENTIFYING HEART SOUNDS

Heart sounds result from the closure of the valves and any vibration or turbulence of blood produced by that valve closure. Two primary sounds, S_1 and S_2, are heard when the chest is auscultated.

- S_1, the first heart sound, is produced by closure of the tricuspid and mitral valves at the beginning of ventricular contraction. The two valves close almost simultaneously to prevent the back flow of blood into the atria.
- S_2, the second heart sound, is produced by the closure of the aortic and pulmonic valves. Once blood has reached the pulmonic and aortic arteries, the valves close to prevent back flow into the ventricles.

Clinical Tip

To distinguish between S_1 and S_2 heart sounds in each listening area, palpate the carotid pulse while auscultating the heart. The heart sound heard simultaneously with the pulsation is S_1.

Sound is easily transmitted in liquid, and it travels best in the direction of blood flow. Auscultate heart sounds at specific areas on the chest wall in the direction of blood flow, just beyond the valve (Figure 5–24). The sounds produced by the heart valves or blood turbulence are heard throughout the chest in thin infants and children. Both S_1 and S_2 can be heard in all listening areas.

Auscultate heart sounds for quality (distinct versus muffled) and intensity (loud versus soft). First, distinguish between S_1 and S_2 in each listening area. Heart sounds are usually distinct and crisp in children because of their thin chest wall. Muffled or indistinct sounds may indicate a heart defect or congestive heart failure. Document the area where heart sounds are heard the best. Table 5–12 and Figure 5–24 review the location where each sound is normally best heard for assessment of quality and intensity. If an extra heart sound is heard (e.g., a murmur), auscultate the heart in the sitting, reclining, and left lateral recumbent positions to detect any differences associated with position change.

SPLITTING OF THE HEART SOUNDS

After distinguishing the first and second heart sounds, try to detect a split S_2. When the child takes a deep breath more blood returns to the right ventricle than the left ventricle, causing the pulmonic valve to close a fraction of a second later than the aortic valve; this is called *physiologic splitting*. Auscultate over the pulmonic area while the child breathes normally and then while the child takes a deep breath. The S_2 splitting may be heard after a deep breath, and then with regular breathing, it is heard as a

TABLE 5–12 Listening Sites for Auscultation of the Quality and Intensity of Heart Sounds

HEART SOUND	SITES WHERE BEST HEARD	SITES WHERE HEARD SOFTLY
S_1	Apex of the heart Tricuspid area Mitral area	Base of the heart Aortic area Pulmonic area
S_2	Base of the heart Aortic area Pulmonic area	Apex of the heart Tricuspid area Mitral area
Physiologic splitting	Pulmonic area	
S_3	Mitral area	

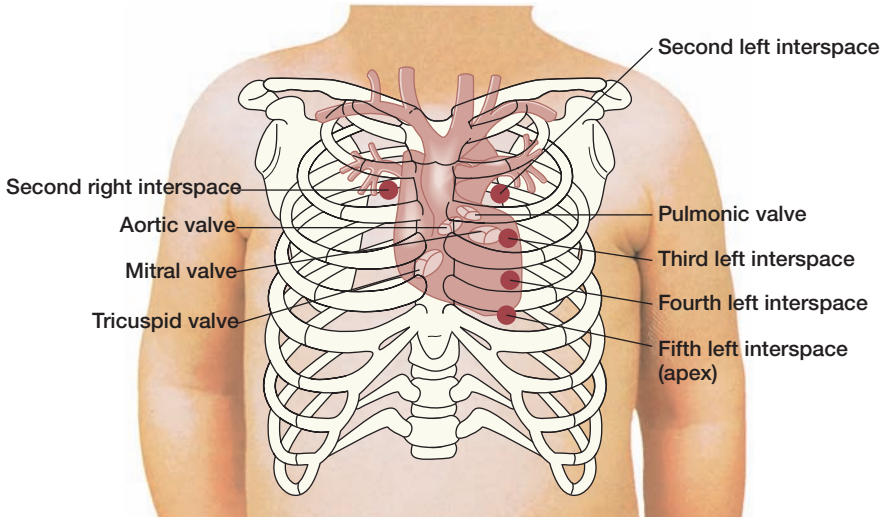

Figure 5–24 **Remember that sound travels in the direction of blood flow when auscultating heart sounds. Rather than listen for heart sounds over each heart valve, auscultate heart sounds at specific areas on the chest wall away from the valve itself. These areas are named for the valve producing the sound. *Aortic*: second right intercostal space near the sternum. *Pulmonic*: second left intercostal space near the sternum. *Tricuspid*: fifth right or left intercostal space near the sternum. *Mitral* (apical): in infants—third or fourth intercostal space, just left of the left midclavicular line; in children—fifth intercostal space at the left midclavicular line.**

single sound. If S_2 splitting does not vary with normal and deep respirations, it is called *fixed splitting*, which is an abnormal finding associated with an atrial septal defect in the heart.

EXTRA HEART SOUNDS

A third heart sound, S_3, is occasionally heard in children as a normal finding. The S_3 heart sound is caused when blood rushes through the mitral valve and splashes into the left ventricle. It is heard in diastole, just after S_2. It is distinguished from a split S_2 because it is louder in the mitral area than in the pulmonic area.

Murmurs, or abnormal heart sounds, are sometimes auscultated. These sounds are produced by blood passing through a defective valve, great vessel, or other heart structure. Some murmurs are benign or innocent, whereas others may indicate a congenital heart defect. Consult an experienced examiner to distinguish between murmurs.

It takes practice to hear murmurs in children. Often, murmurs must be very loud to be detected. For softer murmurs, normal heart sounds must be distinguished before an extra sound is recognized. When a murmur is detected, define the characteristics of the extra sound, including:

- *Intensity.* How loud is it? Can a thrill also be palpated? (See *Clinical Tip*.)
- *Location.* Where is the murmur the loudest? Identify the listening area and precise topographic landmarks. Is the child sitting or lying down? Do the murmur characteristics change when the child changes position?
- *Radiation or transmission.* Is the sound transmitted over a larger than expected area of the chest, to the axilla, or to the back?
- *Timing.* Is the murmur heard best after S_1 or S_2? Is it heard during the entire phase between S_1 and S_2?
- *Quality.* Describe what the murmur sounds like—for example, machine-like, musical, or blowing.

Clinical Tip

Following are guidelines for grading the intensity of a murmur:

Intensity	Description
Grade I	Barely heard in a quiet room
Grade II	Quiet, but clearly heard
Grade III	Moderately loud; no thrill palpated
Grade IV	Loud; a thrill is usually palpated
Grade V	Very loud, heard when the stethoscope is barely on the chest wall; a thrill is easily palpated
Grade VI	Heard without the stethoscope in direct contact with the chest wall; a thrill is palpated

VENOUS HUM

A venous hum is caused by turbulent blood flow in the internal jugular veins. Auscultate over the supraclavicular fossa above the middle of the clavicle or over the upper anterior chest with the bell of the stethoscope. A venous hum is heard as a continuous low-pitched hum throughout the cardiac cycle. It is heard louder during diastole and does not change with respirations. It may be quieted when the child turns the neck, lies down, or when the jugular vein is occluded. A venous hum may be associated with anemia, but it has no pathologic significance.

Completing the Heart Examination

A complete assessment of heart function also includes palpating the pulses, measuring the blood pressure, and evaluating signs from other systems.

PALPATION OF THE PULSES

Palpate the characteristics of the pulses in the extremities to assess the circulation. The technique and sites for palpating the pulse are

the same as those used for adults. Evaluate the pulsation for rate, regularity of rhythm, and strength in each extremity and compare your findings bilaterally. Palpate the femoral pulses, which should be as strong as the brachial pulsations. A weaker femoral pulse is associated with coarctation of the aorta.

Growth and Development

Infants have a low systolic blood pressure, and detecting the distal pulses is often difficult. Use the brachial artery in the arms and the popliteal or femoral artery in the legs to evaluate the pulses. The radial and distal tibial pulses are normally palpated easily in older children.

BLOOD PRESSURE

To assess the blood pressure, wait until the child has been seated and quiet for 3 to 5 minutes. To obtain the most accurate reading, select an appropriately sized cuff for the extremity selected. Use the right arm when possible, as this arm was used for development of blood pressure standards. See the *Clinical Skills Manual* SKILLS for the technique for obtaining the blood pressure in children.

With the cuff snugly wrapped around the arm, hold the arm with the antecubital fossa at the level of the heart. Use the bell of the stethoscope to hear softer Korotkoff sounds. The systolic reading is the onset of Korotkoff sounds. The diastolic reading is the fifth Korotkoff sound (Lande, 2016).

Measure the blood pressure twice and average the two readings. Compare the systolic and diastolic readings with the standard blood pressure values by age, gender, and height percentilein Appendix B. A blood pressure value at the 50th percentile for the child's age, gender, and height percentile is considered the midpoint of the normal blood pressure range. A systolic or diastolic reading at or above the 95th percentile indicates hypertension.

For any child with a potential heart condition, obtain a blood pressure reading in both an arm and a leg and compare the readings. The blood pressure in the leg should be 10 to 20 mmHg higher than the arm reading (Bernstein, 2016). If the reading in the leg is lower than that in the arm, coarctation of the aorta may be present.

OTHER SIGNS

Skin color, capillary refill, and respiratory effort are additional elements of a complete heart examination. Cyanosis is most commonly associated with a congenital heart defect in children. A capillary refill time of greater than 2 seconds indicates poor perfusion of the tissues. Signs of respiratory distress (tachypnea, flaring, and retractions) may be associated with the child's attempts to compensate for hypoxemia caused by a congenital heart defect.

Assessing the Abdomen for Shape, Bowel Sounds, and Underlying Organs

The location of underlying organs and structures of the abdomen must be considered when the abdomen is examined. The abdomen is commonly divided by imaginary lines into quadrants for the purpose of identifying underlying structures (Figure 5–25). A stethoscope is needed to examine the abdomen. Perform inspection and auscultation before palpation and percussion because touching the abdomen may change the characteristics of bowel sounds.

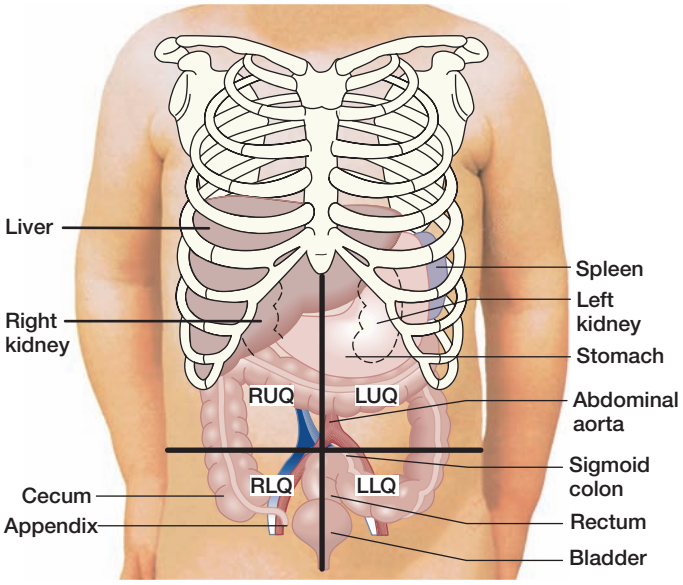

Figure 5–25 Topographic landmarks of the abdomen. The abdomen is commonly divided by imaginary lines into quadrants for the purpose of identifying underlying structures.

Inspection of the Abdomen

Begin the examination of the abdomen by inspecting the shape and contour, condition of the umbilicus and rectus muscle, and abdominal movement. Inspect the shape of the abdomen from the front and side with good lighting to identify an abnormal contour. The child's abdomen is normally symmetric and rounded or flat when the child is supine. A scaphoid or sunken abdomen is abnormal and may indicate dehydration.

After a newborn's umbilical stump falls off, inspect the umbilicus for continued drainage, which may indicate an infection or a granuloma. Inspect the umbilicus in infants and toddlers because these children often have an *umbilical hernia*, a protrusion of abdominal contents through an open umbilical muscle ring.

Inspect the abdominal wall for any depression or bulging at midline above or below the umbilicus, indicating separation of the rectus abdominis muscles. The depression may be up to 5 cm (2 in.) wide. Measure the width of the separation to monitor change over time. As abdominal muscle strength develops, the separation usually becomes less prominent. However, the splitting may persist if congenital muscle weakness is present.

ABDOMINAL MOVEMENT

Infants and children up to 6 years of age breathe with the diaphragm. The abdomen rises simultaneously with the chest during inspiration and falls with expiration. Other abdominal movements such as peristaltic waves are abnormal. **Peristaltic waves** are visible rhythmic contractions of the intestinal wall smooth muscle, which moves food through the digestive tract. Their presence generally indicates an intestinal obstruction, such as pyloric stenosis (see Chapter 25).

Auscultation of the Abdomen

To evaluate bowel sounds, auscultate the abdomen with the diaphragm of the stethoscope. Bowel sounds normally occur every 10 to 30 seconds. They have a high-pitched, tinkling, metallic quality. Loud gurgling (borborygmi) is heard when the child is hungry. Listen in each quadrant long enough to hear at least one

bowel sound. Before determining that bowel sounds are absent, auscultate at least 5 minutes in each quadrant. Absence of bowel sounds may indicate peritonitis or a paralytic ileus. Hyperactive bowel sounds may indicate gastroenteritis or a bowel obstruction.

Next, auscultate over the abdominal aorta and the renal arteries for a vascular hum or murmur. No murmur should be heard. A murmur may indicate a narrowed or defective artery.

Percussion of the Abdomen

Indirect percussion is often used by experienced examiners to evaluate borders and sizes of abdominal organs and masses while the child is supine. To perform indirect percussion, lay the middle finger of your nondominant hand on the child's abdomen, keeping your other fingers off the abdomen. With a springlike motion, use the fingertip from your other hand to tap the finger resting on the abdomen. Listen for the tone to detect underlying structures. Dullness is found over the liver, spleen, and full bladder. Tympany is found over the stomach or the intestines when an obstruction is present. Tympany may be found over areas beyond the stomach in infants because of air swallowing. A resonant tone may be heard over other areas.

Palpation of the Abdomen

Both light and deep palpation are used to examine the abdominal organs and to detect any masses. *Light palpation* is used to evaluate the tenseness of the abdomen (how soft or hard it is), the liver, the presence of any tenderness or masses, and any defects in the abdominal wall. *Deep palpation* is used to detect masses, define their shape and consistency, and identify abdominal tenderness.

Perform the abdominal examination when the child is calm and cooperative to get the best assessment. To begin palpation, position the child supine with knees flexed. Stand beside the child and place your warmed fingertips across the child's abdomen. Organs and other masses are more easily palpated when the abdominal wall is relaxed. Watch the child's face during palpation for signs of pain (e.g., a grimace or constriction of the pupils).

Growth and Development **Abdominal Assessment**

Infants and toddlers often feel more secure for the abdominal assessment when lying supine across both the parent's and the examiner's laps. A bottle, pacifier, or toy may distract the child and improve cooperation for the examination.

When examining the child, use suggestive words to help the child relax the abdomen. "How soft will your tummy get when my hand feels it? Does it get softer than this? Yes. See, it softens as you breathe out. Will it also be softer here?" The child learns to relax the abdomen and is challenged to do it better.

When a child is ticklish, use a firm touch and do not pretend to tickle the child at any point in the examination. Alternatively, put the child's hand on the abdomen and place your hand over the child's. Let your fingertips slide over to touch the abdomen. The child has a sense of being in control, and you may be able to palpate directly.

Older children may need distraction, especially when abdominal tenderness and guarding are present. Have the child perform a task that requires some concentration, such as pressing the hands together or pulling locked hands apart.

LIGHT PALPATION

For light palpation, use a superficial, gentle touch that slightly depresses the abdomen. Usually, the abdomen feels soft and no tenderness is detected. Palpate any bulging along the abdominal wall, especially along the rectus muscle and umbilical ring, which could indicate a hernia. If an umbilical hernia is present, measure the diameter of the muscular ring rather than the protrusion. The muscle ring normally becomes smaller and closes by 4 years of age.

Locate and lightly palpate the lower liver edge. Place the fingerpads in the right midclavicular line at the level of the umbilicus and move the fingers closer to the costal margin with each expiration. As the liver edge descends with inspiration, a flat, narrow ridge is usually felt. The liver edge is normally palpated 2 to 3 cm (about 1 in.) below the right costal margin in infants and toddlers, but it may not be palpated in older children. If the liver edge is more than 3 cm (a little over 1 in.) below the right costal margin, the liver is enlarged, possibly due to congestive heart failure or hepatic disease.

DEEP PALPATION

To perform deep palpation, press the fingers of one hand (for small children) or two hands (for older children) more deeply into the abdomen. Because the abdominal muscles are most relaxed when the child takes a deep breath, ask the child to take regular deep breaths when palpating each area of the abdomen.

The spleen tip may be felt at the left costal margin in the midclavicular line when the child takes a deep breath. The spleen is enlarged if it is easily palpated below the left costal margin. The kidneys are in a deep layer of abdominal muscles and intestines, and they are rarely palpated except in newborns. A tubular mass commonly palpated in the lower left or right quadrant is often an intestine filled with feces. A distended bladder is often palpated as a firm, central, dome-shaped mass above the symphysis pubis in young children.

SAFETY ALERT!

If an enlarged kidney or unexpected mass is detected during abdominal palpation, do not continue to palpate the kidney. Notify the primary healthcare provider immediately. The mass could be a Wilms tumor.

Assessment of the Inguinal Area

The inguinal area is inspected and palpated during the abdominal examination to detect enlarged lymph nodes or masses. The femoral pulse, a part of the heart examination, may be assessed simultaneously with the abdominal examination.

Inspect the inguinal area for any change in contour, comparing sides. A small bulging noted over the femoral canal in girls may be associated with a femoral hernia. A bulging in the inguinal area in boys may be associated with an inguinal hernia.

Palpate the inguinal area for lymph nodes and other masses. Small lymph nodes, less than 1 cm (½ in.) in diameter, are often present in the inguinal area because of minor injuries on the legs. Any tenderness, heat, or inflammation in these palpated lymph nodes could be associated with a local infection.

Assessing the Genital and Perineal Areas for External Structural Abnormalities

Nurses may perform an external genital examination or assist another healthcare provider. In younger children, the genital and perineal examination is performed immediately after assessment of the abdomen. Gloves, lubricant, and a penlight are needed for the examination.

Examination of the genitalia and perineal area can cause stress in children because they sense invasion of their privacy. To make young children feel more secure, position them on the parent's lap with their legs spread apart. Children can also be positioned on the examining table with their knees flexed and the legs spread apart like a frog.

Clinical Tip

Preschool-age children are often taught that strangers are not permitted to touch their "private parts." When a child this age actively resists examination of the genital area, ask the parent to tell the child you have permission to look at and touch these parts of the body. You may wish to reinforce the teaching by saying the nurse or doctor can look only when the parent is in the room.

Some children develop modesty during the preschool period. Briefly explain what you need to examine and why. Then calmly and efficiently examine the child.

Inspection of the Female External Genitalia

Inspect the external genitalia of girls for color, size, and symmetry of the mons pubis, labia, urethra, and vaginal opening (Figure 5–26). Simultaneously look for any abnormal findings such as swelling, inflammation, masses, lacerations, or discharge.

Inspect the mons pubis for pubic hair and its characteristics. See Figure 5–29 (shown later in the chapter) for guidelines to assess the stage of pubic hair development.

The labia minora are usually thin and pale in preadolescent girls but become dark pink and moist after puberty. In young infants, the labia minora may be fused and cover the structures in the vestibule. If fused, the adhesions should be separated by another health professional.

Use the thumb and forefinger of one gloved hand to separate the labia minora to inspect the structures in the vestibule. No lesions or signs of inflammation are expected around the urethral or vaginal opening. Redness and **excoriation** (scratches and abrasions of the skin) are often associated with an irritant such as bubble bath. The hymen is just inside the vaginal opening. In preadolescents, it is usually a thin membrane with a crescent-shaped opening. The vaginal opening is usually about 1 cm (½ in.) in adolescents when the hymen is intact. Sexually active adolescents may have a vaginal opening with irregular edges.

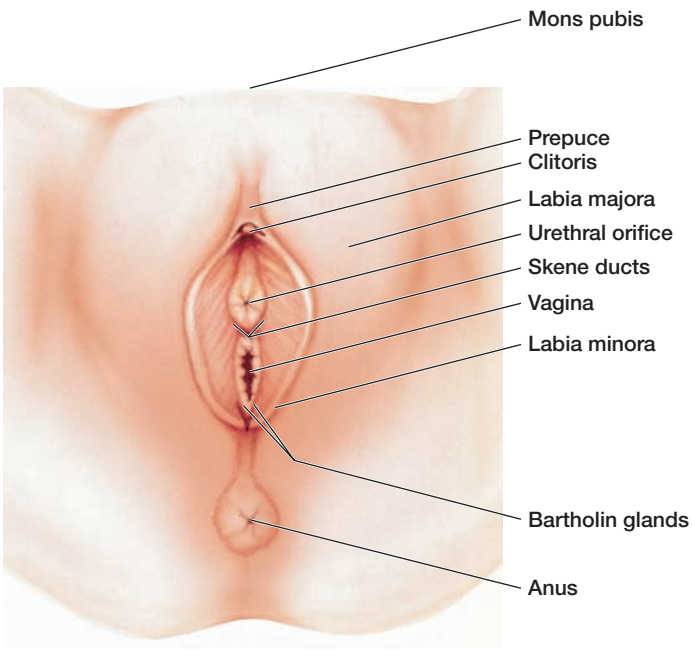

Figure 5–26 **Anatomic structures of the female genital and perineal area.**

Preadolescent girls do not normally have a vaginal discharge. Adolescents often have a clear discharge without a foul odor. Menses generally begin approximately 2 years after breast bud development. A foul-smelling discharge in preschool-age children may be associated with a foreign body. Various organisms may cause a vaginal infection in older children.

An internal vaginal examination and palpation of the female genitalia by an experienced health professional is indicated when abnormal findings such as a vaginal discharge or trauma to the external structures is noted.

SAFETY ALERT!

Signs of sexual abuse in young children include bruising or swelling of the vulva, foul-smelling vaginal discharge, enlarged opening of the vagina, and rash or sores in the perineal area (see Chapter 17).

Inspection of the Male Genitalia

Inspect the male genitalia for the structural and pubertal development of the penis, scrotum, and testicles. Have boys sit with their legs crossed in front of them. This position puts pressure on the abdominal wall to push the testicles into the scrotum. See Figure 5–30 (shown later in the chapter) for guidelines to assess the staging of pubic hair and external genital development.

PENIS

Inspect the penis for size, foreskin, hygiene, and position of the urethral meatus. The length of the nonerect penis in the newborn is normally 2 to 3 cm (about 1 in.). The penis enlarges in length and breadth during childhood and puberty. The penis is normally straight. A downward bowing of the penis may be caused by a **chordee**, a fibrous band of tissue associated with hypospadias.

When the penis is circumcised, the glans penis is exposed, and it is normally clean and smooth without inflammation or ulceration. The urethral meatus is a slit-shaped opening near the tip of the glans. No discharge should be present. If the penis is not circumcised, a foreskin opening large enough for a good urinary stream is normal even when the foreskin does not fully retract, which is a common finding in boys between 3 and 6 years of age. To inspect the glans penis of an uncircumcised boy, the foreskin is gently retracted by the child, parent, or examiner. Avoid forcible retraction of the foreskin to prevent damage to the tissues and the formation of adhesions between the foreskin and glans. Evaluate the degree of foreskin retraction and the meatal location and size. It is usually possible to visualize the meatus.

Location of the urethral meatus at another site on the penis is abnormal, indicating hypospadias or epispadias (see Chapter 26). A round, pinpoint urethral meatus may indicate meatal stenosis. *Phimosis* is the presence of an abnormal ring of tissue distal to the glans that prevents retraction of the foreskin to allow visualization of the meatus. Erythema and edema of the glans (*balanitis*) may result from an infection or trauma.

Inspect the urinary stream. The stream is normally strong without dribbling.

SCROTUM

Inspect the scrotum for size, symmetry, presence of the testicles, and any abnormalities. The scrotum is normally loose and pendulous with *rugae* (wrinkles). The scrotum of infants often appears large in comparison to the penis. A small, undeveloped scrotum that has no rugae indicates undescended testicles. Enlargement or swelling of the scrotum is abnormal. It may indicate an inguinal hernia, hydrocele, torsion of the spermatic cord, or testicular inflammation. A deep cleft in the scrotum may indicate ambiguous genitalia.

Palpation of the Male Genitalia

Palpate the shaft of the penis for nodules and masses. None should be present.

Palpate the scrotum for the presence of the testicles. Make sure your hands are warm to avoid stimulating the cremasteric reflex that causes the testicles to retract. Place your index finger and thumb over the inguinal canal on the side palpated. This keeps the testicle from retracting into the abdomen (Figure 5–27). Gently palpate each testicle. The testicles are normally smooth and equal in size. They are approximately 1 to 1.5 cm (½ in.) in diameter until puberty, when they increase in size. A hard, enlarged, painless testicle may indicate a tumor.

If a testicle is not palpated in the scrotum, an experienced examiner palpates the inguinal canal for the presence of the testicle and may try to move the testicle to the scrotum to palpate its size and shape. The testicle is descendable when it can be moved into the scrotum. An undescended testicle is one that will not move out of the inguinal canal or one that cannot be palpated. An experienced examiner also palpates the length of the spermatic cord between the thumb and forefinger from the testicle to the inguinal canal. It normally feels solid and smooth. No tenderness is expected.

When bulging or swelling of the scrotum is present, an experienced examiner palpates the scrotum to identify the characteristics of the mass and whether it is unilateral or bilateral. If the mass pushes back through the external inguinal ring, it is a reducible inguinal hernia rather than incarcerated. A bright penlight under the scrotum is used to see if a red glow is seen (transillumination), indicating a hydrocele rather than a hernia.

Figure 5–27 **When palpating the scrotum for descended testicles and spermatic cords, place the index finger over the inguinal canal to keep the testicle in the scrotum. Gently palpate the testicle with only enough pressure to detect the size and shape.**

Anus and Rectum

When the child is supine or prone, inspect the anus for sphincter control and any abnormal findings such as inflammation, fissures, or lesions. The external sphincter is usually closed. Inflammation and scratch marks around the anus may be associated with pinworms. A protrusion from the rectum may be associated with a rectal wall prolapse or a hemorrhoid.

Lightly touching the anal opening should stimulate an anal contraction or "wink." Absence of a contraction may indicate the presence of a lower spinal cord lesion. Passage of meconium by newborns indicates a patent anus.

Only an experienced examiner should perform a rectal examination. It is indicated for symptoms of intra-abdominal, rectal, bowel, or stool abnormalities. To assist the examiner and to reduce the child's anxiety, distract the child with an age-appropriate toy or discussion. Let the child know that the lubricant might feel cold. As the examiner's finger is positioned, help the child to relax the sphincter by "pushing out the poop."

Assessing Pubertal Development and Sexual Maturation

The age when secondary sexual characteristics appear can vary with race and ethnicity, environmental conditions, geographic location, and nutrition. For example, in the United States, Black girls and boys have an earlier onset of secondary sexual characteristics than non-Hispanic White and Hispanic girls and boys (Herman-Giddens et al., 2012). A higher body mass index appears to contribute to earlier development of puberty in girls, but not in boys (Biro et al., 2013). If no pubertal changes are seen by age 13 years in female adolescents or 14 years in male adolescents, further evaluation is needed (Loomba-Albrecht & Styne, 2012).

Girls

Inspect the adolescent's breasts while she is sitting to determine the stage of development. Breast development in girls usually precedes other pubertal changes. Figure 5–28 shows the stages of breast development. *Thelarche,* or breast budding, is the first stage of pubertal development in the majority of girls, indicating breast stage 2. Breast tissue is seen and palpated below a slightly enlarging areola (1 cm [½ in.] in diameter of palpable glandular tissue) (Herman-Giddens, Bourdony, Dowshen, et al., 2011). Breast budding normally occurs between 8 and 10 years of age (Biro et al., 2013). A girl's breasts often develop at different rates and appear asymmetric. Breast development prior to 6 years of age may need further evaluation.

During the genital examination, observe for pubic hair development. Preadolescent girls have no pubic hair. Initial pubic hair is lightly pigmented, sparse, and straight along the labia majora. Figure 5–29 illustrates the normal stages of female pubic hair development. Breast development usually precedes pubic hair development. The presence of pubic hair

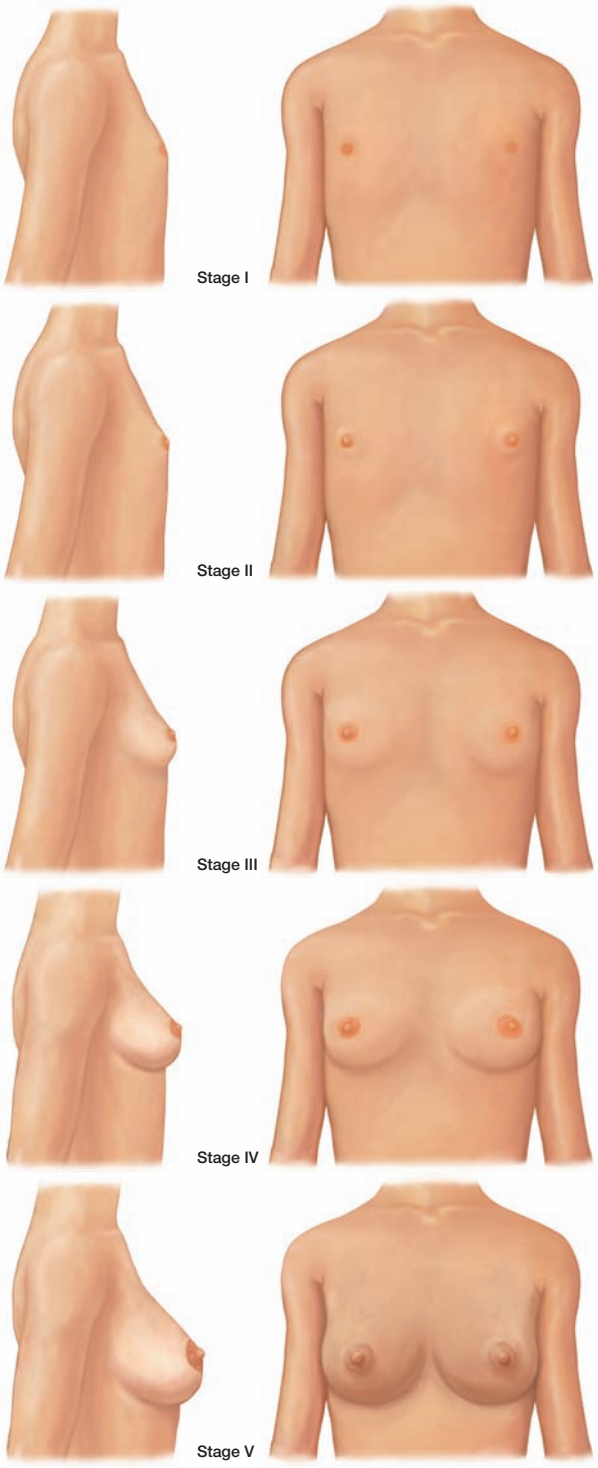

Figure 5–28 **Normal stages of breast development.**

before 8 years of age is unusual and may indicate premature pubertal development. The progression of puberty changes often takes 5 years to reach maturity.

Boys

Initial signs of pubertal development in boys are enlargement of the testicles and thinning of the scrotum at a mean age of 9 to 10 years of age, depending on ethnicity. Straight, downy pubic hair first appears at the base of the penis at a mean age of 10 to 11.5 years, depending on ethnicity. Penis enlargement generally follows testicular enlargement about 2 years later in genitalia Tanner stage 3 (Herman-Giddens et al., 2012). The pubic hair becomes darker, dense, and curly, extending over the pubic area in a diamond pattern by the completion of puberty. The mean age for completing pubertal development for male adolescents (stage 5) in the United States is 15 years of age (Herman-Giddens et al., 2012). Stages of pubic hair and external genital development follow a standard pattern, as seen in Figure 5–30.

Sexual Maturity Timeline

The sexual maturity rating (SMR) is an average of the breast and pubic hair development stages in girls and of the genital and pubic hair stages in boys. The rating is a number between 2 and 5, as stage 1 is prepubertal. The SMR is then related to other physiologic events that happen during puberty. Compare the stage of the child's secondary sexual characteristics with information in Table 5–13.

TABLE 5–13 Sexual Maturity Timeline

GENDER AND DEVELOPMENT CATEGORIES	TIME SPAN AND PHYSIOLOGIC CHANGES
Girls	
Breast development	Over 4 to 4.5 years, proceeding from stages 2 to 5
Pubic hair development	Over 4 to 4.5 years, usually initiated after breast development
Onset of menstruation	At about breast stage 4 (see Figure 5–28), 1 year after peak height velocity
Growth spurt	Height velocity begins increasing about 6 months before breast budding. Peak height velocity occurs between breast and pubic hair stages 3 and 4 (see Figures 5–28 and 5–29)
Boys	
Genital (penis and testes) development	Over 4.5 years, proceeding from stages 2 to 5; testicular development precedes growth of the penis (see Figure 5–30)
Pubic hair development	Over 3.5 years
Facial and axillary hair	Begins about 2 years after pubic hair development begins
Voice change	Greatest change between genital stages 3 and 4
Onset of ejaculation	At about genital stage 3
Growth spurt	Over 4 to 5 years, greatest height velocity is in the first 2 to 3 years with peak height velocity between genital and pubic hair stages 3 and 4 (see Figure 5–30)

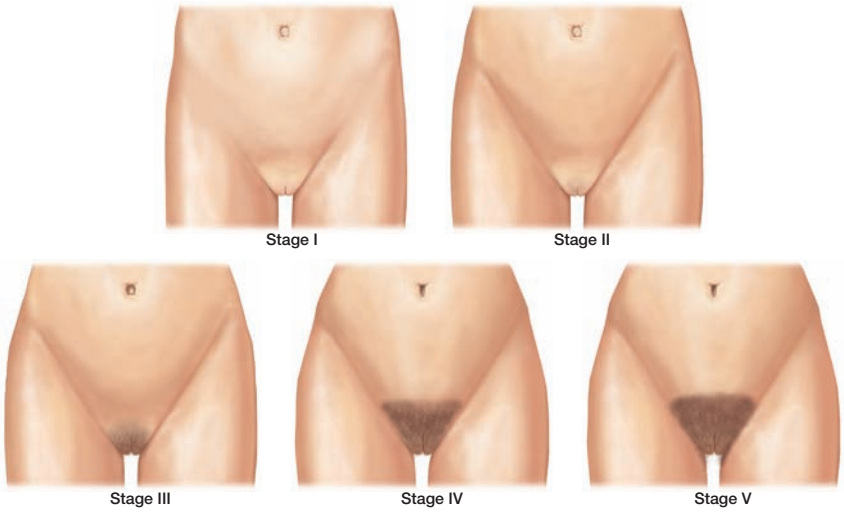

Figure 5–29 **The stages of female pubic hair development with sexual maturation. In stage 2, soft downy hair along the labia majora is an indication that sexual maturation is beginning. Hair grows progressively coarse and curly as development proceeds.**

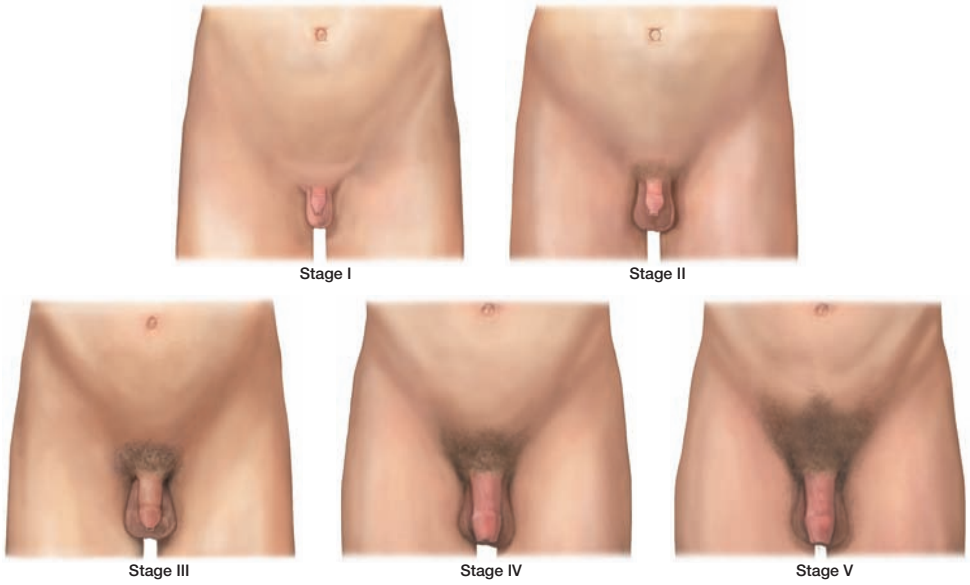

Figure 5–30 **The stages of male pubic hair and external genital development with sexual maturation.**

Assessing the Musculoskeletal System for Bone and Joint Structure, Movement, and Muscle Strength

Inspection of the Bones, Muscles, and Joints

Inspect and compare the arms and then the legs for differences in alignment, contour, skinfolds, length, and deformities. The extremities normally have equal length, circumference, and numbers of skinfolds bilaterally. Extra skinfolds and a larger circumference may indicate a shorter extremity.

Inspect and compare the joints bilaterally for size, discoloration, and ease of voluntary movement. Joints are normally the same color as surrounding skin, with no sign of swelling. Children should voluntarily flex and extend joints during normal activities without pain. Redness, swelling, and pain with movement may indicate injury or infection.

Palpation of the Bones, Muscles, and Joints

Palpate the bones and muscles in each extremity for muscle tone, masses, or tenderness. Muscles normally feel firm, and bony masses are not normally present. Doughy muscles may indicate poor muscle tone. Rigid muscles, or hypertonia, may be associated with an active seizure or cerebral palsy. A mass over a long bone may indicate a recent fracture or a bone tumor.

Palpate each joint and surrounding muscles to detect any swelling, masses, heat, or tenderness. None is expected when the joint is palpated. Tenderness, heat, swelling, and redness can result from injury or a chronic joint inflammation such as juvenile idiopathic arthritis.

Range of Motion and Muscle Strength Assessment

RANGE OF MOTION

Observe the child during typical play activities, such as reaching for objects, climbing, and walking, to assess range of motion of all major joints. Children spontaneously move their joints through the full normal range of motion with play activities when no pain is present. Limited range of motion may indicate injury, inflammation of a joint, or a muscle abnormality.

When a joint is suspected of having limited active range of motion, perform passive range of motion. Flex and extend, abduct and adduct, or rotate the affected joint cautiously to avoid causing extra pain. Full range of motion without pain is normal. Limitations in movement may indicate injury, inflammation, or malformation. Increased passive range of motion may indicate muscle weakness.

MUSCLE STRENGTH

Observe the child's ability to climb onto an examining table, throw a ball, clap hands together, or move around on the bed. The child's ability to perform age-appropriate play activities indicates good muscle tone and strength. Attainment of age-appropriate motor development is another indicator of good muscle strength (Table 5–14).

To assess the strength of specific muscles in the extremities, engage the child in some games. Compare muscle strength bilaterally to identify muscle weakness. For example, the child squeezes the examiner's fingers tightly with each hand; pushes against and pulls the examiner's hands with the hands, lower legs, and feet; and resists extension of a flexed elbow or knee. Children normally have good muscle strength bilaterally. Unilateral muscle weakness may be associated with a nerve injury. Bilateral muscle weakness may result from a congenital disorder such as Down syndrome. Asymmetric weakness may be associated with conditions such as cerebral palsy.

When generalized muscle weakness is suspected in a preschool- or school-age child, ask the child to stand up from the supine position. Children are normally able to rise to a standing position without using their arms as levers. Children who push their body upright using their arms and hands may have generalized muscle weakness, known as a positive *Gowers sign*. This may indicate muscular dystrophy (see Chapter 29).

TABLE 5–14 Selected Gross Motor Milestones for Age

GROSS MOTOR MILESTONES	AVERAGE AGE ATTAINED (MONTHS)
If prone, pushes up on elbows	4
Rolls over in both directions	6
Gets to sitting position and sits without support	9
Creeps or crawls	9
Pulls self to standing position	12
Takes a few steps walking alone	12
May walk up steps	18
Climbs on furniture without help	24
Rides tricycle	36

TABLE 5–15 Normal Development of Posture and Spinal Curves

AGE	POSTURE AND SPINAL CURVES
2–3 months	Holds head erect when held upright; thoracic kyphosis when sitting
6–8 months	Sits without support; spine is straight
10–15 months	Walks independently; straight spine
Toddler	Protruding abdomen; lumbar lordosis
School-age child	Height of shoulders and hips is level; balanced thoracic convex and lumbar concave curves

Posture and Spinal Alignment

POSTURE

Inspect the child's posture when standing from a front, side, and back view. The shoulders and hips are normally level. The head is held erect without a tilt, and the shoulder contour is symmetric. After beginning to walk, young children often have a pot-bellied stance because of lumbar lordosis. The spine has normal thoracic convex and lumbar concave curves after 6 years of age. Table 5–15 describes normal posture and spinal curvature development.

SPINAL ALIGNMENT

Assess the school-age child and adolescent for **scoliosis**, a lateral spine curvature. Stand behind the child, observing the height of the shoulders and hips (Figure 5–31). Ask the child to bend forward slowly at the waist, with the head and arms toward the floor. No lateral curve should be present in either position. The ribs normally stay flat bilaterally. The lumbar concave curve

Figure 5–31 When evaluating spinal alignment, look at the level of the iliac crests and shoulders to see if they are level. Are creases at the waist similar or more prominent on one side? What signs does this child have? This child may have scoliosis.

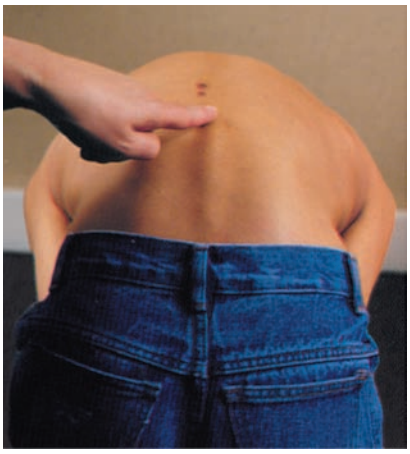

Figure 5–32 **To inspect the spine for scoliosis ask the child to slowly bend forward at the waist with arms extended toward the floor. Run your forefinger down the spinal processes, palpating each vertebra for a change in alignment. A lateral curve to the spine or a one-sided rib hump is an indication of scoliosis.**

should flatten with forward flexion (Figure 5–32). A lateral curve to the spine or a one-sided rib hump is an indication of scoliosis (see Chapter 29).

Inspection of the Upper Extremities

The alignment of the arms is normally straight, with a minimal angle at the elbows, where the bones articulate.

Count the fingers. Extra finger digits (*polydactyly*) or webbed fingers (*syndactyly*) are abnormal. Inspect the creases on the palmar surface of each hand (Figure 5–33). Multiple creases across the palm are normal.

Inspect the nails for size, shape, and color. Nails are normally convex, smooth, and pink. **Clubbing**, widening of the nail bed with an increased angle between the proximal nail fold and nail, is abnormal (see Figure 21–3 in Chapter 21). Clubbing is associated with chronic respiratory and cardiac conditions.

Figure 5–33 **Transverse crease on palmar surface of the hand is associated with Down syndrome.**

SOURCE: EVAfotografie/Getty Images.

Inspection of the Lower Extremities

Assess the hips of newborns and young infants for dislocation or subluxation. First inspect and compare the number of skinfolds on the upper legs. If the number of skinfolds is unequal, a hip dislocation or difference in leg length may be present. The Ortolani and Barlow maneuvers are used to assess an infant's hips for dislocation or subluxation during the first year (Figure 5–34). Then check for the Allis sign, a difference in knee height symmetry (Figure 5–35).

View the child from behind and observe as the child stands on one leg and then the other. The iliac crests should stay level. If the iliac crest on the lifted leg appears lower, the hip abductor muscles on the weight-bearing side are weak, known as the *Trendelenburg sign*.

LEGS AND FEET

Inspect the alignment of the legs with the child standing. After a child is 4 years of age, the alignment of the long bones is expected to be straight at the knees and ankles. The alignment of the lower extremities in infants and toddlers changes as bones straighten with weight bearing. To evaluate the toddler with bowlegs, have the child stand on a firm surface. Measure the distance between the knees when the child's ankles are together. No more than 1.5 in. (3.5 cm) between the knees is normal. See Figure 5–36 for assessment of knock-knees.

Growth and Development **Leg Alignment**

Infants are often born with a twisting of the tibia caused by positioning in utero (tibial torsion). The infant's toes turn in as a result of the tibial torsion. Toddlers go through a skeletal alignment sequence of bowlegs (genu varum) and knock-knees (genu valgum) before the legs assume a straight alignment.

Inspect the feet for alignment, the presence of all toes, and any deformities. The weight-bearing line of the feet is usually in alignment with the legs. Many newborns have a flexible forefoot inversion (*metatarsus adductus*) that results from uterine positioning. Any fixed deformity is abnormal.

Inspect the feet for the presence of an arch when the child is standing. Children up to 3 years of age normally have a fat pad over the arch, giving the appearance of flat feet. Older children normally have a longitudinal arch. The arch is usually seen when the child stands on tiptoe or is sitting. Inspect the nails of the feet as for the hands.

Assessing the Nervous System

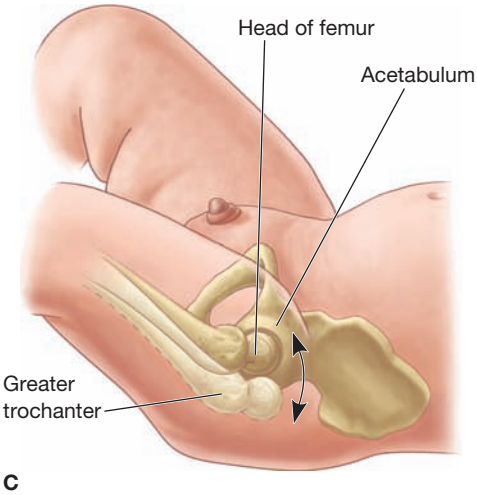
The nervous system is assessed for cognitive function, balance, coordination, cranial nerve function, sensation, and reflexes. Equipment needed for this examination includes a reflex hammer, cotton balls, a penlight, and tongue blades.

Clinical Tip

The neurologic examination provides an opportunity to develop rapport with the child. Many of the procedures can be presented as games that young children enjoy. You can assess cognitive function by how well the child follows directions for tests of strength and coordination. As the assessment proceeds, the child develops trust and may be more cooperative with examination of other body systems.

A

B



C

D

Figure 5–34 *A*, The asymmetry of the gluteal and thigh fat folds seen in infant with left developmental dysplasia of the hip. *B*, For the Barlow (dislocation) maneuver grasp adduct the infant's femur and apply gentle downward pressure. *C*, Dislocation is palpable as the femoral head slips out of the acetabulum. *D*, For the Ortolani maneuver place downward pressure on the hip and then inward rotation. If the hip is dislocated, this maneuver will force the femoral head back into the acetabulum with a noticeable "clunk."

Figure 5–35 To check knee height symmetry flex the infant's hips and knees so the heels are as close to the buttocks as possible. Place the feet flat on the examining table. The knees are usually the same height. A difference in knee height (Allis sign), as seen here, is an indicator of hip dislocation.

SOURCE: International Hip Dysplasia Institute.

Figure 5–36 To evaluate the child with knock-knees, have the child stand on a firm surface. Measure the distance between the ankles when the child stands with the knees together. The normal distance is not more than 2 in. (5 cm) between the ankles.

Cognitive Function

Observe the child's behavior, facial expressions, gestures, communication skills, activity level, and level of consciousness to assess cognitive functioning. Match the neurologic examination to the child's stage of development. For example, cognitive function is evaluated much differently in infants than in older children because infants cannot use words to communicate.

BEHAVIOR

The alertness of infants and children is indicated by their behavior. Infants and toddlers are curious but seek the security of the parent either by clinging or by making frequent eye contact. Older children are often anxious and watch the examiner's actions. Lack of interest in assessment or treatment procedures may indicate a serious illness. Excessive activity or an unusually short attention span may be associated with an attention deficit hyperactivity disorder.

COMMUNICATION SKILLS

Speech, language development, and social skills provide good clues to cognitive functioning. Listen to speech articulation and words used, comparing the child's performance with standards of social development and expected language development for age (Table 5–16). Toddlers can normally follow simple directions such as, "Show me your mouth." By 3 years of age, the child's speech should be easily understood. Delay in language and social skill development may be associated with cognitive disability or hearing loss.

MEMORY

Immediate, recent, and remote memory can be tested in children starting at approximately 4 years of age. Immediate memory can be tested by asking the child to repeat a series of words or numbers, such as the names of favorite characters from a book, television show, or movie. Children can remember more words or numbers with age: three words or numbers at age 4 years, four words or numbers at age 5 years, and five words or numbers at age 6 years.

To evaluate recent memory, ask the child to repeat and then remember a special name or object (e.g., Cinderella or hamburger). Then 5 to 10 minutes later during the examination, have the child recall the name or object. To evaluate remote memory, ask the child to repeat his or her address or birth date or a nursery rhyme. By 5 or 6 years of age, children are normally able to recall this information without difficulty.

TABLE 5–16 Expected Language Development for Age

LANGUAGE MILESTONES	AGE ATTAINED
Babbles speechlike sounds, including *p*, *b*, and *m*	4–6 months
Has 1–2 words like *mama*, *dada*, *bye-bye*	12 months
Increases words each month; two-word combinations (e.g., "Where baby?" and "Want cookie")	1–2 years
Two- to three-word sentences to ask for things or talk about things; large vocabulary; speech understood by family members	2–3 years
Sentences may have four or more words; speech understood by most people	3–4 years
Says most sounds correctly except a few like *l*, *s*, *r*, *v*, *z*, *ch*, *sh*, *th*; tells stories and uses same grammar as rest of family	4–5 years

Source: Data from American Speech and Language Association. (2014). *How does your child hear and talk?* Retrieved from http://www.asha.org/public/speech/development/chart.htm

TABLE 5–17 Expected Balance Development for Age

BALANCE MILESTONES	AGE ATTAINED
Stands without support briefly	12 months
Walks alone well	15 months
Walks backwards	2 years
Balances on 1 foot momentarily	3 years
Hops on 1 foot	4 years

LEVEL OF CONSCIOUSNESS

When approaching infants or children, observe their level of consciousness and activity, including facial expressions, gestures, and interaction. Children are normally alert, and sleeping children arouse easily. The child who cannot be awakened is unconscious. A lowered level of consciousness may be associated with a number of neurologic conditions such as a brain injury, seizure, infection, or brain tumor.

Cerebellar Function

Observe the young child at play to assess coordination and balance. Development of fine motor skills in infants and preschool children provides clues to cerebellar function.

BALANCE

Observe the child's balance during play activities such as walking, standing on one foot, and hopping. See Table 5–17 for expected balance milestones for age. The Romberg procedure can also be used to test balance in children over 3 years of age (Figure 5–37). Once balance and other motor skills are

Figure 5–37 Use the Romberg procedure to evaluate balance. Ask the child to stand with feet together and eyes closed. Protect the child from falling by standing close. Preschool-age children may extend their arms to maintain balance, but older children can normally stand with their arms at their sides.

attained, children do not normally stumble or fall when tested. Poor balance may indicate cerebellar dysfunction or an inner ear disturbance.

COORDINATION

Tests of coordination assess the smoothness and accuracy of movement. Development of fine motor skills can be used to assess coordination in young children (Table 5–18). After 6 years of age, the tests for adults (finger-to-nose, finger-to-finger, heel-to-shin, and alternating motion) can be used (Figure 5–38). Jerky movements or inaccurate pointing (past pointing) indicate poor coordination, which can be associated with delayed development or a cerebellar lesion.

GAIT

A normal gait requires intact bones and joints, muscle strength, coordination, and balance. Inspect the walking child from both the front and rear views. The iliac crests are normally level during walking, and no limp is expected. Toddlers beginning to walk have a wide-based gait and limited balance, and eventually gain more balance and a more narrow-based gait.

A limp may indicate injury or joint disease. Staggering or falling may indicate cerebellar ataxia. *Scissoring*, in which the thighs tend to cross forward over each other with each step, may be associated with cerebral palsy or other spastic conditions.

TABLE 5–18 Expected Fine Motor Development for Age

FINE MOTOR MILESTONES	AVERAGE AGE ATTAINED (MONTHS)
Reaches for a toy with one hand	4
Transfers objects between hands, brings objects to mouth	6
Thumb finger grasp to pick up small objects	9
Bangs items together, releases toy without help	12
Uses spoon to feed self	18
Builds tower of four or more blocks	24

Source: Data from Centers for Disease Control and Prevention. (2014). *Developmental milestones*. Retrieved from http://www.cdc.gov/ncbddd/actearly/milestones/index.html

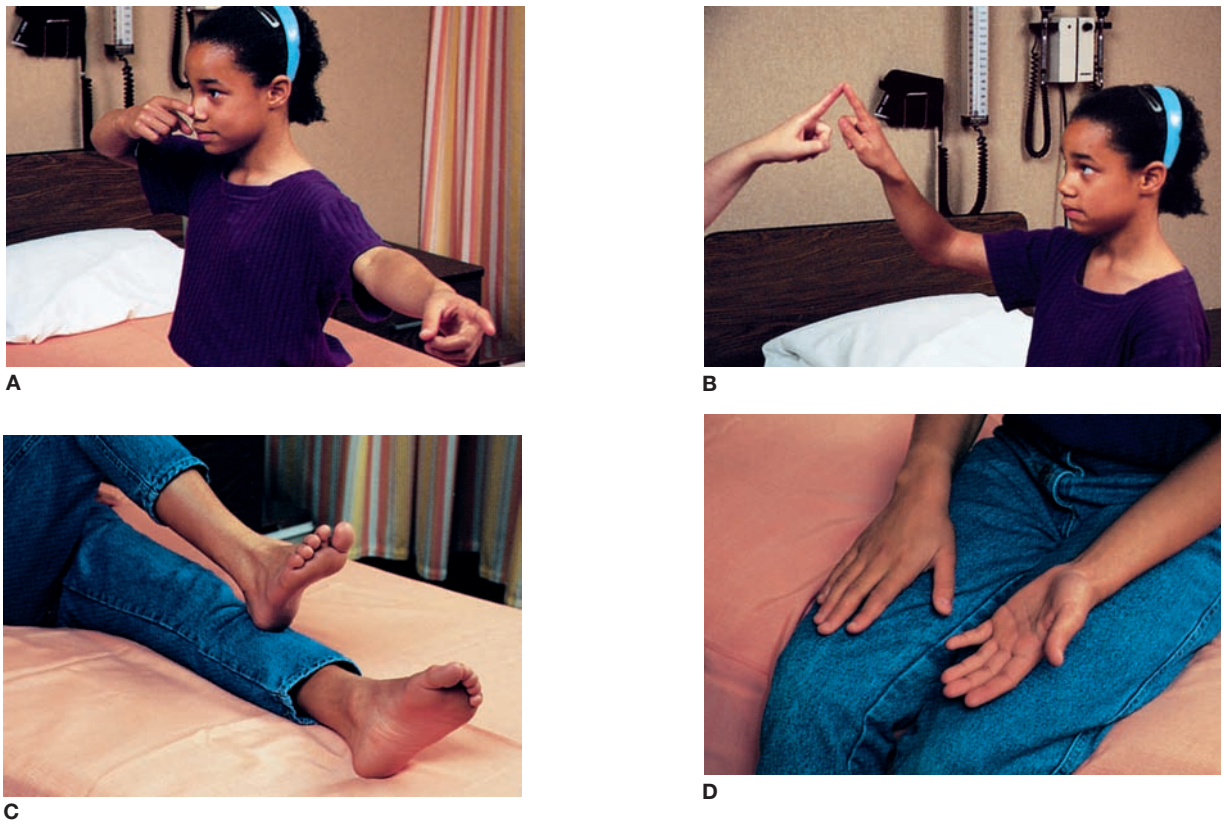


Figure 5–38 Tests of coordination. *A, Finger-to-nose test*. Ask the child to close the eyes and touch the nose, alternating the index fingers of the hands. *B, Finger-to-finger test*. Ask the child to alternately touch his or her nose and your index finger with his index finger. Move your hand to several positions within the child's reach to test pointing accuracy. Repeat the test with the child's other hand. *C, Heel-to-shin test*. Ask the child to rub his or her leg from the knee to the ankle with the heel of the other foot. Repeat the test with the other foot. This test is normally performed without hesitation or inappropriate placement of the foot. *D, Rapid alternating motion test*. Ask the child to rapidly rotate his or her wrist so the palm and dorsum of the hand alternately pat the thigh. Repeat the test with the other hand. Hesitating movements are abnormal. Mirroring movements of the hand not being tested indicate a delay in coordination skill refinement.

TABLE 5–19 Age-Specific Procedures for Assessment of Cranial Nerves in Infants and Children

CRANIAL NERVE[a]	ASSESSMENT PROCEDURE AND NORMAL FINDINGS[b]
I Olfactory	Infant: Not tested. Child: Not routinely tested. Give familiar odors to child to sniff, one naris at a time. *Identifies odors such as orange, peanut butter, and chocolate*.
II Optic	Infant: Shine a bright light in eyes. *A quick blink reflex and dorsal head flexion indicate light perception*. Child: Test vision and visual fields if cooperative. *Visual acuity appropriate for age*.
(III Oculomotor) (IV Trochlear) (VI Abducens)	Infant: Shine a penlight at the eyes and move it side to side. *Focuses on and tracks the light to each side*. Child: Move an object through the six cardinal points of gaze. *Tracks object through all fields of gaze*. All ages: Inspect eyelids for drooping. Inspect pupillary response to light. *Eyelids do not droop and pupils are equal size and briskly respond to light*.
V Trigeminal	Infant: Stimulate the rooting and sucking reflex. *Turns head toward stimulation at side of mouth and sucking has good strength and pattern*. Child: Observe the child chewing a cracker. Touch forehead and cheeks with cotton ball when eyes are closed. *Bilateral jaw strength is good. Child points to location touched by cotton ball*.
VII Facial	All ages: Observe facial expressions when crying, smiling, frowning, etc. *Facial features stay symmetric bilaterally*.
VIII Acoustic	Infant: Produce a loud sound near the head. *Blinks in response to sound, moves head toward sound or freezes position*. Child: Whisper words and ask for them to be repeated. *Repeats words correctly*.
(IX Glossopharyngeal) (X Vagus)	Infant: Observe swallowing during feeding. *Good swallowing pattern.* All ages: Elicit gag reflex. *Gags with stimulation*.
XI Spinal accessory	Infant: Not tested. Child: Ask child to raise the shoulders and turn the head side to side against resistance. *Good strength in neck and shoulders*.
XII Hypoglossal	Infant: Observe feeding. *Sucking and swallowing are coordinated*. Child: Tell the child to stick out the tongue. Listen to speech. *Tongue is midline with no tremors. Words are clearly articulated*.

[a] Bracketed nerves are tested together.

[b] Italic text indicates normal findings.

Cranial Nerve Function

To assess the cranial nerves in infants and young children, modify the procedures used to assess school-age children and adults (Table 5–19). Abnormalities of cranial nerves may be associated with compression due to an injury, tumor, or infection in the brain.

Sensory Function

To assess sensory function, compare the responses of the body to various types of stimulation. Bilateral equal responses are normal. Loss of sensation may indicate a brain or spinal cord lesion. Withdrawal responses to painful procedures indicate normal sensory function in an infant.

To test *superficial tactile sensation*, stroke the skin on the lower leg or arm with a cotton ball or a finger while the child's eyes are closed. Cooperative children over 2 years of age can normally point to the location touched.

To test *superficial pain sensation*, ask the child to close the eyes, and touch the child in various places on each arm and leg. Alternate the sharp and dull ends of a broken tongue blade or a paper clip. Children over 4 years of age can normally distinguish between a sharp and d ull sensation each time. To improve the child's accuracy with the test, let the child practice describing the difference between the sharp and dull stimulations.

An inability to identify superficial touch and pain sensations may indicate sensory loss. Identify the extent of sensory loss, such as all areas below the knee. Other sensory function tests (temperature, vibratory, deep pressure pain, and position sense) are performed when sensory loss is found. Refer to other texts for a description of these procedures.

Common Newborn Reflexes

Evaluate the movement and posture of newborns and young infants by the Moro, palmar grasp, plantar grasp, placing, stepping, and tonic neck newborn reflexes. These reflexes appear and disappear at expected intervals in the first few months of life as the central nervous system develops. Movements are normally equal bilaterally. An asymmetric response may indicate a serious neurologic problem on the less responsive side (Table 5–20).

TABLE 5–20 Common Newborn Reflexes

Tonic neck reflex (fencer position). Elicited when the newborn is supine and the head is turned to one side. In response, the extremities on the same side straighten, whereas on the opposite side they flex. This reflex may not be seen during the early newborn period, but once it appears, it persists until about the third month.

Moro reflex. Elicited when the newborn is startled by a loud noise or lifted slightly above the crib and then suddenly lowered. In response the newborn straightens arms and hands outward while the knees flex. Slowly the arms return to the chest, as in an embrace. The fingers spread, forming a C, and the newborn may cry. This reflex may persist until about 6 months of age.

Stepping reflex. When held upright with one foot touching a flat surface the newborn puts one foot in front of the other and "walks." This reflex is more pronounced at birth and lost in 4 to 8 weeks.

Palmar grasp reflex. Elicited by stimulating the newborn's palm with a finger or object; the newborn grasps and holds the object or finger firmly enough to be lifted momentarily from the crib.

Rooting reflex. Elicited when the side of the newborn's mouth or cheek is touched. In response, the newborn turns toward that side and opens the lips to suck (if not fed recently).

Source: Michele Davidson

Sucking reflex. Elicited when an object is placed in the newborn's mouth or anything touches the lips. Newborns suck even when sleeping; this is called nonnutritive sucking, and it can have a quieting effect on the baby. Disappears by 12 months.

Superficial and Deep Tendon Reflexes

Evaluate the superficial and deep tendon reflexes to assess the function of specific segments of the spine.

SUPERFICIAL REFLEXES

Assess superficial reflexes by stroking a specific area of the body. The plantar reflex, testing spine levels L4 to S2, is routinely evaluated in children (Figure 5–39). The cremasteric reflex is assessed in boys by stroking the inner thigh of each leg. The testicle and scrotum on the stroked side normally rise.

DEEP TENDON REFLEXES

To assess the deep tendon reflexes, tap a tendon near specific joints with a reflex hammer (or with the index finger for infants), comparing responses bilaterally. Inspect for movement in the associated joint and palpate the strength of the expected muscle contraction. The numeric scoring of deep tendon reflexes is as follows:

Grade	Response Interpretation
0	No response
1+	Slow, minimal response
2+	Expected response, active
3+	More active or pronounced than expected
4+	Hyperactive, clonus may be present

Table 5–21 provides guidelines for assessment of the biceps, triceps, brachioradialis, patellar, and Achilles deep tendon reflexes. The best response to deep tendon reflex testing is achieved when the child is relaxed or distracted. Making the child focus on another set of muscles may provide a more accurate response. When testing the reflexes on the lower legs, have the child press the hands together or try to pull them apart when

Figure 5–39 To assess the plantar reflex, stroke the bottom of the infant's or child's foot in the direction of the arrow. Watch the toes for plantar flexion or the *Babinski response*, fanning, and dorsiflexion of the big toe (as seen here). The Babinski response is normal in children under 2 years of age. Plantar flexion of the toes is the normal response in older children. A Babinski response in children over 2 years of age can indicate neurologic disease.

TABLE 5–21 Assessment of Deep Tendon Reflexes and the Associated Spinal Segment Tested

DEEP TENDON REFLEX	TECHNIQUE AND NORMAL FINDINGS*	SPINE SEGMENT TESTED
Biceps	Flex the child's arm at the elbow, and place your thumb over the biceps tendon in the antecubital fossa. Tap your thumb. *Elbow flexes as the biceps muscle contracts.*	C5 and C6
Triceps	With the child's arm flexed, tap the triceps tendon above the elbow. *Elbow extends as the triceps muscle contracts.*	C6, C7, and C8

TABLE 5–21 Assessment of Deep Tendon Reflexes and the Associated Spinal Segment Tested (*continued*)

DEEP TENDON REFLEX	TECHNIQUE AND NORMAL FINDINGS*	SPINE SEGMENT TESTED
Brachioradialis	Lay the child's arm with the thumb upright over your arm. Tap the brachioradial tendon 2.5 cm (1 in.) above the wrist. *Forearm pronates (palm facing downward) and elbow flexes.*	C5 and C6
Patellar	Flex the child's knees, and when the legs are relaxed, tap the patellar tendon just below the knee. *Knee extends (knee jerk) as the quadriceps muscle contracts.*	L2, L3, and L4
Achilles	While the child's legs are flexed, support the foot and tap the Achilles tendon. *Plantar flexion (ankle jerk) as the gastrocnemius muscle contracts.*	S1 and S2

* Italic text indicates normal findings.

gripped together. Responses are normally symmetric bilaterally. The absence of a response is associated with decreased muscle tone and strength. Hyperactive responses are associated with muscle spasticity.

Performing an Intermittent Examination

In a hospital setting after a more comprehensive physical examination at time of admission, the nurse performs a focused assessment to monitor the child's status at intervals appropriate for the child's condition. This assessment includes a general health status overview and a more focused review of the body systems or body regions affected by the child's condition. Findings are compared with prior assessments to determine a change that would indicate a need for a more comprehensive assessment.

The general health status overview for all children includes the following:

- Alertness, responsiveness, or ability to interact
- Cardiorespiratory status—color, ease of breathing, vital signs
- Comfort level or pain score
- Movement of extremities

- Behavior—age appropriateness
- Skin—color, temperature, resilience, swelling
- Fluid and food intake
- Bowel function and urinary output
- Focused assessment of the body systems or body regions affected by child's condition and response to treatment (e.g., respiratory infection, surgery, wound)

If findings during this focused assessment reveal differences from a prior assessment, a more thorough assessment is needed.

Analyzing Data From the Physical Examination

Once the physical examination has been completed, group any abnormal findings for each system with those of other systems. Use clinical judgment to identify common patterns of physiologic responses associated with health conditions. Individual abnormal physiologic responses are also the basis of many nursing diagnoses. Be sure to record all findings from the physical assessment legibly, in detail, and in the format approved by your institution.

Chapter Highlights

- The elements of a health history include the chief concern, details about the present illness or injury, past health history, current health status, psychosocial and developmental data, family history, and review of systems. A birth history may be collected for infants.
- Communication strategies that may improve the quality of health information collected include the following: introducing yourself and explaining the purpose of the interview, providing privacy and confidentiality, using open-ended questions, and asking one question at a time. Ask the child questions when appropriate. Seek feedback to confirm your understanding of information provided.
- Several strategies may help improve the cooperation of the young child for the physical examination, such as allowing the child to stay on the parent's lap, providing an opportunity for the child to hold and inspect any equipment before it is used, and making a game out of tests for muscle strength, coordination, and developmental assessment.
- The sequence for performing a physical examination varies by the age of the child.
  - For infants and toddlers, perform procedures in a feet-to-head sequence to postpone the ear and throat examination that cause anxiety until the end. Take advantage of opportunities to listen to the lungs, heart, and abdomen when the infant is quiet or sleeping.
  - A head-to-feet sequence can be used for all other ages; however, the genital examination may be saved to the end.
- Special assessment techniques used for infants and toddlers include measuring the head circumference, palpating the fontanelles, using toys to assess vision and hearing, and keeping the child on the parent's lap.
- Examination modifications for preschoolers include using easily recognized names or words to assess hearing and memory, using play and games to assess muscle strength and coordination, and asking the child to show the teeth to begin assessment of the mouth.
- Adolescents should be asked their preference for having a parent present during the examination, and pubertal development should be assessed.
- Examples of normal variations found when examining children include hyperpigmented patches (Mongolian spots), epicanthal folds of the eyes, sucking pads in the mouth of an infant, breath sounds heard over the entire chest, a rounded chest in infants, abdominal movement with breathing, bowlegs and knock-knees, and pubertal changes.
- Evaluating the growth pattern of a child involves accurate measurements of infant length, child height, weight, and head circumference and then plotting the measurements on the appropriate growth curve for age. The child's percentile of growth for each measurement is then compared to prior measurements. The body mass index is used to determine if the child's weight is appropriate for height.
- Examples of unexpected physical examination findings that require urgent nursing intervention include altered level of consciousness, bradycardia, tachypnea, pain, signs of dehydration, stridor, retractions, and cyanosis.

Clinical Reasoning in Action

It is a relatively calm night in the children's hospital emergency department when a 6-month-old infant named Colby is brought in by emergency personnel from an automobile crash. Colby was buckled in his infant rear-facing car safety seat, riding with his parents when another car rear-ended them. The parents were not hurt and did not need to go to the hospital. The father immediately called 9-1-1 on his cell phone after the crash. When the ambulance arrived at the emergency department, the EMT gave you this report. Colby was alert and quiet in his father's arms when the ambulance arrived on the scene, and he did not have any obvious signs of injury. Colby and his father were brought to the hospital to make sure Colby did not sustain any injuries from the crash. His vital signs are as follows: temperature—98.9°F, respirations—32, pulse—110, and blood pressure—85/39. Colby is in no apparent distress. His pupils are equal, round, and reactive to light. His anterior fontanelle is flat, and he has equal movements of extremities. His breath sounds are clear and equal bilaterally. His heart sounds have a regular rate and rhythm without murmur. He voided around 2 hours ago, before the accident.

1. The fontanelles are an important body part to examine in infants and toddlers. In the scenario with Colby, it can give an indication of increased intracranial pressure related to a brain injury. Describe the placement of the fontanelles, and when they are expected to close and no longer be palpated. Why is the head more likely to sustain injury in an infant like Colby versus an adult?
2. After reviewing the scenario, what can you tell the parents about Colby's vital signs at this time? What is the difference between adult vital signs and Colby's vital signs?
3. What observations are made to check Colby's mental status?
4. If a heart murmur were to be found on examination of Colby, what would be the five ways to describe it?

Chapter 6
Introduction to Health Promotion and Maintenance

Clarence is so active, and we try to keep up with him, but after working all day we find it hard to have so little quiet time in the evenings. I know we missed his 12-month visit because we were busy with moving.

—Karie, mother of 15-month-old Clarence

Learning Outcomes

6.1 Define health promotion and health maintenance.

6.2 Describe how health promotion and health maintenance are facilitated by partnering with families during health supervision visits.

6.3 Describe the components of a health supervision visit.

6.4 Analyze the nurse's role in providing health promotion and health maintenance for children and families.

6.5 Perform the general observations made of children and their families as they come to the pediatric healthcare home for health supervision visits.

6.6 Synthesize the areas of assessment and intervention for health supervision visits—growth and developmental surveillance, nutrition, physical activity, oral health, mental and spiritual health, family and social relations, disease prevention strategies, and injury prevention strategies.

6.7 Plan health promotion and health maintenance strategies employed during health supervision visits.

6.8 Apply the nursing process in assessment, diagnosis, goal setting, intervention, and evaluation of health promotion and health maintenance activities for children and families.

A major goal of *Healthy People 2020* is to help individuals attain long, healthy lives free of preventable disease, disability, injury, and premature death across all life stages (U.S. Department of Health and Human Services, 2011). The concepts of health promotion and health maintenance provide for nursing interventions that contribute to meeting these goals. Many students in health professions begin their studies with a strong interest in the care of ill individuals. However, as time progresses, students learn that "well" people also require care. They need teaching to improve diet, reduce stress, and obtain

immunizations. They may seek information about how to exercise properly or ensure a safe environment for their children. These examples of care and teaching are components of health promotion and health maintenance.

Nursing is a holistic profession that examines and works with all aspects of the lives of individuals, and has a strong focus on family and community as well. Nurses are uniquely positioned to provide health promotion and health maintenance activities, and indeed these activities should be a part of each encounter with families. What is the difference between health promotion and health maintenance? When should nurses engage in activities that focus on health? How are these activities integrated into health supervision visits for the infant and young child? How do nurses partner with other healthcare professionals to offer comprehensive health services in settings accessible to parents and young children? How can nurses help children and their families to maximize length and quality of life? These are some of the questions that will be explored in this chapter, with examples provided for the application of nursing management.

General Concepts

To understand health promotion and health maintenance, it is important to develop a definition of health. The World Health Organization (WHO) defines **health** as a state of complete physical, mental, and social well-being and not merely the absence of disease and infirmity (WHO, 2016). Others view the quality of "complete well-being" as impossible to attain, and therefore have further developed the concept to apply to persons with health challenges as well as those who are "healthy." Health in this expanded view is dynamic, changing, and unfolding; it is the realization of a state of actualization or potential (Pender, Murdaugh, & Parsons, 2015). This basic human right is necessary for the development of societies, so social determinants of health status are increasingly the focus of research and public policy.

Health promotion refers to activities that increase well-being and enhance wellness or health (Pender, Murdaugh, & Parsons, 2015). These activities lead to actualization of positive health potential for all individuals, including those with chronic or acute conditions, as well as persons whose social experiences puts them at risk for poor health. Examples include providing information and resources in order to:

- Enhance good nutrition at each developmental stage
- Integrate physical activity into the child's daily events
- Provide adequate housing
- Promote oral health
- Foster positive personality development

Health promotion is concerned with development of strategies that seek to foster conditions that allow populations to be healthy and to make healthy choices (WHO, 2016). Nurses engage in health promotion by partnering with children and families to promote family strengths in the areas of lifestyles, social development, coping, and family interactions. They also provide **anticipatory guidance** for families because they understand the child's upcoming developmental stages, and they teach families how to provide an environment that helps children achieve the milestones of each stage. This concept is explored more fully later in this chapter. Some nurses become involved in public policy forums in their communities in order to improve the social determinants of health, such as access to care, nutritious foods, and safe environments.

TABLE 6–1 Levels of Preventive Health Maintenance Activities

LEVEL	DESCRIPTION	EXAMPLES OF NURSING ACTIONS
Primary prevention	Activities that decrease opportunity for illness or injury	Giving immunizations Teaching about car safety seats
Secondary prevention	Early identification and treatment of a condition to lessen its severity	Developmental screening Vision and hearing screening
Tertiary prevention	Reduction in the consequences of a disease or condition with aim of restoring optimal function	Rehabilitation activities for child after a car crash

Source: Data from Centers for Disease Control and Prevention (CDC). (2013). *The concept of prevention*. Retrieved from http://www.cdc.gov/arthritis/temp/pilots-201208/pilot1/online/arthritis-challenge/03-Prevention/concept.htm

Health maintenance (or health protection) refers to activities that preserve an individual's present state of health and that prevent disease or injury occurrence. Examples of these activities include conducting developmental screening or surveillance to identify early deviations from normal development, providing immunizations to prevent illnesses, and teaching about common childhood safety hazards. Health maintenance activities are commonly preventive, and terminology common to community or public health nursing explains the levels and aims of preventive actions. Prevention levels are identified as primary prevention, secondary prevention, and tertiary prevention (Table 6–1).

While it is clear that health promotion and health maintenance activities are closely linked and often overlap, there are some differences. Health maintenance focuses on known potential health risks and seeks to prevent them or to identify them early so that intervention can occur. Health promotion looks at the strengths and goals of individuals, families, and populations, and seeks to use them to assist in reaching higher levels of wellness. It involves partnerships with the family as health goals are set, and with other health professionals and resources to provide for meeting a family's goals. Nurses apply both health promotion and health maintenance concepts when providing health care, recognizing that the concepts overlap. Health promotion and health maintenance are integrated into healthcare visits for children, with the care provider applying both knowledge of health maintenance concepts and adding information the family has identified that will assist in increasing health or wellness (health promotion). These activities commonly take place at "well-child" or health supervision visits.

Health supervision for children is the provision of services that focus on disease and injury prevention (health maintenance), growth and developmental surveillance, and health promotion at key intervals during the child's life. What health promotion and health maintenance activities are parts of health supervision visits? How can these activities be integrated into all settings where care is provided for children? What are the recommended times for health visits to occur and what care is provided at certain times? How can health supervision visits be organized to accomplish the goals of the family and health professionals? In this chapter and the following three chapters, we discuss the integration of health supervision in various settings, recommended schedules for health supervision visits, and partnering with families to achieve health goals and promote child development.

All children need a medical home, where accessible, continuous, and coordinated health supervision is provided during the developmental years. *Accessibility* refers to both financial and geographic access; *continuous* indicates that the care is ongoing with consistent care providers; *coordination* refers to the need for communication among health professionals to provide for the needs of the child. A medical home or **pediatric healthcare home** is therefore the site where comprehensive, family-centered, culturally effective, and compassionate health care is provided by a pediatric healthcare professional focused on the overall well-being of children and families (American Academy of Pediatrics, 2014). When a family has an established partnership with a healthcare provider, family-centered health services can be provided based on the family's risks and protective factors. These services may be provided in physicians' offices, community health clinics, the home, schools, childcare centers, shelters, or mobile vans (Figure 6–1). Coordination of care among these entities promotes the concept of a medical neighborhood that includes all components of care, with seamless flow of health information (Taylor, Lake, Nysenbaum, et al., 2011). The U.S. Department of Health and Human Services, the American Academy of Pediatrics (AAP), and the American Medical Association have developed national guidelines for preventive healthcare services for infants, children, and adolescents. The National Association of Pediatric Nurse Practitioners (NAPNAP) supports the list of comprehensive services of a pediatric healthcare home identified by the AAP (AAP, 2014).

Healthy People 2020

(MICH-30.1) Increase the proportion of children who have access to a medical home

- While 57.5% of children under age 18 years had an established medical home in 2007, the objective of 63.3% of children with such access is the present goal (U.S. Department of Health and Human Services, 2011).

The health supervision visit is individualized to the family and child. Standardized screenings and examinations are included, and time is provided for the family's specific concerns and questions about the child's health and development. Nurses play an integral part in these comprehensive visits, and they partner with other healthcare providers to accomplish health supervision.

A tracking system in the pediatric healthcare home site helps to identify appropriate health supervision activities for each child at every visit. Most often, computers are used to list appropriate topics for visits at specific ages. If a child misses a visit, the family can be contacted by phone, text, or e-mail, and encouraged to come in for the recommended care. A family may be called if their child is lacking some immunizations. Recognizing that not all families get into the healthcare home for each recommended visit, every health encounter, including an episodic illness visit or care for a chronic illness, is a potential time to complete health promotion and health maintenance activities. For example, immunizations may sometimes be given during a visit for an acute condition such as otitis media (ear infection) if the child has missed a prior health supervision visit. Even when children are seen in hospitals, emergency departments, or other settings, it is important to ask about their pediatric healthcare home and when the last visit occurred. Identify children who need basic health supervision services and provide them or refer to other settings for meeting these needs at another time.

Nurses play an important role in managing health supervision visits. Depending on the setting, the nurse may provide all services or support other healthcare providers by obtaining an updated health history, screening for diseases and other conditions, conducting a developmental assessment, and providing immunizations, anticipatory guidance, and health education. Nurses in all settings are instrumental in identifying children who need health supervision and are not obtaining recommended care (Figure 6–2).

While health supervision visits can address many health-related topics, there is generally a limited time in which to engage a child or family. The nurse needs to direct the encounters and have some ideas for pertinent agendas. *Bright Futures* booklets

A B C

Figure 6–2 Identifying children who need health care. The nurse plays many roles in providing health promotion and health maintenance for children. *A,* Data are collected from the time a nurse calls the child and family to the examination room and during the history-taking phase. The nurse asks questions while observing the child's behaviors and the relationship between parent and child. The nurse also performs screening tests, including blood pressure, tuberculosis, vision and hearing, and developmental screening. *B,* Interventions that include teaching may take place. *C,* A nurse may administer immunizations as parents watch and assist by holding the child. Nurses also play important roles in teaching families information to enhance health.

provide guidance about how the nurse can manage health supervision visits. Six concepts should be integrated into care (Hagan, Shaw, & Duncan, 2008):

1. The healthcare provider *builds effective partnerships* with the family. A **partnership** is a relationship in which participants join together to ensure healthcare delivery in a way that recognizes the critical roles and contributions of each partner in promoting health and preventing illness. The partners in child health include the child, family, health professionals, and the community.
2. The nurse *fosters family-centered communication* by showing interest in the child and family, and effectively conveying information and understanding.
3. The nurse *focuses on health promotion and health maintenance topics during visits*, recognizing that families may not initiate these discussions.
4. The nurse *manages time well* to enable health promotion topics to be addressed during visits. This includes reviewing the child's health record and selecting topics pertinent to the child's age and the family's situation.
5. The nurse *educates the family during "teachable moments."* Large teaching plans are not always needed; children and families often learn best when presented with small bits of information based on the parent's questions or the nurse's observations.
6. The nurse *becomes an advocate for child health issues*. When an issue arises while caring for a child, seek additional data from various sources, talk with others, and strategize how the problem could be solved.

Components of Health Promotion/Health Maintenance Visits

The nurse identifies and addresses pertinent topics for health promotion and health maintenance during health supervision visits. Nurses also apply their knowledge of areas that need to be addressed with an infant or child of a particular age, and then make general observations of the child and family to identify additional topics for discussion. While categories to consider vary depending on the age of the child, the family's particular needs, and community resources, there are some common topics that generally require attention. Often, nurses start with the topics suggested for the child's age, integrating general observations as the visit progresses and further identifying assessment areas needed in particular situations. The American Academy of Pediatrics and other organizations review and make recommendations for the screening and health assessments to be included at each age.

Professionalism in Practice Schedule for Preventive Health Services

The Recommendations for Preventive Health Care, for the child from the prenatal visit of the mother through age 21 years, were updated in 2016 and published in the journal *Pediatrics* (American Academy of Pediatrics Committee on Practice and Ambulatory Medicine, 2016). The Patient Protection and Affordable Care Act requires the coverage of these recommendations. Some changes in the 2016 schedule include addition of congenital heart disease screening of all newborns; alcohol, drug, and depression screenings; expansion of cholesterol screening; anemia identification; and HIV screening in adolescents.

The nurse should be aware of the screening guidelines and integrate these recommendations into health supervision visits and other child healthcare settings. Screening tools for specific age groups should be readily accessible and provided to the family and primary care providers during visits. Plans should be in place for further evaluation and referral as necessary when screenings result in abnormal findings. The integration of recommended screenings and follow-up should be carefully documented in the child's record.

Pediatric nurses make *general observations* of infants and their families whenever they encounter them. Nurses who are observant during the health supervision visit have many opportunities for assessing the family. These general observations begin when the family is called in and welcomed by the nurse to the facility. They continue as the infant or child is weighed and measured, and throughout the visit. Nurses observe the physical contact between the child and other family members, the developmental tasks displayed by the child, and parental level of stress or ease in conducting childcare activities.

Growth and developmental surveillance provides important clues about the child's condition and environment. The child's height, weight, and body mass index are calculated at each health supervision visit, and results are placed on percentile charts (see Chapters 4 and 14 for more information). Parents are given the information in written form and it is interpreted for them if needed. A thorough physical assessment is performed to ensure the child is growing as expected and has no abnormal or unexplained physical findings (see Chapter 5). **Developmental surveillance** is a flexible, continuous process of skilled observations that provides data about the child's capabilities, allows for early identification of any neurologic problems, and helps verify that the home environment is stimulating. Early development is important to later health, and it must be evaluated consistently and systematically during healthcare visits (Centers for Disease Control and Prevention [CDC], 2014a). Information may be collected from several sources—for instance, a questionnaire that the parent completes, questions asked during the interview, or observation of the child during the visit. Parents can also be interviewed to identify any developmental concerns they may have about the child or adolescent. When talking with parents, review physical, social, and communication milestones for infants, young children, older children, or adolescents. Detailed milestones for each age group are found in Chapter 4. Standardized developmental questionnaires are effective for developmental surveillance of most children, especially when time for health supervision visits is limited. Screening tests should be administered at the 9-, 18-, and the 24- or 30-month visits (CDC, 2014a; Lipkin, 2011). See Tables 6–2 and 6–3. When performing developmental monitoring with standardized screening tools, nurses make sure all directions are followed by:

- Choosing the proper test for the child's age and desired information
- Reading directions thoroughly or using specific training tools available
- Practicing as needed until proficient with the test
- Calculating the infant's or child's age correctly, especially if premature
- Attempting to develop rapport with the infant or child to get the best performance
- Following directions for administration of items; in some cases, parents can be asked if a child demonstrates specific skills at home, especially if the child is not willing to perform an item during testing
- Noting the behavior and cooperativeness of the child during the screening process
- Analyzing the findings using the test instructions to make the correct interpretation

Failure to perform an item on a screening tool does not mean the child has failed the test (see *Developing Cultural Competence: English Language Learners and Developmental Testing*). The child should be reevaluated at a future visit. Schedule the appointment at a time of day when the child is awake and rested. Provide parents with guidance on specific methods for stimulating the child. Failure of multiple items is of greatest concern. Follow the guidelines of the particular developmental screening test for referral to further diagnostic developmental assessment.

TABLE 6–2 Developmental Surveillance Questionnaires

QUESTIONNAIRE	GUIDELINES FOR ADMINISTRATION
Parent's Evaluation of Developmental Status[a] (birth to 8 years)	Consists of 10 questions for parents to answer in interview; based on research about parents' concerns. Requires less than 5 minutes to complete. English and Spanish forms are available.
Prescreening Development Questionnaire (birth to 6 years)	Parents complete an age-specific form. Helps identify children who need Denver II (PDQ and Revised-PDQ)[b] assessment. Requires less than 10 minutes to complete. PDQ is available in English, Spanish, and French versions; R-PDQ in English only.
Ages and Stages Questionnaire[c] (4–48 months)	Questionnaires for 11 specific ages, with 10 to 15 items each in areas of fine motor, gross motor, communication, adaptive, personal, and social skills. Parents try each activity with the child. Requires less than 10 minutes to complete. English and Spanish versions are available.
Child Development Inventories[d] (3–72 months)	Consists of 60 yes–no descriptions for three separate instruments to identify children with developmental difficulties. Requires about 10 minutes to complete.

TABLE 6–3 Developmental Screening Tests for Infants and Young Children

SCREENING TEST	GUIDELINES FOR ADMINISTRATION
Denver II[a] (birth to 6 years)	Consists of observation of the child in four domains: personal social, fine motor-adaptive, language, and gross motor. Requires 30 minutes to complete. A training video is available.
Bayley Infant Neurodevelopmental Screener (BINST)[b] (3–24 months)	Consists of observation of the child with 10 to 13 items for each of six age-specific scales to assess neurologic processes, neurodevelopmental skills, and developmental accomplishments. Requires 10–15 minutes to complete.
McCarthy Scales of Children's Abilities[b] (2.5–8.5 years)	Consists of observation of the child in domains of motor, verbal, perceptual-performance, quantitative, general cognition, and memory. Requires 45 minutes to complete.
Denver Articulation Screening Exam (DASE)[a] (2.5–6 years)	Consists of observation of the child's articulation of 30 sound elements and intelligibility. Requires 5 minutes to complete.
Early Language Milestone Scale—2 (ELM)[c] (birth to 36 months)	Consists of observation of the child to assess auditory expressive, auditory receptive, and visual components of speech. Requires 5–10 minutes to complete.

Nutrition evaluation is a vital part of each health supervision visit. It makes important contributions to general health and fosters growth and development. Include observations and screening relevant to nutritional intake at each health supervision visit. Eating proper foods for age and activity ensures that children have the energy for proper growth, physical activity, cognition, and immune function. Nutrition is closely linked to both health promotion and health maintenance. See Chapter 14 for detailed nutritional assessments for each age group. Find out what questions parents have about feeding their children. Use the information gathered to provide both health promotion and health maintenance interventions.

Developing Cultural Competence English Language Learners and Developmental Testing

Children who have recently come from other countries and even some born in this country who live in families from minority ethnic groups may have difficulty with some items on developmental screening tests. For example, children who are not skilled in the English language may not understand some instructions or be able to answer questions about definitions of words. When parents do not speak English as a primary language and the examiner uses English, common terms might be misinterpreted. Parents might not understand what is meant if you ask, "Does your baby have a mobile over the crib at home?" or "Is she starting to be afraid of strangers?" How can you be alert for language differences and become sensitive to miscommunication?

Physical activity provides many physical and psychologic health benefits. However, there is a growing disparity between recommendations and reality among most children. Research by the Centers for Disease Control and Prevention (CDC) identified that 15.2% of children from 9th to 12th grades report no free-time physical activity, while 47% had recommended activity 5 days/week and only 27% met the recommendation 7 days/week (CDC, 2014b). When schools do not offer daily physical education, many children have no regular activity. Participation in physical activity declines as youth get older, and females are considerably less active than males (CDC, 2014b). Inquire about activities the child prefers and amount of time for activity during the day. As the child grows older, include questions about sedentary activities such as number of hours spent watching television or playing computer games. Inquire if the child plays sports at school or in the community. Ask about activities in a typical day to measure amount of activity. Once the nurse gathers data about physical activity, interventions are implemented to enhance activity patterns.

Although *oral health* may seem to require the knowledge of a specialist, it has many implications that relate to general health care. Oral health is important because teeth assist in language development, impacted or infected teeth lead to systemic illness, and teeth are related to positive self-image formation. Dental caries is the most common chronic disease of children. Many youth in the United States are affected by tooth decay and pain that interfere with activities of daily living such as eating, sleeping, attending school, and speaking (CDC, 2011a, 2011b). The nurse applies health promotion to dental health by teaching about oral care and access to dental visits. Health maintenance activities relate to prevention of caries and illness related to dental disease.

Mental and spiritual health are important concepts to address in health promotion and health maintenance visits. Parents can be encouraged to keep a record of mental health issues to bring to health supervision visits. This helps them understand that the healthcare professional is willing to partner with them to assist in dealing with mental health. Suggest topics such as child and parental mood, child temperament, stresses and ways that family members manage stress, or sleep patterns. Make notes in the record as a reminder of questions to ask at the next visit.

Developing Cultural Competence Unmet Dental Needs

About 6% of U.S. children have unmet dental needs, but 7% of children from families living in poverty have such needs (Child Trends, 2013). In addition, Hispanic children, children with disabilities, children with parents who have a low educational level, or those without health insurance are also more likely to have unmet dental needs (Child Trends, 2013). All children in the Medicaid program are eligible for dental coverage through the Early and Periodic Screening, Diagnostic, and Treatment (EPSDT) program. Private and public clinics in many communities provide low-cost or free care for families with limited financial resources. Many families do not realize their children could receive these services. Find out what resources are available in your state and community, and refer as needed. See Chapter 1 for further description of programs mentioned here.

Figure 6–3 **Blood screening test. This young child is having a blood screening test to detect iron deficiency anemia. Children are often screened for adequate levels of iron in later infancy and during toddlerhood.**

The child and family are both observed for appropriateness of affect and mood. Be alert for signs of depression, stress, anxiety, and child abuse or neglect. The nurse establishes both health promotion and health maintenance goals related to child and family mental health. Health promotion goals relate to adequate resources to meet family challenges and protective factors such as involvement in extended family and the community. Teaching stress reduction techniques such as meditation, relaxation, and imagery is helpful. Resources for yoga or other relaxation techniques can be provided. Health maintenance goals relate to prevention of mental health problems. Examples include providing resources when domestic violence occurs, or referring cases of suspected child abuse or neglect. The **spiritual dimension** is a connection with a greater power than that in the self, and guides a person to strive for life purpose, joy, peace, and fulfillment (Pender, Murdaugh, & Parsons, 2015). For some, spiritual health may be fostered by membership in a faith-based group; for others, it may be feeling part of a society with a purpose of greater good, or setting goals for the future. Ask about the family's meaningful activities. Provide links to faith-based groups as needed.

The *relationships* that a child establishes with others begin at birth. The first and most important set of relationships develops with the family. The mother, father, siblings, and perhaps extended family are the contexts in which the baby learns to relate with others. With growth, the world widens to encompass other children, friends of the family, peers, school, and the larger community network. Analyzing the child's relationships at all ages provides important clues to social interactions. From the moment the family is called in from a waiting area, be alert for clues to family interactions. Likewise, other social interactions are important to evaluate. Does the young infant interact in an age-appropriate manner with the healthcare provider or other children in the area? Ask the parents questions about family and social interactions. Once assessment has taken place, establish goals and interventions related to family and social relationships.

Disease prevention strategies focus mainly on health maintenance, or prevention of disease. Some health disruptions can be detected early and treatment for the condition can begin. **Screening** is a procedure used to detect the possible presence of a health condition before symptoms are apparent. It is usually conducted on large groups of individuals at risk for a condition and represents the secondary level of prevention (Figure 6–3). Most screening tests are not diagnostic by themselves but are followed by further diagnostic tests if the screening result is positive. Once a screening test identifies the existence of a health condition, early intervention can begin, with the goal of reducing the severity or complications of the condition (secondary prevention). Another way to prevent diseases is to immunize children against common communicable diseases (primary prevention). See Chapter 16 for the complete list of childhood immunizations and schedules for administration.

Most childhood mortality and hospitalization is related to injury (CDC, 2012) (see Chapter 1 for more information). Therefore, it is important for the nurse to integrate *injury prevention* strategies in all health supervision visits. The family is constantly challenged to maintain a safe environment as the child grows older, reaches more advanced developmental levels, is exposed to a widening world outside of the family, and has less supervision. Safety teaching should be integrated with developmental progression. Asking parents to bring their questions about safety to each visit can be a good starting point for discussion. The nurse considers knowledge about the age of the child and information from the health supervision visit to plan health maintenance interventions related to injury. Teaching is performed, resources are made available, and parents and children who have experienced injury are invited to present their experiences.

Many other topics might be discussed during health supervision visits. They may relate to either health maintenance activities designed to preserve health, or health promotion activities designed to enhance or improve the state of wellness. Topics include extended family members and their role in the child's life, cultural variations or inclusion, or development of moral values and ethical behaviors.

Nursing Management

Nursing Assessment and Diagnosis

During health supervision visits, a mental portrait of a child and family should be drawn. Observe the parent–child interaction in the waiting room and all throughout the examination. If siblings are present, watch for interactions among all family members. Observe the affect and mood of the child and parents. Nursing assessment of the child and family at each visit for health supervision then focuses on the following:

- Interviewing the family and child to update the health history, asking about the child's developmental or educational progress, and identifying dietary habits, physical activity, and safety practices
- Eliciting questions and concerns that the parent or child may have
- Conducting developmental surveillance assessments, including review of questionnaires completed by the parent in the waiting room
- Performing age-appropriate screening tests
- Performing a physical assessment

Following a thorough assessment, the nurse derives nursing diagnoses that are pertinent for the child's health status and that consider the family's needs. Nursing diagnoses are developed jointly with the family as an essential component of the partnership between nurse and family. Examples of nursing diagnoses for an 18-month-old child for regular health supervision and immunizations may include the following (NANDA-I © 2014):

- ***Overweight*** related to lack of basic nutritional knowledge
- ***Poisoning, Risk for,*** related to lack of proper precautions with increased mobility to reach and climb
- ***Health Management, Readiness for Enhanced,*** related to needed immunizations
- ***Parenting, Risk for Impaired,*** related to mother's plans to return to full-time work

Planning and Implementation

Nursing management for health supervision visits begins with collaborative planning with the family. They share their concerns and questions, and the nurse also lists procedures and discussion topics to be addressed. (See *Families Want to Know: Health Supervision Visits*.) These may include providing immunizations, offering anticipatory guidance about discipline, educating parents and children about healthy behaviors, addressing health promotion regarding nutrition, suggesting ways to prevent disease and injury, and providing referrals for follow-up care. For more information about the recommended schedule for immunizations and the nurse's role in ensuring full immunization status for children, refer to Chapter 16.

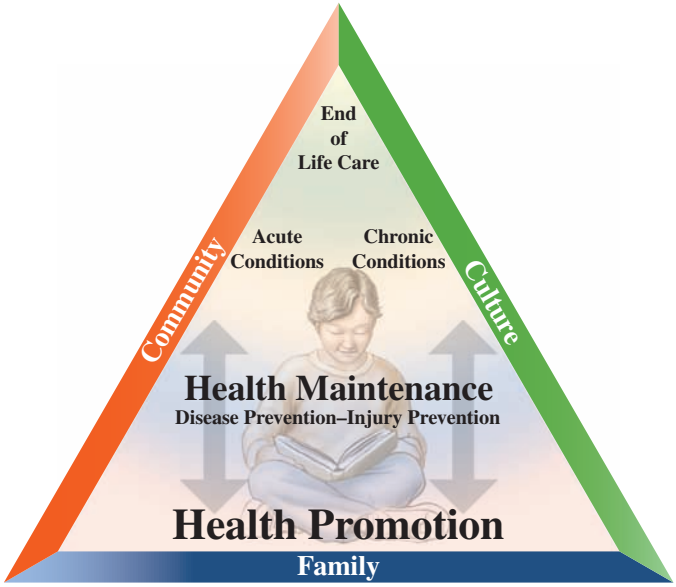

Figure 6–4 Bindler-Ball Healthcare Model. Health promotion and maintenance are foundational to all pediatric health care. They are integrated into every healthcare visit, whether for health supervision or acute and chronic conditions.

Most parents want to know how to contribute to their child's growth and development and need linkages to additional community resources to foster child development. Discussions at the conclusion of the health supervision assessments should focus on building family strengths by promoting the development of competence, confidence, and self-esteem in the growing child. Offering health promotion activities such as these provides a positive ending for the visit. Inquire about the family stresses and strengths to plan with them to provide for the child's health promotion.

Although health supervision most likely takes place in an office or clinic setting, nursing management for health supervision can occur in any setting. The nurse recognizes that health promotion and health maintenance activities are key to any nurse–family relationship. Health promotion and maintenance are constant and foundational aspects of all pediatric care. This approach to health care closely reflects a partnership with families and is essential to every healthcare encounter (Figure 6–4).

Families Want to Know

Health Supervision Visits

Focus groups with parents were conducted to learn parental views about health supervision visits with their children. Parents wanted reassurance about the child's behaviors and wanted an opportunity to discuss health with a professional. An ongoing relationship with one professional was important. Parents requested additional information on development and child behaviors, and additional ways to communicate with healthcare providers (Radecki, Olson, Frintner, et al., 2009). Nurses should:

- Ask what the parent priorities are at each healthcare visit.
- Provide handouts and information on the child's expected developmental achievements.
- Discuss child behaviors such as sleep, discipline, and other parent concerns.
- Integrate communication methods such as phone calls and Internet contact into the care setting.

PROVIDE ANTICIPATORY GUIDANCE

Anticipatory guidance involves prediction of the upcoming developmental tasks or needs of a child and gears teaching to those needs. It provides the family with information on what to expect during the child's current and next stage of development. Topics for each visit should include age-appropriate information about healthy habits, illness and injury prevention, poison prevention, nutrition, oral health, and sexuality. Use health promotional guidance to help the child and family develop strategies that support and enhance social development, family relationships, parental health, community interactions, self-responsibility, and school or vocational achievement.

Clinical Reasoning **Health Promotion**

The pediatric nurse should apply concepts of health promotion and maintenance in all healthcare settings. If the child is seen in an emergency room for treatment of a fracture, what questions should the nurse ask about immunization status and safety issues? If the nurse sees a child with a chronic disorder of cerebral palsy in the outpatient clinic at an orthopedic hospital, what health promotion and health maintenance services should be integrated?

Because the time for each visit is limited, build on the parents' current knowledge and care practices, and start with a topic about which they express interest. Time can be used to focus on anticipatory guidance to introduce new information, to reinforce what the family is doing well, and to clear up any poorly understood concepts.

Take advantage of other sources of information in the community to enhance the guidance provided. For example, state and local SAFE KIDS coalitions help inform families about injury-prevention strategies. School health programs such as the National Fire Prevention Association's "Risk Watch" may educate children about injury prevention, and other school programs may educate students about smoking and drug avoidance. Keep informed about the types of health education provided in different community settings so it is easier to reinforce the concepts already being taught.

ENCOURAGE HEALTH PROMOTION ACTIVITIES

Families often need health education and counseling to promote healthy behaviors in their own child. Examples of focused health education and counseling may be information about limiting sedentary behaviors, integrating dietary changes to increase fruit and vegetable intake, and increasing daily physical activity.

Patient education and counseling are most effective when the family understands the relationship between a behavior change and the resulting health outcome. When identifying that a family would benefit from a change in health behavior, consider the family members' perceptions about the health change, consider the barriers and benefits to change, and plan interventions to enhance the possibility for change.

Steps in promoting patient education and counseling include (Hagan, Shaw, & Duncan, 2008):

- Clarifying learning needs of child and family
- Setting a limited agenda
- Prioritizing needs with the family
- Selecting a teaching strategy (explaining, showing, providing resources, questioning, practicing, giving feedback)
- Evaluating effectiveness

PERFORM HEALTH SUPERVISION INTERVENTIONS

After all the information from the interviews, physical assessment, and screening tests is collected and analyzed, specific health and developmental achievements should be summarized for the parents and child. Immunizations are provided as appropriate. Anticipatory guidance may be offered at various points during the health supervision visit.

When a child is found to be at risk for a health condition, integrate health maintenance interventions to lessen the possibility of disease or injury. If an actual health problem is detected, follow-up care must be arranged. The child may need to return for another visit to the primary care provider for further evaluation, or referral to another provider may be needed. The nurse needs to learn about all the available community resources to make appropriate referrals. The range of such services may include the following:

- Hospital and community-based healthcare specialists from many disciplines (e.g., dentists, physicians, physical therapists, speech therapists, nutritionists, social workers)
- Community-based programs (e.g., childcare centers, developmental stimulation programs, home visitor programs, early intervention programs, mental health centers, diagnostic and evaluation centers, schools, family support centers, food and nutrition referral centers, public health clinics, churches, and other organizations that support families and children)

Evaluation

Expected outcomes of nursing care include the following:

- The child and family collaborate in a partnership with the healthcare provider in joint problem solving and decision making regarding the management of the child's healthcare needs after appropriate education and counseling.
- The child and family prepare for future health supervision visits by identifying questions or concerns they want to discuss.

Chapter Highlights

- Health is a dynamic state of physical, mental, and social well-being and is the objective of health promotion and health maintenance activities.
- Health supervision visits are healthcare encounters designed to provide assessment, screening, developmental surveillance, immunizations, and health information.
- Health supervision visits include general observations, as well as growth and development, nutrition, physical activity, oral health, mental health, spiritual, and relationship surveillance.
- Partners in providing health supervision are the child, family, health professionals, and community.
- Health promotion and health maintenance interventions are essential components of all child health care, even during periods of acute or chronic illness.

Clinical Reasoning in Action

SOURCE: Steven Rubin/The Image Works

Sahil is a 6–month-old boy who is brought to the clinic by his mother, Clarisse, and his grandmother, who just moved into the home to help Clarisse. Sahil's father recently needed to leave the country on a prolonged work assignment. Clarisse is very nervous about being the main adult responsible for Sahil since her husband's departure. As you assess Sahil, you find that he is smiling readily, is able to sit on his own with little support, and has length and weight at the 50th percentiles. His mother told you that she is breastfeeding and has been feeding Sahil some table food such as rice and tofu. She has returned to work so the grandmother will provide care during the day while Clarisse is at work. You review the immunization record and find that several immunizations are due at today's visit.

1. As Clarisse returns to work, Sahil will likely be consuming less breast milk and have more table foods and formula added to the diet. What questions will you ask Clarisse and Sahil's grandmother to evaluate their knowledge of dietary recommendations for infants? Compose a teaching plan that is appropriate for integration of increasing types of food into the diet of a 6-month-old child.
2. What immunizations are generally needed for 6-month-old infants? When should Sahil return for his next immunizations?
3. You have identified that Clarisse needs support and socialization with other young mothers. How will you locate community resources that are helpful to young families? Decide what parenting information would be helpful to build Clarisse's confidence in caring for Sahil without her husband present. Suggest some ways that she, Sahil, and the father can communicate with each other regularly.
4. The major health problem for infants is related to safety hazards. Sahil is becoming more mobile and curious. Write a teaching plan that includes topics and specific teaching requirements at his age.

Chapter 7
Health Promotion and Maintenance for the Newborn and Infant

Anneka/Shutterstock

I knew having twins would be a challenge, but so far it has worked well. I am just concerned that as they continue to grow we will have trouble getting them both to sleep and eat on the same schedule.

—Mother of Sheridan and Cyrus, twin 10-day-old boys

Learning Outcomes

7.1 Synthesize the areas of assessment and intervention for health supervision visits of newborns and infants: growth and developmental surveillance, nutrition, physical activity, oral health, mental and spiritual health, family and social relations, disease prevention strategies, and injury prevention strategies.

7.2 Plan health promotion and health maintenance strategies employed during health supervision visits of newborns and infants.

7.3 Recognize the importance of family in newborn and infant health care, and include family assessment in each health supervision visit.

7.4 Integrate pertinent mental health care into health supervision visits for newborns and infants.

7.5 Evaluate data about the family and other social relationships to promote and maintain health of newborns and infants.

Health Promotion and Maintenance for the Newborn and Infant

The month following delivery is a time of huge transition for the new mother and her family. Not only is the mother coping with hormonal shifts and a **postpartum** (after giving birth) body, but roles and relationships are also changing. The role of the nurse is to assess knowledge about self-care and newborn care, teach health promotion and maintenance activities, promote parental confidence in newborn caregiving, and facilitate a partnership among healthcare professionals and the family.

Infancy is a major life transition for the baby and parents. The infant accomplishes phenomenal physical growth and many developmental milestones while the family adapts to the addition of a new member and establishes new goals for each of its existing members. Infant health supervision visits are very important to support the health of the baby and the family unit. These visits begin after the newborn period, at about 1 month of age. This is the time when parents establish an ongoing partnership with a healthcare provider. A "medical home" or "pediatric healthcare home" is identified to serve the baby's health needs. The goals of health supervision visits are to identify and address the health promotion and health maintenance needs of the infant.

Facilitating breastfeeding, helping parents understand their newborn's/infant's temperament, and employing strategies to ensure adequate sleep by the baby and parents are examples of health promotion activities. Health maintenance activities focus on disease and injury prevention. Some examples of these interventions include administering immunizations and teaching about infant car seats.

An established relationship with a healthcare provider and agency is important so that trust develops and the family will feel comfortable about turning to the professionals for information and guidance as the baby grows. Nurses play a vital role in welcoming new families into office and clinic settings, establishing rapport, and applying principles of communication so that trust and positive partnerships develop between providers and families. Infancy is a time when the child grows in physical, psychologic, and cognitive ways; health supervision visits play a key role in fostering healthy growth and development. When should the infant be seen for health supervision visits? What are key components of these visits? How can the nurse best assess and intervene to ensure the infant's health and safety? These are some of the questions that will be answered in the chapter.

Early Contacts With the Family

Most obstetric healthcare providers encourage the expectant mother to choose her newborn's healthcare provider prior to the baby's birth (see *Clinical Reasoning: Choosing the Newborn's Healthcare Provider*). Pediatric healthcare providers usually welcome a short office visit, sometimes at no charge, to allow the expectant mother and healthcare provider to assess their compatibility prior to initiating the healthcare provider relationship. Many pediatric healthcare providers provide written information to expectant parents, explaining their professional philosophy of care as well as information about services.

Clinical Reasoning **Choosing the Newborn's Healthcare Provider**

Parents are encouraged to visit the pediatric healthcare home before the baby is born. This will help the parents decide if the healthcare provider offers the type of care they want for their infant. Prepare a list of questions that parents could ask during a visit to the provider they are interested in interviewing. Be sure this list addresses the availability of healthcare providers, frequency of well-child supervision, cost and insurance information, and other pertinent topics.

Health promotion and maintenance for the newborn begin during the stay in the hospital or birthing center. On discharge, referral may be indicated to a lactation consultant or follow-up healthcare visit. The hospital length of stay for a healthy mother and newborn after term delivery is short, approximately 48 hours for a vaginal birth and 72 to 96 hours for an uncomplicated cesarean birth. Discharge of the mother and baby should occur only after appropriate growth is confirmed and a thorough physical examination shows normal results. There should be time to identify any problems and to make certain that the family can care for the newborn at home, and ideally the mother and newborn should be discharged together (AAP, 2011a; AAP, n.d.). For newborns discharged between 48 and 72 hours of age, the first follow-up healthcare visit should occur by 5 days of age. The purpose of this visit is to ensure that the newborn is continuing to progress normally and that no previously undiscovered problems have surfaced. At this initial contact, the nurse promotes maternal confidence in caregiving and offers education and anticipatory guidance. Careful assessments are made for hyperbilirubinemia, feeding problems, or other abnormalities. Further visits are established as needed from 5 days to 1 month; the first scheduled health supervision of infancy is at 1 month of age.

Health promotion and maintenance for infancy occur in a series of health supervision visits during the first year of life. Schedules vary among facilities, but a common pattern includes visits at about 1 month, 2 months, 4 months, 6 months, 9 months, and 1 year of age. In addition, most children have some episodic illnesses such as gastrointestinal illness or otitis media and visit the facility at other times for treatment of these illnesses. A few children have chronic or serious healthcare problems during the first year, and have extensive contact with the healthcare home and other services.

During these first visits, assess the family for protective factors and risks. Protective factors might include knowledge level of infant needs, support from family and friends, and the mother's good health and nutritional state during pregnancy. Risk factors could include limited financial resources, lack of preparation for the baby, and illness or other stress among family members. Ask about how the family traveled to the visit, and if convenient times and transportation are available. Lack of access during times the family is not at work and other health system barriers sometimes interfere with attendance at health supervision visits. Knowledge of risk factors will shape the nursing interventions during the first health supervision in infancy. The nurse applies health promotion principles by building on strengths and fosters health maintenance by intervening to minimize risks.

General Observations

When the family comes to the clinic or office for care with a newborn or infant, general observations should begin at first contact (Figure 7–1). Welcome the family warmly to the facility and

Figure 7–1 **General observations. The nurse begins assessment of the infant's family when they are seen in the waiting room and called in for care. What observations can you make of the infant's general appearance? Developmental accomplishments? Interaction of parents with the baby?**

comment on the baby. Ask how the family is doing with the baby and how the adjustment is going. Be alert for signs of fatigue or depression in the parents, as these can occur when caring for an infant and can interfere with bonding and positive transition. Look for clues about cultural orientation. The nurse gathers information in order to assess the needs of the family, to invite discussion, to validate positive parenting efforts, and to promote partnership between the family and the healthcare team. When entering the examination room, it is helpful to explain the plans for the visit, such as:

> I will weigh and measure Sarah now and show you how she is growing. Then I'll ask a few questions about her eating, sleeping, and other things. Then the nurse practitioner will be in to do Sarah's physical examination. Do you have any questions as we start? Will you undress Sarah now so we can weigh her accurately?

Growth and Developmental Surveillance

Assessment of growth and development begins at birth and continues in newborn and infant health promotion and maintenance visits. (See Chapter 4 for important background/theoretical information about growth and development.) Note the posture, flexion, reflexes, and physical attributes that help evaluate gestational age. Physical growth and meeting of developmental milestones provide important information about infants. The baby is measured for accurate length, weight, and head circumference (Figure 7–2). (See the *Clinical Skills Manual* SKILLS and Chapter 5 for detailed information about the physical examination.) The measurements should be placed on growth grids and interpreted. Parents enjoy seeing how the baby is progressing and are usually eager to learn about the child's weight gain and growth percentiles. Be alert for an infant who demonstrates a change in percentile range. For example, if the baby was in the 75th percentile for length and weight at birth, but has fallen to below the 50th percentile for weight, additional assessment of the baby's feedings is needed. Likewise, if the head circumference is much lower or higher than the length and weight percentiles, further neurologic and developmental assessment should be done.

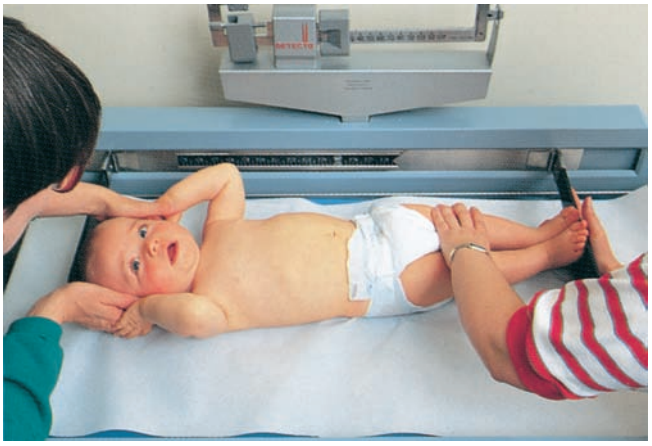

Figure 7–2 Measuring physical growth. Weighing and measuring length during health supervision visits provides important information about the child's nutrition and general development. This young infant was measured and then while the parents dressed the child the nurse placed the findings on the growth grid.

Growth measurement is followed by a physical assessment. The nurse may complete parts of the assessment, with the remainder performed by the physician, nurse practitioner, or other primary care provider. The assessment evaluates each body system, with particular attention being paid to the heart, skin, musculoskeletal system, abdomen, and neurologic status. See Chapter 5 for assessment of the newborn and a thorough discussion of physical assessment throughout infancy and childhood.

Developmental surveillance is integrated into each infant healthcare visit by observing developmental milestones in the infant. (See Chapter 4 for a summary of milestones expected at different ages.) When there is no opportunity to observe a skill directly, ask parents about whether the infant performs the skill (see *Developing Cultural Competence: Cultural Influences on Developmental Tests*). In addition to direct observation, parents are usually requested to fill in a form that asks questions about common developmental tasks. Review the results and determine if additional questions should be asked. Signs of **developmental delay**—a delay in mastering functions, such as motor coordination and behavioral skills—in a full-term infant usually merit immediate investigation by a pediatrician, pediatric developmental specialist, pediatric neurologist, or a multidisciplinary team of professionals. Parents require additional emotional support, clear and honest communication, and resources to cope with the stress of this situation.

Developing Cultural Competence Cultural Influences on Developmental Tests

Be alert for differences in cultural practices and beliefs that may influence developmental milestones. For example, if a child is kept on a cradleboard for much of the time, the baby may be slow in learning to crawl. This baby may progress directly to standing by furniture without demonstrating as much creeping or crawling as other infants. If an item such as "waves good-bye" or "plays patty-cake" represents a practice not common in another culture, the child may not have had exposure to the skill. Be alert for cultural variations, allow the child time to learn a developmental skill, and retest during future healthcare visits.

The nurse establishes health promotion and maintenance interventions related to growth and development assessment data. Anticipatory guidance related to development is a major component of health promotion. The nurse anticipates the next milestones the infant will be meeting, and recommends ways for the parents to support the infant in progression. Some health promotion activities include:

- Teach about introducing foods that will foster growth.
- Encourage use of toys and activities that will assist in meeting the next developmental milestones.
- Demonstrate gross and fine motor skills that the infant has achieved.
- Demonstrate to parents how the child will focus on their faces and mimic their vocal sounds.

Other interventions are focused on health maintenance or disease and injury prevention. Safety hazards and ways to avoid them are discussed, and parents are given brochures, website addresses, or videotapes to enhance injury prevention information. Can you outline additional health promotion and health maintenance interventions that relate to the newborn's/infant's growth and development?

Nutrition

The importance of nutrition during the newborn period and the first year of life cannot be overemphasized. Babies will triple their birth weight by 1 year of age and therefore have a great need for nutritional balance. From the first sips of breast milk or formula as a newborn, to eating the family meal at 1 year of age, the fast progression of nutritional intake patterns is obvious. See Chapter 14 for details about the importance of breastfeeding and a thorough description of nutritional needs for the infant.

During each visit the nurse seeks to learn what the baby is eating, and whether the family has any questions or concerns related to intake (Holt, Wooldridge, Story, et al., 2011). Open-ended questions are a good way to begin, with more specific questions inserted after the parent's perceptions are known. Breastfeeding is encouraged and supported during the newborn and infancy periods, and information about safe formula feeding is provided when the family has chosen that method of feeding. Once the baby is in the second half of the first year, food patterns of the family become more important. Consider childcare settings as well.

Observations from other portions of the visit can provide clues about additional questions to ask. If an infant has not gained weight as expected and has fallen into a lower weight percentile, more specific analysis of intake is needed. Ask for a recall of the baby's intake in the previous day. When the baby does not meet developmental milestones on schedule or is lethargic, intake may be inadequate for age. In these cases, support may be needed to ensure adequate intake; a thorough description of feeding may be the first step in analyzing the problem and planning interventions. When the child's ability to take in nutrients or the parent's ability to feed the baby is questioned, an observation of a feeding might take place, either at the healthcare setting or during a home visit.

Additional nutritional assessment measures are used at certain points in the first year. A hematocrit or hemoglobin is generally performed between 9 and 12 months of age. Lead screening may be needed in certain population groups (see Chapter 17 for more information). Food security screening can be used when appropriate (see Chapter 14) (AAP Committee on Nutrition, 2013). Each visit includes nutritional teaching about important items. The topics for discussion vary according to age group. See Table 7–1 for suggested teaching topics at specific ages. Desired outcomes for nutrition in infancy include adequate growth, normal nutritional assessment findings, and knowledge by parents of the nutritional needs of the infant.

Physical Activity

Muscle development begins early in fetal life. The flexed position of the newborn demonstrates development of the flexor muscles and relaxation of the extensor muscles. This flexed position protects the newborn, conserves energy by reducing movement, and reduces heat loss. During the first month of life, the newborn gradually "unfolds" and the body straightens. Movements begin to change from reflexive to purposeful.

TABLE 7–1 Nutrition Teaching for Health Promotion and Health Maintenance Visits

AGE	NUTRITION TEACHING	
Newborn	Support breastfeeding efforts. Teach correct formula types and preparation if used. Teach burping and rate of feeding information.	Encourage families to view feedings as social interactions; emphasize importance of holding the newborn and not propping bottles.
1 month	Continue teaching listed above. Offer support for breastfeeding and reinforce that breast milk is the only intake needed by infants at this age.	
2 months	Continue teaching listed above. Review fluid needs of infants. Reinforce food safety for partially used bottles of breast milk or formula. Use warm water for heating bottles rather than microwave to avoid burning.	Warn against feeding honey in the first year of life due to risk of botulism. Begin daily cleaning of infant gums. Provide information about any supplements needed (e.g., iron for premature infant; continuation of 400 International Units/day of vitamin D for all infants).
4 months	Continue teaching listed above. Discuss introduction of first foods between 4 and 6 months, and surveillance for symptoms of allergy or intolerance.	Discuss changing food patterns such as increasing amounts and decreasing numbers of daily milk feedings.
6 months	Continue teaching listed above. Reinforce proper introduction of new foods, to include rice cereal, vegetables, and fruits. Discuss any unusual food reactions observed. Introduce cup for drinking. Introduce soft finger foods.	Serve juice only in a cup and limit to no more than 6 oz daily. Caution about common choking foods and items. Provide information about fluoride supplement if water supply is not fluoridated.
9 months	Continue teaching listed above. If mother does not continue to breastfeed, teach family to use iron-fortified formula for the first year of life. Encourage self-feeding of finger foods, integrating common foods for the family.	Introduce source of protein such as tofu, cheese, mashed beans, and slivers of meats.
12 months	Continue teaching listed above. Support mother who wishes to continue breastfeeding beyond 1 year of age.	Encourage cups for all feedings other than breast.

TABLE 7–2 Risk and Protective Factors Regarding Physical Activity in the Newborn and Infancy Periods

RISK FACTORS	PROTECTIVE FACTORS
• Premature birth • Delayed developmental milestones • Limited stimulation by family or other care providers • Lack of knowledge by family about infant's physical activity needs • Limited community resources for families with infants	• Meets developmental milestones at expected ages • Has contact with parents, siblings, and others for significant time each day • A supportive environment with room to play safely; stimulating surroundings • Physically active family • Family knowledge about infant's physical activity needs • Community programs that promote physical activity in infants and information for families

Source: Data from Hagan, J. F., Shaw, J. S., & Duncan, P. M. (Eds.). (2008). *Bright futures: Guidelines for health supervision of infants, children, and adolescents* (3rd ed.). Elk Grove Village, IL: American Academy of Pediatrics.

Physical activity is needed for adequate development of fine and gross motor skills in infancy. Unlike other times of life, the focus is on providing only the opportunities for activity, without a need to focus on motivation. As long as infants are meeting developmental milestones and have a stimulating environment that provides opportunity for fine and gross motor activity, they will use their motor skills, thus enhancing their performance. Time should be provided each day for the infant to reach for objects, freely exercise legs and arms, and increasingly use head control.

Playing with parents or others and being surrounded by toys and other stimulating items will encourage motor behavior in all body parts. Ask the parents for a description of the infant's typical day and listen for these types of play periods. Infants should sleep on their backs, but they also need supervised play periods when they are awake that are spent on their stomachs. This encourages developmental skills and lessens flattening of the back of the head from excessive positioning on back (Kadey & Roane, 2012). Observe the physical skills of the infant (see Chapter 4) for motor developmental norms, ask questions about play periods provided, and compose a list of the family protective factors and risk factors in this area. Table 7–2 lists some risk and protective factors related to physical activity of newborns and infants.

Based on the results of assessment and using the concept of anticipatory guidance, the nurse plans appropriate teaching for health promotion. Health maintenance deals with prevention of physical development delays. Examples of nursing activities are teaching parents to allow the arms and legs of infants to be outside of covers for some period each day to enhance movement, and suggesting toys that encourage attention and movement, such as mobiles and music boxes. The nurse evaluates the success of interventions by the child's progression in physical activity milestones at each health supervision visit. Adequate parental understanding of the importance of physical activity and the means of supporting the child's activities is an important outcome of care.

Oral Health

The first teeth begin to erupt about midway during infancy. Two front teeth are common at about 6 months of age. However, even before this, parents lay the foundation for good oral health. The mother's intake during pregnancy and breastfeeding is essential to ensuring adequate availability of calcium and other nutrients that will be used as the infant's teeth develop. The nurse in child health supervision settings ensures that the infant has adequate intake of these nutrients via breastfeeding and other foods. A dietary recall of the mother's intake, as well as the infant's, is one way of assessing for nutrients. When the water supply is not fluoridated, inquire about use of fluoride drops.

Help the family establish healthy dental habits. The parents should wipe the infant's gums with soft moist gauze once or twice daily. This helps to clean residues of food from the gums and gets the infant accustomed to having something wiping the gums, a practice that may assist when toothbrushing begins. Families are also cautioned to avoid having the infant breastfeed when sleeping, to avoid use of bottles in bed, and not to allow the infant to drink at will from a bottle during the day. These practices are linked to **early childhood caries** (see Chapter 14) and can lead to tooth decay. Nurses assess for the presence of teeth and whether patterns are similar to those expected (see Chapter 5 for additional information). It is wise to ask if the infant has had any difficulty with teeth eruption. Many infants have increased crying and disrupted sleep when teething. Suggest comfort measures such as offering cool beverages and safe "teething toys" for the infant. The American Academy of Pediatric Dentistry (AAPD) recommends an oral examination within 6 months of the eruption of the first tooth and no later than 12 months of age. They recommend that the parents establish a "dental home" by that time to ensure ongoing oral care for the child (AAPD, 2013).

Mental and Spiritual Health

The infant's mental health is related to early experiences, inborn characteristics such as temperament and resilience, and relationships with caregivers. The first year of life provides many opportunities for the infant to develop positive mental health; interventions during this important period can enhance the child's future mental status.

One way to evaluate mental health is to look carefully at the growth and development surveillance data that were described earlier. Children who feel secure and have nurturing environments usually grow as expected and perform milestones at usual times. Slow growth and delayed development are sometimes related to feeding disorders of infancy and early childhood (see Chapter 14). In these cases, a disturbed relationship with the primary caregiver influences the psychologic state of the infant and results in decreased food intake. Another way to assess mental health is to observe the child and parent interacting. Does the parent hold the newborn securely and does the infant cuddle and settle into the parent's arms? (See Figure 7–3.) Is there eye contact between parent and infant? Does the parent appear comfortable in holding and comforting the newborn? These interactions indicate bonding or positive attachment.

Figure 7–3 Assessing mental health. Interactions between the parent and infant provide clues to mental health. Do the adult and child appear comfortable with each other? Is eye contact and vocalization present? Are their bodies soft and relaxed or tense?

During the first year, the infant learns to identify the primary caregivers; beginning at about 6 months of age, infants may cry or protest when a person other than a familiar caregiver holds them. This is called **stranger anxiety** and indicates expected attachment to parents. Similarly, infants in the second half of the first year of life may exhibit **separation anxiety** by inconsolable crying and other signs of distress when parents are not present. These behaviors are normal, demonstrate healthy attachment to primary caregivers, and indicate mental health. Help parents to recognize them as expected occurrences. Provide ideas of how to deal with this behavior. The parents can remain in sight and talk to the baby during health supervision examinations. They should be encouraged to hold and comfort the baby after painful procedures like immunizations. Once the infant has experienced that the parent leaves and returns, security in the care of others can emerge.

Another important indication of infant mental health is the ability to comfort oneself. **Self-regulation** is the process of dealing with feelings, learning to soothe self, and focusing on activities for increasing periods of time. Newborns learn how to comfort and calm themselves. Ask parents if the newborn or infant sucks a finger, softly rocks, or otherwise comforts self when distressed. Some infants prefer to be alone and quiet when tired or distressed; others calm better when held, rocked, or placed in an infant swing. Help the parents identify and reinforce the baby's methods of self-soothing, and teach swaddling and rocking techniques. Self-regulation is needed by the baby when learning to go to sleep while tired and agitated. Nurses use health promotion principles to teach about sleep patterns in infants, and implement health maintenance when partnering with families to deal with problem sleep behaviors that lead to infant and parent fatigue (see *As Children Grow: Infant Sleep Patterns* and *Evidence-Based Practice: Infant Sleep*).

The newborn enters a family with spiritual strengths and limitations. The nurse assesses the family and provides additional resources when needed. Although the infant is not mature enough to understand the family's spiritual framework, the atmosphere in the family that relates to nurturing, valuing children, providing a safe and secure environment, and recognizing mental balance is conveyed readily to the infant. The infant's social and psychologic health are closely related to these factors. Assess the family's meaningful activities and engagement in faith-based practices. Ask if they have needs or desires for

EVIDENCE-BASED PRACTICE | Infant Sleep

Clinical Question

Many babies have limited sleeping periods during the night, and their night awakenings disturb parents' sleep. Parents may have busy days and be unable to nap and, hence, possibly not be able to perform at a safe and productive level during the day. Parental stress and depression are associated with frequent child awakenings. What strategies are needed to assist them in supporting the infant's sleep?

The Evidence

Sleep of the infant is an important concern for many parents, but there is little research-based evidence about what strategies really improve infant sleep. A study of 314 twin pairs found that most sleep disturbances in early childhood are linked to environmental factors, and thus behavioral interventions with parents are suggested for altering infant sleep patterns (Brescianini, Volzone, Fagnani, et al., 2011). Consistent with these findings, a study evaluating 170 parents for knowledge of child sleep found that most parents could not answer the majority of questions correctly. The researchers suggested that evaluating parental knowledge and teaching about developmental progression of sleep patterns should occur during health visits (Schreck & Richdale, 2011). A cross-cultural study found that parents from predominantly Asian countries were more likely to identify sleep disturbance in their children than those from countries with a majority of White parents. These findings suggest that information is needed about cultural differences in sleep expectations of parents (Sadeh, Mindell, & Rivera, 2011).

Best Practice

This evidence-based practice provides implications for nursing care. Ask parents of young newborns to record the infant sleep patterns. As the infant nears 3 to 4 months of age, patterns should demonstrate few night wakenings and feedings. Teach parents about how to minimize stimulation and interaction at night. Provide opportunities to review results at future health supervision visits, or offer telephone or other support to parents.

Clinical Reasoning

What reasons might working parents have for responding eagerly and interacting with an infant who awakens at night? Do you think there are other reasons why infants awake at night? What clues help you to decide if an infant sleep problem exists?

As Children Grow: Infant Sleep Patterns

- **In the first 6 months, infants sleep from 14 to 18 hours each day.**
- **The number of night awakenings varies for infants and may even vary from night to night.**
- **Nurses can teach parents that variability in sleep patterns is common, and not usually the result of changes in the infant's daily schedule.**
- **From 6 to 12 months, infants generally sleep 12 to 14 hours daily, with longer sleep periods at night and accompanied by one to three naps daily.**
- **Parents can be encouraged to settle on a nighttime routine for the infant, such as a short quiet playtime, bath, breastfeeding, or bottlefeeding with decreased lighting and soothing music.**

Source: Data from Middlemiss, W., Yuare, R., & Huey, E. L. (2014). Translating evidence-based knowledge about sleep into practice. *Journal of the American Association of Nurse Practitioners*. doi:10.1002/2327–6924.12159

referrals in the community such as to an organized religious body or other meaningful activities.

Many of the nurse's interventions are aimed at healthy mental health development in the infant. Health promotion activities focus on teaching parents the needs of infants for security and interaction. Suggest healthy sleep patterns starting with the newborn visit and explain how they can be achieved. Teach self-regulation skills so that the parents can help the infant become quiet and calm. Health maintenance seeks to identify infants with disruptions in mental health status, often manifested by growth or interaction abnormalities. When the infant has disturbed sleep patterns or difficulty calming self when upset, or the parents do not interpret infant cues related to hunger or discomfort, the nurse plans interventions to help prevent further problems. An expected outcome for these activities is the reestablishment of expected growth and development and age-appropriate interactions of the infant with others.

Relationships

Family adaptation to a new baby begins in pregnancy, and evidence of initial family adaptation to pregnancy may be predictive of future parental coping (Hagan, Shaw, & Duncan, 2008). The family is the primary site where the infant learns to interact with other people. Therefore, family dynamics must be examined during health supervision visits. Strengths and needs of the family are identified during psychosocial screening. Some factors in the mental health of the parents directly affect the atmosphere in the home, and the resulting health of the newborn and infant. Depression in parents or other family members is an important condition that has the potential to influence the infant's health. Interactions with parents who are depressed will be altered; caretaking, both physical and emotional, can be impaired. Another challenge to the mental health of families and the infants in these families is that of domestic violence, a situation in which parents or adult care providers commit violent acts toward one another. Child abuse or maltreatment is another risk that occurs in some families with infants. This problem is a serious issue that causes disturbed mental status in the baby. See Chapter 17 for a detailed description of child abuse and its effect on infants and older children. Suspected child abuse must be reported to legal authorities in order to protect children.

The infant's social interactions both within and outside the family display unbelievable growth in the first year. The role of the nurse related to infant social interactions in health supervision visits is to evaluate the social skills of the infant, learn what parents have noticed about the baby's temperament and how it fits with their lives, and make suggestions for positive social development. Desired outcomes for the infant include establishment of close relationships with parents and other family members, a stimulating home environment that is responsive to the baby's temperament, and developmental progression in social interactions.

Disease Prevention Strategies

Disease prevention in the newborn period includes metabolic screening, hearing screening, eye examination, immunization, prevention of environmental smoke exposure, sudden infant death syndrome (SIDS) risk reduction, formula safety, minimizing exposure to disease, and hand hygiene for the family.

Infants are prone to many infectious diseases, especially once passive immunity from the mother wanes at about 6 months of age (see Chapters 16 and 22). Recommended immunizations are administered on schedule to provide protection from some diseases. Recommended immunizations for newborns and infants are listed in Table 7–3. Further details on immunizations can be found in Chapter 16. Instruct parents about upcoming immunizations and when the infant should be seen again. Be sure the parent understands the risks and benefits of each immunization. Answer their questions truthfully, and have resources on hand such as brochures and videotapes for interested parents.

TABLE 7–3 Routine Immunizations Recommended During Newborn and Infancy Periods

IMMUNIZATION	AGE RECOMMENDED
Hepatitis B	At birth (1st dose) 1–2 months (2nd dose) 6–18 months (3rd dose)
Hepatitis A	12 months (1st dose) 18 months or at least 6 months after 1st dose (2nd dose)
Diphtheria, tetanus, pertussis	2, 4, and 6 months (3 doses)
Rotavirus	2 and 4 months (2 doses) **OR** 2, 4, and 6 months (3 doses) (The requirement of 2 or 3 doses is related to which of the two available vaccines is used.)
Haemophilus influenza type b	2, 4, and 6 months (3 doses; 3rd dose is not needed if PRP-OMP [Pedvax HIB or Comvax] is used for primary series)
Inactivated poliovirus	2, 4, and 6–18 months (3 doses)
Pneumococcal	2, 4, and 6 months (3 doses)
Influenza	Annually from 6 months

Families Want to Know

When to Contact the Healthcare Provider

Instruct parents to contact a healthcare provider if the child has:

- Axillary temperature ≥99.3°F (37.4°C) (Identify for the provider the technique used for temperature measurement, such as axillary, forehead, oral, rectal, or ear, so adequate evaluation can be made.)
- Seizure
- Skin rash, purplish spots, petechiae
- Change in activity or behavior that makes the parent uncomfortable
- Unusual irritability, lethargy
- Failure to eat
- Vomiting
- Diarrhea
- Dehydration
- Cough

Source: Data from Hagan, J. G., Shaw, J. S., & Duncan, P. M. (Eds.). (2008). *Bright futures: Guidelines for health supervision of infants, children, and adolescents* (3rd ed.). Elk Grove Village, IL: American Academy of Pediatrics.

During each health supervision visit in infancy, the nurse performs recommended screenings and counsels the parents about why such screenings are important. Vision and hearing screenings are consistently performed. Screenings for anemia and lead poisoning are added at particular times or with certain groups. Families with certain genetic diseases such as sickle cell disease or cystic fibrosis may choose to have screening for the infant so that supportive care can begin early if the child has the disease. Parents benefit from learning about common diseases and conditions of young children and measures for their prevention. Ask about secondhand smoke (environmental tobacco smoke) and encourage smoking parents to quit. Teach parents to put infants to sleep on their backs to assist in lowering the chance of SIDS (see Chapter 20 for a thorough discussion of SIDS). Be sure parents have a phone number to call when they have questions about conditions or whether the baby should be seen by the healthcare provider (see *Families Want to Know: When to Contact the Healthcare Provider*). Evaluate the family's ability to understand verbal and written instructions. Desired outcomes for disease prevention strategies include adequate management of health problems, integration of immunization and other preventive measures into care of the infant, and family understanding of preventive measures recommended for infants.

Injury Prevention Strategies

New parents are sometimes unaware of sources of potential injury for the newborn. Some aspects of injury prevention are pertinent to the newborn's immediate care and other topics promote discussion and provide opportunities for anticipatory guidance during all of infancy. In the immediate newborn period, the nurse should assess the parents' knowledge of injury prevention strategies, and promote healthy and safe behaviors. Injury prevention strategies include proper and consistent use of an infant car seat and strategies to prevent falls, burns, choking, drowning, and suffocation.

During the first year of life, injury becomes an increasingly common cause of mortality. Strategies must be included in every health supervision visit to lower the risk of injury. Nurses should never assume that parents understand how to insert an infant car seat correctly or what types of toys and foods can lead to choking. Know the most common hazards at each age and teach parents methods of avoiding them (Tables 7–4 and 7–5).

Begin the conversation by asking parents what safety hazards they are aware of in the child's environment. Use this information as the starting point for discussion. Give positive feedback for their awareness of hazards and measures they have taken to prevent them. Consider using a home assessment survey that assists parents in identifying hazards that may be present in their homes. When infants visit friends, relatives, or neighbors, they may be exposed to other hazardous situations. Grandparents may not have a home that is "baby-proofed" and the infant could have access to electrical cords, machinery, medicines, or other hazards. Help the parents to evaluate the childcare home or center. Focus on car safety since this is a frequent cause of injury for infants. Provide brochures and other types of information about recommendations. Refer every family for a car seat examination at a certified examination center. Provide resources for car seats if the family is not able to afford one. Discuss other possible safety hazards such as extensions on the parent's bicycle and use of baby strollers in areas where cars are present.

Nursing Management

For the Health Promotion and Maintenance of the Newborn and Infant

Nursing Assessment and Diagnosis

The nurse working in clinics, offices, and other settings that offer primary care for newborns and infants should be skillful in assessing health promotion and health maintenance. The infant's growth, developmental level, general physical health, and mental/social health are assessed. Family interactions and other settings where the infant spends time are evaluated for risks and protective factors that influence the child's development. Assess the health of siblings and patterns of integrating the infant into the rest of the family. Particular attention is directed at assessment of risk for diseases and injuries. The data-gathering phase always provides parents with the opportunity to ask questions and relay concerns. Further assessment may need to be directed at these areas.

TABLE 7–4 Injury Prevention in Infancy

HAZARD	DEVELOPMENTAL CHARACTERISTICS	PREVENTIVE MEASURES
Falls	Mobility increases in first year of life, progressing from squirming movements to crawling, rolling, and standing.	Do not leave the newborn or infant unsecured in infant seat, even in newborn period. Do not place on high surfaces such as tables or beds unless holding child. ***(A)*** Once mobile by crawling, keep doors to stairways closed or use gates. Standing walkers have led to many injuries and are not recommended.
Burns	Infant is dependent on caretakers for environmental control. The second half of the first year is marked by crawling and increased mobility. Objects are explored by touching and placing in mouth.	Check temperature of bath water and food/liquids for drinking. Cover electrical outlets. Supervise infant so that play with electrical cords cannot occur.
Motor vehicle crashes	Infant is dependent on caretakers for placement in car. On impact with another motor vehicle, an infant held on a lap acts as a missile.	Use only approved restraint systems (according to federal motor vehicle safety standards). The seat must be used for every trip, even if very short. The seat must be properly buckled to the car's lap belt system. ***(B)***
Drowning	Infant cannot swim and is unable to lift head.	Never leave a newborn or infant alone in a bath of even 2.5 cm (1 in.) of water. Supervise when in water even when a life preserver is worn. Supervision should be provided by adults, not older children. Flotation devices such as arm inflatables are not certified life preservers.
Poisoning	Newborns and infants are dependent on caretakers to keep harmful substances out of reach.	Keep medicines out of reach. Teach proper dosage and administration of medicines to parents. Cleaning products and other harmful substances should not be stored where the infant can reach them. Remove plants from play areas. Have poison control center number by telephone.
Choking	The second half of infancy is marked by exploratory reaching and mouthing of objects. Infant explores objects by placing them in the mouth. ***(C)***	Avoid foods that commonly cause choking. Keep small toys away from infants, especially toys labeled "not intended for use by those under 3 years."
Suffocation	The newborn and young infant have minimal head control and may be unable to move if vomiting or having difficulty breathing.	Position newborn and infant on back for sleep. ***(D)*** Do not place pillows, stuffed toys, bumpers, blankets, or other objects in the crib (AAP, 2011b). Do not use plastic in crib. Avoid latex balloons. Co-sleeping with the parent is discouraged because of the danger of suffocation. Sleep with the baby near but not in the parental bed.
Strangulation	Infant is able to get head into railings or crib slats but cannot remove it.	Be sure older cribs have slats spaced no more than 6 cm (2⅜ in.) apart. The mattress must fit tightly against the crib rails.

A Never leave infant unsecured or on high surface.

B Always use approved restraint system.
Place infant in rear-facing seat in back seat of car.

C Explores objects with mouth.

D Place infant on back for sleeping; keep toys clear.

TABLE 7–5 Injury Prevention Topics by Age

AGE	INJURY PREVENTION	TEACHING TOPICS
Birth–1 month	Use car safety seat approved for the newborn or infant; install as directed in rear-facing direction in the back seat. Put baby to sleep on back. Avoid loose bedding and toys in crib; avoid clothes and blankets with loose strings and do not tie a pacifier around the neck. Avoid tobacco use in the environment. Provide adult supervision of the baby at all times by trusted individuals. Test bath water temperature and never leave the baby alone in the bath.	Never place baby on high object such as counter, table, or bed; always keep one hand on the baby during activities like diaper changes to prevent falling. Wash hands correctly and often. Avoid contact with persons with communicable diseases. Have smoke alarms and avoid fire hazards. Learn infant CPR and airway obstruction removal. Never shake the baby. Have plans for emergency care.
2 months	Follow the above. Use only recommended playpens or cribs and keep sides up. Avoid moldy environments. Keep baby toys cleaned.	Avoid exposure to direct sunlight for the baby. Keep sharp and small objects out of baby's environment. Keep hot water heater lower than 120°F (49°C). Review emergency plan with all care providers.
4 months	Follow the above. Get all poisonous substances out of baby's view and reach; install locks to keep them inaccessible.	Do not use latex balloons or plastic bags near the baby.
6 months	Follow the above. Use only a car seat approved for the weight of the child and always use the seat in rear-facing position in the back seat. Empty containers of water immediately after use; be sure pools or other bodies of water are locked and not accessible to baby. Use sunscreen, hat, and long sleeves when baby is in the sun. Keep heavy and sharp objects out of reach; check that all poisons are locked away including in homes visited; keep pet food and cosmetics out of reach.	Do not drink hot liquids or eat soup while holding the baby. Have poison control number by phones and programmed into cell phones. Be alert for dangers of hot curling irons and other appliances. Have electrical cords out of reach and not hanging down. Have home and environment checked for lead hazards. Lower infant crib mattress if still in upper position. Install gates and guards on stairs and windows. Never use an infant walker.
9 months	Follow the above. Crawl on the floor and look for hazards at baby's eye level. Pad sharp corners on tables and other furniture.	Watch for tables, chairs, and other devices the baby may use for climbing to unsafe places.
12 months	Follow the above. Keep the infant in a rear-facing car seat until 2 years of age; place in back seat and never in front seat with a passenger air bag; have installation checked for safety. Start teaching the child to wash hands frequently, demonstrating and washing with the child. Provide own personal items such as clothing and blankets to childcare providers; wash often. Change batteries in home smoke alarms and check system.	Turn handles to back of stove; use back rather than front burners; watch for hot liquids. Check care provider setting for safety hazards. Remember that responsible adults should always supervise your infant, not other children. Peruse home once again for hazards now that the child is more active, climbing, and walking. Check playgrounds for hazards and always supervise the child in a playground.

Source: Data from Hagan, J. G., Shaw, J. S., & Duncan, P. M. (Eds.). (2008). *Bright futures: Guidelines for health supervision of infants, children, and adolescents* (3rd ed.). Elk Grove Village, IL: American Academy of Pediatrics.

Based on the assessment data, the nurse establishes nursing diagnoses that become the basis for nursing interventions. Both areas of strength and need are included; often the family's strengths can be used to further promote health. Nursing diagnoses established during a health supervision visit of an infant might include the following (NANDA-I © 2014):

- ***Breastfeeding, Readiness for Enhanced,*** related to the mother's confidence and knowledge
- ***Breastfeeding, Interrupted,*** related to the mother's resumption of employment outside the home
- ***Coping: Family, Compromised,*** related to recent role changes
- ***Attachment, Risk for Impaired (Parent/Child),*** related to anxiety associated with parenting role
- ***Sleep Pattern, Disturbed (Infant),*** related to frequently changing sleep routines and cycles

- ***Skin Integrity, Impaired (Infant),*** related to developmental factors
- ***Infection, Risk for (Infant),*** related to inadequate acquired immunity
- ***Injury, Risk for (Infant),*** related to design of environment
- ***Development: Delayed, Risk for,*** related to parental substance abuse

Planning and Implementation

The nurse plays a vital role in successful health promotion and health maintenance activities. The newborn period is essential for building a relationship between parents and healthcare professionals that sets the stage for the months and years to come. Explain to the parents what procedures are being performed and their purpose. Encourage them to ask questions and share their perceptions of the infant's personality, development, and other traits. This will enhance their understanding that health care involves a partnership between them and the care providers. It will lead to trust that promotes their ability to share concerns honestly. The first year of the baby's life is a key time for establishing a trusting relationship with health professionals.

Recognize the importance of data provided by simple assessments such as length and weight. Analyze all findings to learn if the child is developing as expected. Much of the visit is spent in teaching parents about topics such as safety measures, providing anticipatory guidance related to development, assisting with integration of the newborn into the family, and relaying resources for support of the family in the community, on the Internet, or in other areas. Parenting classes, childcare facilities, and family planning resources are examples of common parental needs. Perform recommended physical and developmental assessment, administer screening tests, and give immunizations. Be sure parents understand the need for tests and treatments, and relay the results of tests to them.

Nurses who work in hospitals, emergency services, and other facilities are an important link in health supervision. Ask where and how often the child is seen for care. Check immunization schedules to be sure they are up-to-date. When the child is not being seen regularly, find out if the family does not know the importance of these visits or lacks resources to obtain the necessary care. Refer them to resources as needed so that they can identify a pediatric healthcare home. Some agencies that provide health supervision are equipped to perform home visits on a regular basis or in case of special need. When nurses make regular home visits to families with many risk factors, health outcomes are improved. Seeing the family in the natural setting enables the nurse to tailor interventions to the specific situation. Nutrition, safety, and other teaching is more effective when it matches the family's needs. For example, showing how to set up a stimulating environment with safe materials, even if toys are limited, is an effective nursing strategy. Ensure that home visits are performed whenever appropriate and available either through the pediatric healthcare home or other community agency.

Before the family leaves the facility, be sure they have the next appointment scheduled. Summarize content of the present visit, emphasizing the family's strengths and the baby's newly acquired developmental skills. Sensitively list any areas that require work in the coming weeks, such as baby-proofing the home or encouraging the infant to reach for objects. Provide a journal or notebook in which the parents can record the infant's development and write down questions to ask during future visits. Suggest possible topics for the parents to think about, and provide books, brochures, and other printed material.

Evaluation

Expected outcomes of nursing care for the infant and family in health promotion and health maintenance include the following:

- Parents state common safety hazards at the infant's present and upcoming ages.
- The newborn and infant demonstrate normal patterns of growth and progression in developmental milestones.
- The newborn and infant remain free of disease and injury.
- The newborn and infant are well adjusted, showing positive response to the environment and interactions with significant others.

Chapter Highlights

- The first contact between the infant's pediatric healthcare home and the parents should ideally occur prior to birth.
- A trusting relationship between the family and the healthcare provider fosters a partnership that is influential in promoting the development of the newborn or infant.
- The nurse establishes diagnoses based on a thorough assessment of the child and family during healthcare visits.
- The nurse and family collaboratively establish goals for the newborn or infant, and the nurse plans interventions to meet these goals.

Clinical Reasoning in Action

Lipik/Shutterstock

Chad and Jeremy are parents of an adopted newborn. They are eager to learn as much as possible about newborn development, nutrition, and general care. Chad will remain home from work for about 3 months to provide childcare, and both parents will be present on evenings and weekends. They live in a small community and both have supportive family members close. The newborn, Barry, was born after 38 weeks' gestation to a healthy teen mother who allowed the new adoptive fathers to be present soon after birth to meet the baby.

1. Barry is feeding every 2 to 3 hours, and the parents want to know if this is normal. What information about feeding patterns of infants can you provide?
2. Chad and Jeremy are eager to learn as much as possible. What community resources can you explore that provide information to new parents? Does their child's pediatric healthcare home provide educational resources?
3. The birth mother has requested periodic updates and photos about Barry's progress but will not meet him in person. What information is likely to be helpful to her as the baby grows?
4. What questions will you ask to evaluate the parents' knowledge of safety concerns for the newborn?

Chapter 8
Health Promotion and Maintenance for the Toddler and Preschooler

Mommy was really glad to go see the nurse today. She brought our baby and me. Grandma said that they would give us a card that would help us buy food. I'm glad because I'm tired of eating peanut butter. Mommy said we could get some milk and juice, and even some chicken.

—Melody, age 4, sister of 7-month-old Amanda

Learning Outcomes

8.1 Describe the areas of assessment and intervention for health supervision visits for toddler and preschool children: growth and developmental surveillance, nutrition, physical activity, oral health, mental and spiritual health, family and social relations, disease prevention strategies, and injury prevention strategies.

8.2 State components of self-concept for preschool children.

8.3 Plan health promotion and health maintenance strategies employed during health supervision visits of toddlers and preschoolers.

8.4 Discuss the importance of family in child health care, and include family assessment in each health supervision visit.

8.5 Integrate pertinent mental health care into health supervision visits for toddlers and preschoolers.

8.6 Examine data about the family and other social relationships to prioritize interventions and to maintain health of toddlers and preschoolers.

Health Promotion and Maintenance for the Toddler and Preschooler

The years following infancy are challenging for parents as the child grows and acquires new developmental skills. The child progresses from the first tentative steps and words at 1 year of age through the "terrible twos" of toddlerhood and into preschool age when over half of children attend some type of education program, have developed effective verbal communication, and acquire many gross and fine motor skills (Child Trends, 2012). Toddler and preschool ages are often grouped as "young childhood" since the family remains the primary system within which the child interacts. Healthcare providers address common health concerns such as nutrition, sleep, and growing independence. Facing consistent changes in development, parents rely on the "pediatric healthcare home" ("medical home") for advice and information (see Chapter 6). Regular health visits are recommended at 12, 15, 18, 24, and 30 months and at about 3, 4, and 5 years of age. The Recommendations for Preventive Pediatric Health Care (American Academy of Pediatrics Committee on Practice

and Ambulatory Medicine, 2016) provide guidance for the screenings to perform during the toddler and preschool ages. Nurses apply concepts of anticipatory guidance during visits for health promotion and health maintenance to assist parents in the transitions they face. The child should have an established "dental home" as well. Dental visits are generally recommended twice annually.

Health supervision of young children applies to the following:

1. *Assessment*, including screening tests, evaluations, and observations
2. *Education*, including anticipatory guidance about coming developmental tasks
3. *Intervention*, including parent counseling, home visits when appropriate, and scheduling of future visits
4. *Care coordination* among resources serving the family

General Observations

The relationship with the family should be established as a partnership in care of the child. If, however, the family is new to this healthcare home, reach out to welcome family members warmly and express interest in them as individuals and parents. Families may feel uncomfortable in healthcare settings, and it is important to establish positive rapport so they will be able to ask questions and bring up concerns about the child.

While calling the toddler in from the waiting room, it is amazing that this young child is now able to walk in, even if needing some parental guidance. Watch for the child's desire for independence or signs of continuing reliance on the parent. By preschool age, the child is totally independent in walking and usually engages in conversations easily. After welcoming the preschool child warmly, assess the child's social skills and motor activities. Direct greetings or questions to the child to evaluate stranger anxiety and ability to understand simple commands or questions. What verbal skills are observed? Observe the child's general appearance, nutrition, and state of health.

Health supervision visits are adapted for older toddlers and preschoolers to include observations of parental discipline and interaction style. Does the parent respond to the child's questions? Were age-appropriate toys or activities brought to the visit to help occupy the child while waiting? Is the child alert and observant of the environment?

Growth and Developmental Surveillance

An essential assessment integrated into the visit is measurement of growth. Weight and length are measured and compared to expected patterns of growth. When the child can stand upright to be measured, sometime between 2 and 3 years of age, charts for standing height rather than recumbent length are used. Body mass index (BMI) is first calculated at 2 years of age and provides information about the relationship of height and weight (see Chapter 14 for additional information). Head circumference is usually measured until 2 years of age. (Consult growth grids in Appendix A.)

Growth continues to be a primary way of evaluating the child's nutritional status. It may also provide clues about conditions that have not yet been evaluated such as endocrine, cardiac, or other disorders. Depending on the results of growth measurements, the nurse may gather additional data. For a child under the 5th percentile for weight or BMI, detailed recording of nutritional intake should begin. Laboratory studies such as hematocrit and hemoglobin can be performed. Patterns of family growth can be examined. What size are the parents and siblings? Ask if the child has had any illness or hospitalization. For children above the 85th percentile for BMI, detailed dietary intake and physical activity history should be taken.

The physical assessment is performed, with some parts conducted by the nurse and others by the primary care provider such as a physician or nurse practitioner. See Chapter 5 for a thorough discussion of physical examination. The order of the examination and the approaches to the child are particularly important at this age. Leave intrusive procedures such as ear and eye examinations and visualization of genitalia until the end of the examination. Integrate techniques such as allowing the child to play with the stethoscope, asking the child to "blow out" the light from the otoscope, or having the child make a game of pushing the legs against the examiner to measure symmetry of strength (Figure 8–1). Preschoolers are generally interested in their bodies, and teaching about parts of the examination is helpful. During the physical examination, ask the parents pertinent questions. Consider the young child's expected developmental milestones (see information in Chapter 4) and ask questions related to these milestones. Recommended screenings include blood pressure, vision and hearing, autism (at 18 and 24 months; see Chapters 5, 19, and 28), and, for the child at risk, hematocrit, hemoglobin, and lead screening (see Chapters 17 and 23).

Nurses generally have in-depth knowledge of child development through growth and development courses and pediatric nursing curricula, and are thus well positioned to address parental concerns related to child development. Development is the key organizing principle of early childhood health care. Developmental screening and services should be integrated within health care, child care, and school settings to include the multiple sites common for young children. (Refer to Chapter 4 for expected milestones at each stage.) Developmental surveillance is integrated throughout the healthcare visit as you observe the child's fine motor, gross motor, language, and social/emotional skills. Developmental screening or testing is also performed; inquire if the child has had developmental testing done at a childcare agency or another site. Ideal screening tools include input from the family in addition to observations by the healthcare provider. Screening tools currently recommended for young children are listed in Table 8–1. See *Evidence-Based Practice: Fetal Alcohol Spectrum Disorders.*

TABLE 8–1 Developmental Screening Tools for Young Children

TOOL	UPPER AGE
Ages and Stages Questionnaire	66 months
Brigance Screens	1st grade
Developmental Assessment of Young Children, 2nd edition	5 years
Early Screening Profiles	7 years
FirstSTEP	6 years
Parents' Evaluation of Developmental Status	8 years
Survey of Well-Being of Young Children	5 years

EVIDENCE-BASED PRACTICE | Fetal Alcohol Spectrum Disorders

Clinical Question

Alcohol ingestion by the pregnant woman can result in birth defects called *fetal alcohol spectrum disorders (FASD)*, ranging from fetal alcohol syndrome to fetal alcohol effects. Children may have characteristic facial and other physical abnormalities, or they may appear normal but have learning and behavioral difficulties. Early identification of these disorders can prevent one of the primary causes of developmental delay in children. (See Chapter 28 for further information.) What is the nursing role in prevention of FASD, evaluation of young children for the problem, and becoming knowledgeable about community resources for families when a child exhibits FASD?

The Evidence

In a study of First Steps program (designed to provide pregnancy guidance for women at high risk), retrospective analysis of participants demonstrated significant improvement in alcohol abstinence by participants (Rasmussen et al., 2012). However, in spite of prevention efforts, alcohol exposure during pregnancy occurs and can result in serious consequences for young children. A recent meta-analysis found that prenatal alcohol exposure of the fetus was significantly associated with gross motor deficits in children, particularly in balance, coordination, and ball skills (Lucas et al., 2014). Therefore, motor coordination evaluation is critical in young children so that early identification of problems associated with FASD can result in treatment. In a study with practicing nurses and student nurses, student nurses were found to lack knowledge related to binge drinking, facial abnormalities associated with FASD, and diagnosis of the disorder (Zoorob, Durkin, Gonzalez, et al., 2014).

Best Practice

Preventive programs with women at high risk of alcohol ingestion during pregnancy can be helpful to decrease consumption and therefore lower risk of FASD occurrence. In addition, when working with toddlers and preschoolers, the nurse must integrate physical assessment for physical signs of fetal alcohol exposure, as well as developmental screening and, particularly, gross motor performance. Children who have difficulty in this area should be referred for further developmental testing. Student nurses should become familiar with both the physical features present in some children with FASD and the developmental/social behavioral components (see Chapter 28). This is an example of the importance of thorough knowledge of development and comprehensive observations and screening during the physical examination.

Clinical Reasoning

How can you ask questions sensitively to determine use of alcohol and knowledge of FASD among pregnant women? Describe the gross motor skills you expect to see in toddlers and preschoolers and areas that might concern you about their abilities. What resources are present in your community to support the toddler or preschooler who manifests fetal alcohol syndrome disorder?

Topics pertinent for inquiry and anticipatory guidance at health supervision visits of young children include sleep patterns, discipline techniques, toilet training, learning and reading practices, communication, and parental issues and questions. Many children, especially by preschool age, are attending a childcare center (Child Trends, 2012). Ask about the experience and whether developmental skills are a focus of activity. Ask if the parent is pleased with the childcare experience or needs further resources. Guidelines for evaluating childcare settings are available through the National Resource Center for Health and Safety in Child Care and Early Education (2013).

A

B

Figure 8–1 **Examining the toddler or preschooler. The approach to examination of the toddler or preschooler is important in order to elicit cooperation. *A,* The toddler may accept parts of the examination best when seated on the parent's lap as shown in this photo of a boy with his father. *B,* The preschooler likes the opportunity to touch and become comfortable with equipment used or, in this case, holds a doll that receives the same examinations as the child.**

TABLE 8–2 Nutrition Teaching for Health Promotion and Health Maintenance Visits

AGE (YEARS)	NUTRITION TEACHING	
1	Support mother who continues to breastfeed. Wean child from bottle by substituting cup. If beginning to use cow's milk, use whole milk (may change to 2% at 2 years of age). Limit juice to 4–6 oz daily; offer water several times daily; use plain water and avoid flavored water or sugared/electrolyte drinks. Encourage safety measures—use high chair with strap, secure child and use caution in grocery carts, do not allow foods to be eaten in car. Provide information on choking and airway obstruction removal training.	Provide food and water safety guidelines (see Chapter 14). Be sure all major food groups have been introduced. Limit high-fat and high-sugar foods. Review amounts of food commonly consumed and frequency of feedings. Review use of fluoride if water supply is not fluoridated. Educate parents to inquire about water sources in case of lead contamination due to older plumbing systems where pipes could potentially be corroded.
2	Ask if the mother is still breastfeeding and support the decision to continue or to wean child, as she desires. Encourage total removal of bottle if still in use. Ensure that all foods common to family have been offered. Offer child-sized eating utensils. Child can change to low-fat or skim milk if family desires. Limit milk to 2–3 servings daily.	Teach parents methods for dealing with temper tantrums over food—make food available at meal and snack times only, do not force intake, offer a variety of foods. Teach that child may have days of very low intake due to slowing growth rate.
3	Most children are weaned from breastfeeding and drink 1% or 2% milk. Teach normal intake and decreasing number of snacks. Engage child in food preparation and pouring liquids from small pitcher. Recognize that food jags (periods when only 1 or 2 foods are eaten) are common.	Recognize importance of social nature of eating; expect child to sit for a short period at meals with family. Meals and snacks should not be eaten while watching television.
4	Encourage involving child in snack selection and preparation. Start to teach food groups and importance of nutrition for the body.	Alter intake as appropriate depending on weight and BMI. Dairy products consumed should all be low or reduced fat.

Health promotion growth and development issues for toddlers and preschoolers are addressed at each visit. Some common examples include:

- Explaining growth patterns and what is expected in the months ahead
- Providing toys that encourage development of the coming developmental milestones
- Showing parents the child's developmental progression on a screening tool

Likewise, health maintenance activities are included in health supervision visits, with the primary purpose being prevention of disease and injury. Specific examples are included throughout the chapter, but some general areas addressed are:

- Connecting developmental skills with risks for injury such as drowning and motor vehicle crashes
- Recognizing the possibility of exposure to infectious diseases as the child begins a childcare experience and addressing recognition of and treatments for common diseases

Expected outcomes for the child include normal growth and development patterns for motor, language, and social/emotional skills; parental knowledge of stimulating activities for the child; awareness of the family about risks to growth and development; and healthy body systems for the child.

Nutrition

The child's nutritional status continues to play an important part in promoting health and preventing health disruptions during toddler and preschooler years. Good nutrition fosters normal growth patterns, promotes developmental progression, and helps prevent disorders such as anemia, tooth decay, and immune dysfunction. Eating takes on an increasingly social dimension during early childhood as children interact more with adults and other children at mealtimes. See Chapter 14 for further information about nutritional needs and challenges.

For toddlers, questions for the family focus on introduction of foods, the child's eating patterns, and transition from breast or bottle to other liquids. The toddler often consumes small amounts of foods, and parents consequently worry about the change in appetite. Showing them that the child is growing normally can help allay their anxiety about this common developmental variation. Preschoolers interact with others during food preparation and meal consumption. Questions from the nurse should focus on the child's likes and dislikes for particular foods, behavior at the table, and establishment of healthy family eating patterns. Ask how often the family eats out, especially at fast-food restaurants. When parents are busy and older siblings are in activities, both toddlers and preschoolers may be eating foods such as french fries or milk shakes several times weekly. Suggest alternative approaches to the busy lifestyle, such as bringing fresh fruit slices along

when an older sibling is at a sporting event, keeping a cooler in the car to maintain cool items, and limiting fast-food meals to no more than one or two weekly. Obtain nutritional information about common fast-food options in your community and share these with parents. Assist them to make healthy choices when eating out. Encourage the family to set times when they all eat together, even if only a few times weekly. If children help with preparations for this family meal, and then eat together, nutritional knowledge and intake can be positively enhanced. When the child is in a childcare center or home, encourage the parents to find out what food is provided for the child in that setting.

During the toddler and preschool years, children are gaining much more independence about food choices and patterns of eating. At the same time, their eating patterns depend mainly on the family, so assessment should involve the entire family unit (see *Developing Cultural Competence: Family Nutrition*). Parents can benefit from receiving information about nutrition for young children (Table 8–2).

Developing Cultural Competence Family Nutrition

Each family integrates their own cultural backgrounds and past experiences into food preparation and choices. Ask what foods are common in the child's cultural group and help the family learn when to introduce each food. For example, rice may be a first food for an Asian baby rather than rice cereal. Be sure the child also takes in adequate iron sources in the first foods offered. Tofu or bean paste may be a common protein source in some diets. A Native American child may eat fish or wild game, along with berries and roots. Ask and learn about each family's cultural patterns. Learn what you can about cultural groups in your community. Encourage the family to offer the young child their usual foods, as long as they meet needs for requirements, are prepared with minimal salt and seasoning, and are soft enough to avoid choking. Perform diet recalls and analyses to check for any specific teaching needs in all families.

Health promotion interventions include actions such as supporting breastfeeding for young toddlers and being sure preschoolers have a role in selecting foods for healthy snacks. Parental education is influential in shaping their young child's diet and should be integrated into all visits (Holt, Wooldridge, Story, et al., 2011). Important health promotion teaching includes the concept of "5 a day," or ensuring five servings of fruits and vegetables in the daily diet (American Academy of Pediatrics [AAP] Committee on Nutrition, 2013). Likewise, "3 a day of dairy" encourages families to provide at least three servings of dairy for children every day. Nurses and parents partner together to ensure that the young child establishes healthy eating habits at home and in other daily settings. Health maintenance activities focus primarily on disease and injury prevention, with examples of feeding practices that do not include common choking foods, and limiting daily fruit juice intake to prevent dental caries and excessive caloric intake. Desired outcomes related to nutrition include meeting normal growth and development milestones, maintaining a recommended weight, expanding understanding of healthy food patterns, and preventing nutrition-related disorders.

Physical Activity

The toddler and preschooler consistently show gains in fine and gross motor abilities. They walk and run independently and often engage in physical activity in school and other settings. They commonly visit parks, swim, attend childcare centers, and help with some household tasks. These activities are important, both because they assist the child in continuing to develop motor skills and because they limit the amount of time spent in sedentary behavior. The toddler and preschool years are an important time for setting the habits for physical activity during all of childhood.

During toddler years the main emphasis is on providing experiences that encourage further motor development. The child needs to walk, run, hop, push and pull objects, and throw balls. Motor activity is a major component in all playtimes, and activities should engage the child's large and small muscle groups. The National Association for Sport and Physical Education (NASPE) has established recommendations for toddlers and preschoolers: a minimum of 60 minutes per day of unstructured physical activity, a minimum of 60 minutes per day of structured physical activity, and a maximum of 60 minutes of sedentary behavior at any one time exclusive of sleep (Beets, Bornstein, Dowda, et al., 2011; Centers for Disease Control and Prevention [CDC], 2011) (Figure 8–2).

By the preschool years, coordination develops quickly. Physical activity is important for all children, including those with developmental disabilities. The preschooler learns to balance, walk on one foot, skip, and throw and catch with greater accuracy. **Kinesthesia**, or the sense of one's body position and movement, develops during these years. Eye–hand coordination improves at the same time that visual acuity matures. The social component plays an important role as children learn to engage in games and activities cooperatively with others.

Figure 8–2 **This toddler enjoys motor activity that uses large muscle groups. The preschooler spends much of playtime in activities that lead to coordination of both small and large muscle mass. List several physical activities that you can suggest for the parents of children in each of these age groups.**

TABLE 8–3 Risk and Protective Factors Regarding Physical Activity in Toddlerhood and Preschool

RISK FACTORS	PROTECTIVE FACTORS
• Developmental delay • Slow development of social skills	• Expected developmental progression
• Limited stimulation by family or other care providers • Limited social time with other children • Long work hours by parents	• Easily engages socially with others • Regular contact with other young children
• Reluctance to try new physical activity • Limited access to balls, slides, balance beams, tricycles, and other materials that foster physical activity • Adequate safety gear for activities is not available	• Eagerness to try new physical activity • Access to balls, slides, balance beams, tricycles, and other materials that foster physical activity • Adequate safety gear that properly fits child is available
• Parents who have little physical activity on a daily basis • Lack of knowledge by family about child's physical activity needs	• Family members engage in daily physical activity • Family members spend time in physical activity with child • Family understands motor developmental milestones and importance of physical activity in childhood
• Television or other screen activities are engaged in for more than 2 hr daily	• Television and other screen activities are limited to no more than 2 hr daily
• Limited community resources for child care and physical activity • Unsafe neighborhood and lack of lawns, parks, and other facilities	• Neighborhood contains access to child care that integrates physical activity • Neighborhood is safe, and contains lawns, parks, and other facilities

The nurse applies the concept of resilience by identifying both risk and protective factors related to physical activity (Table 8–3). The assessment becomes the basis for nursing interventions, both to reinforce positive physical activity and to make recommendations for changes where needed.

Children and adults are commonly overweight and sedentary in today's society, so emphasis on physical activity should be a part of each health supervision visit. Nurses and parents are partners in planning activities for the young child; patterns set in motion at this early age will continue into the rest of childhood and into adulthood (Simmonds et al., 2015). Suggestions for the family may include setting guidelines to limit television and other screen activities to a maximum of 2 hours daily in order to facilitate adequate physical activity time. Children should not have television and computers in their bedrooms because use of such media can disturb sleep, and children learn best from play rather than media exposure (AAP Council on Communications and Media, 2013). Health promotion teaching imparts to parents the benefits of activity, such as a healthy immune and cardiovascular system, positive self-concept of the child, and the child's learning of important motor skills. Health maintenance teaching focuses on disease prevention, such as avoidance of overweight, and injury prevention, with use of protective gear for sports.

Expected outcomes of health promotion and health supervision related to physical activity are daily inclusion of at least 60 minutes of activity into life patterns, normal developmental progression of the musculoskeletal system, growth in coordination, and appropriate balance between dietary intake and physical activity so that normal weight is maintained.

Oral Health

The early childhood years play an important part in the child's future oral health, and yet dental care remains one of the most preventable and common unmet healthcare needs for children in developed countries. About 28% of children from 2 to 5 years have had dental caries, and 21% have untreated dental caries (National Institute of Dental and Craniofacial Research, 2014). **Early childhood caries (ECC)** is defined as one or more decayed, missing, or filled tooth surfaces in a child 71 months of age or younger (AAP Committee on Nutrition, 2013; Colak, Dulgergil, Dalli, et al., 2013). This condition is promoted by inadequate preventive care, which can include diet, brushing, feeding habits, and lack of dental care. ECC is serious because young children with the condition are more likely to have continuing dental problems that can influence speech, cause pain, and delay development. Teaching prevention at an early age is key to preventing the problem.

The nurse assists the family to ensure oral health for the young child. By 1 year of age, the child should have made a first visit to the dentist. The child should have an established dental home for regular care and recommendations (American Academy of Pediatric Dentistry [AAPD] Council on Clinical Affairs, 2013). By about 2 years of age, the toddler has a full set of 20 primary teeth, called **deciduous teeth**, that will be lost during childhood, beginning at about 6 years. Evaluate these teeth for condition and number. They help maintain space for the permanent teeth, foster positive eating habits, and are needed for language development. Inquire about how the family cleans the teeth and, if the child has any dental decay, ask them to demonstrate their daily care. At the end of preschool, the first of the deciduous teeth are lost, an important developmental event for most children.

By 2 to 4 years of age, young children have discontinued using pacifiers and thumbsucking. These habits are harmful when permanent teeth begin erupting at about age 6 years (American Dental Association [ADA], 2011). Parents should be instructed gradually to remove the pacifier by 1 to 2 years of age. Many young children continue to thumbsuck, which is a comforting and reassuring habit. Usually, the child who is 2 to 4 years old is ready to discontinue thumbsucking, and parents can promote this process by praising the child for not sucking, helping the child find alternative sources of comfort such as rubbing a blanket, putting a sock on the hand at nap or nighttime to serve

as a reminder not to suck, and working with the preschooler to identify the reward when no thumbsucking is seen for a week or more (ADA, 2011).

Based on the results of the assessment of the child's teeth, observation of language skills, and answers to questions directed at parents, plan interventions that will foster maintenance of oral health, thus preventing dental disease. (See Chapter 19 for emergency treatment of dental injury.) These may include referral to low-cost dental clinics, provision of toothbrush and toothpaste, demonstration to the parents and young child about proper brushing technique, and teaching about limiting sweet snacks and drinks. A dental visit will assist in identifying children at moderate or high risk of dental caries; for these children, a "smear" of fluoridated toothpaste should be used for brushing, and in 2- to 5-year-olds, a pea-size amount of fluoridated toothpaste can be used. For other children, nonfluoridated toothpaste is used (American Academy of Pediatric Dentistry [AAPD], 2014). Remember to positively reinforce health promotion practices such as good oral hygiene for toddlers and preschoolers who brush, visit the dentist, and are careful to limit intake of sweets. Desired outcomes for oral health are eruption of a normal set of deciduous teeth, regular dental care, nutrition and hygiene practices that foster dental health, and knowledge of child and parent about oral health.

Mental and Spiritual Health

The family plays a key role in fostering a positive self-image and setting the stage for the young child's mental health. As the family is called in for the visit, begin an assessment of the family's methods of influencing mental health. Observe communication and interactions in the family and the child's ability to interact with healthcare providers. Ask for a description of a typical day or what the child has recently begun to do. The child's sense of self and mental status are related to new accomplishments. Inquire about toilet training, tooth brushing, choosing clothes and getting dressed, using crayons, or other developmental tasks.

Toddlers and preschoolers use **self-regulation** (the ability to soothe and comfort the self) to control anger, excessive desires for objects or foods, and other nonsocial behaviors. To assist the child in developing the ability to control and regulate self, parents often use discipline techniques. Ask about how the parent deals with the child who is having a temper tantrum or showing other undesirable behaviors. Reinforce positive ways of helping the child set limits for self and make suggestions when parents need assistance (*Families Want to Know: Positive Discipline*). The goal of discipline is to help the child develop a sense of right and wrong, and to learn acceptable ways of dealing with other people.

Adequate sleep and rest are needed for children to master self-regulation. Most toddlers have established regular sleeping patterns with occasional night awakenings. They sleep about 10 to 12 hours at night with one or two daytime naps. Parents have usually learned to establish clear routines such as reading a story, back rubbing, and then leaving the child alone. Occasionally, parents who work during the day may feel guilty about putting the child to sleep. Help them alleviate guilt by suggesting that they spend quality time with the child after arriving home, and then establish clear sleeping expectations. Transitional objects such as blankets or toys are important for the toddler and can be used during childcare experiences to provide comfort and help

Families Want to Know

Positive Discipline

First, provide structure that enhances the possibility of desirable behaviors:

- Limit rules to those that are essential. It will be easier to enforce a few important rules than many that are nonessential.
- Provide an environment where the child is mainly free to explore safely in order to avoid constant cautions. For example, have adequate play space for toddlers with limited fragile glassware in the usual daily environment. It is easier for the toddler to learn not to touch a few objects when adequate objects are provided for play.
- Spend time interacting with the child several times each day. Praise positive behaviors frequently. Preschoolers often like to have charts with stars to record picking up toys, helping a parent, and other positive behaviors. Once a certain number of stars is reached, a reward, such as stickers or an outing with the parent, is earned.

When the child shows undesirable behaviors:

- Use distraction as the first approach and praise the child for selecting the new activity suggested by the parent.
- Tell the child one time that the behavior is unsatisfactory and what will happen if the behavior persists.
- Separate the child from a setting in which behavior is undesirable. Place the child in "time-out," a separate place that is safe. Toddlers can be placed in a playpen or crib, while preschoolers are told to sit on a chair. One minute of time-out per year of age is a good length of time. Once time-out is over, provide a positive activity and move the child directly toward the activity.

When undesirable behaviors include other people, such as biting or hitting:

- Tell the child clearly that it is not okay to hurt another person. Encourage and role model proper language to explain feelings.
- Separate the child immediately from the situation and use time-out.
- If there are repeated episodes, be sure the child is getting adequate sleep and food, has opportunities for active play that releases energy, and has positive attention from many people in the environment. Be sensitive to stresses such as a recent trauma or a new sibling.
- Encourage the child to "use words" instead of hitting or biting. Until able to do so on their own, parents can model this behavior. "You feel like saying, 'I am really upset that you took my toy away.' Let's use words instead of hitting so your sister knows that."

maintain normal routines. Some families prefer to have children sleep in the bed with parents. Advise against this pattern, but if this is the parents' decision, be sure they are aware of safety hazards such as suffocation in excessive bedding, injury related to falling between headboard and frame, parental smoking that could lead to a fire, or parental deep sleeping or alcohol and drug use that can lead to such sound sleep that it is possible to roll onto and suffocate the child.

The preschooler sleeps about 9 to 11 hours and may have one or no naps each day. Some quiet playtime can be beneficial even for the preschooler who does not nap. At this age, some children begin to awaken at night and may need some assistance in falling back to sleep. **Nightmares** are frightening dreams that awaken the child, who is often crying and upset. Parents can reassure the child, rub the child's back, provide some repeat of a bedtime routine such as reading a story, and then allow the child to settle into sleep again. It is not advisable to bring children to the parental bed since they may start to awaken at night in order to continue this practice. **Night terrors** (or sleep terrors) are characterized by a child who cries out, appears frightened, and has tachycardia and tachypnea. However, in contrast to nightmares, the child having a night terror is not fully awake and may appear disoriented (Mayo Clinic, 2014). Parents should quietly talk to and comfort the child, allowing the child to return to sleep. The child has no recollection of these events the next morning.

The toddler gains more independence in many aspects of life such as mobility and speech. The control over toileting is another milestone that signals greater independence and can lead to a sense of self-control. Ask parents if the toddler has shown interest in toilet training and how they intend to work with the child to attain control over bowel and bladder. (See Chapter 4 for further discussion about toilet training.) Preschoolers are generally well trained for bowel and bladder with only occasional accidents. These should be treated with understanding rather than blame in order for healthy self-concept to develop.

Preschoolers have a growing awareness of gender and sexuality issues. They may ask questions about kissing, love, or their genitals. These questions should be truthfully answered, leaving the child with a positive sense of sexuality. Some exploration of genitals may occur, and children should be told simply that it is something that should occur in private, and then be offered other activities to engage them when with other people.

The family's spiritual orientation takes on additional meaning for the toddler and preschooler. They can participate in the family's faith-based practices, which enlarge their microsystem influences to include that of the religious group, thus reinforcing the child's learning about right and wrong. The nurse assesses the family's faith-based or spiritual beliefs and provides support for the family's approach, whether it is in established religious organizations or in the family's other meaningful activities (Pender, Murdaugh, & Parsons, 2015).

Health promotion activities focus on development of a healthy self-concept in the toddler and young child by helping parents set up successful play experiences, praise the child for successes, use effective limit-setting techniques, and realize and appreciate the child's unique characteristics. Health maintenance seeks to avoid the poor self-image that can occur with constant criticism or expectations not in alignment with the toddler's or preschooler's developmental capabilities. Further examples of the family interactions that can influence the child's self-concept are provided in the following section on relationships.

Desired outcomes for the child related to mental and spiritual health include emergence of a positive self-esteem, ability to self-regulate behaviors, emergence of methods to handle daily stressors, and normal developmental progression in tasks such as toilet training and sleep.

Relationships

Family members are part of the microsystem for the toddler and preschooler and, as such, form a vital part of the child's environment. Families with members who handle stress well and have healthy lifestyle patterns offer security for the young child. When parents are stressed or depressed, the mental status of all family members can be affected. Ask how things are going for the family in general. Inquire about siblings and whether there are any issues of concern that might influence the toddler or preschooler. Illness or behavior problems in a sibling can decrease the parent's ability to deal with other children. The focus on a sibling in need can be confusing to a toddler or preschooler. Be alert for signs of child abuse and for substance abuse in family members (refer to Chapter 17). Have the parents become separated or divorced? Is there a new stepparent?

During questions and observations, the nurse identifies family risk and protective factors. Reinforce strengths and provide services and referrals to deal with risks. Some strengths include the following:

- The family spends time together each day.
- Parents are proud of the child's accomplishments and knowledgeable about developmental progression.
- Childcare center personnel and family members interact regularly to plan consistent approaches for the toddler and preschooler.
- The teen mother of a toddler is enrolled in a high school continuation program with a childcare component.

Examples of risks to mental health include the following:

- Mother has been diagnosed with depression.
- Family member in home uses street drugs.
- Child awakens with night terrors.
- Child was recently in a serious motor vehicle crash.
- Teen mother is estranged from own family and has few goals and resources.

Toddlers continue to grow in social abilities, while preschoolers demonstrate large strides in socializing with others. Expect that most toddlers will enjoy playing with other children, although they play "side by side" in a parallel manner and not cooperatively. They also engage in play with adults for short periods, such as throwing a ball. However, preschoolers begin to engage in activities that involve other children directly in cooperative play. They play "house" where one child plays the mother and another plays the child. They engage in simple games where each plays a separate role. Their interactions with adults display similar maturity as they take on tasks such as setting the table for dinner or picking up books from the floor. Social skills involve getting along with others. Young children exhibit maturing skill in language development, a primary medium for social exchange. From just a few words at age 1 year, the child has progressed to stating three-word sentences by 3 years of age. Although all parts of speech are not in place, young children certainly have the ability to make needs and thoughts known. Assessment of language skills provides a mirror into this important means of socializing.

Successful social skills involve separating from the parent at times. During toddlerhood, most children spend some time away from parents. Initially they may be fearful and display crying, but gradually they learn to adapt to the new person and place. Preschoolers need to begin developing relationships with other adults and children in order to adapt to the school setting at about 5 years of age. Ask how many people the child has contact with each week and how they manage separation from the parent. Encourage parents to see separation as a skill the child is learning rather than something that is guilt producing for them. When they leave the child in a secure setting, they should hug, provide a favorite object, and leave. Short periods initially will teach the child that the parent can be trusted to return.

Expected outcomes of health promotion and health maintenance activities with young children include appropriate social skills with parents, siblings, and other children and adults; successful management of temperament characteristics; adjustment to time away from the home; and improving language/communication skills.

Disease Prevention Strategies

Toddlers and preschoolers commonly have 6 to 10 upper respiratory infections annually, so teaching good hygiene is a helpful preventive measure (Lucille Packard Children's Hospital, 2012). Some immunizations are given during this age period in order to complete a basic series. For the child who has not had all immunizations, extra visits to catch them up to recommended levels might be needed. At the end of the preschool period, a complete review of the immunization record is done so that any needed immunizations are administered before school entry. See Table 8–4 for immunizations recommended during toddlerhood and preschool (additional immunizations may be needed for children at high risk for certain diseases). Toddlers and preschoolers should be screened for health problems during health supervision visits, such as asthma, obesity, or other issues manifested by a review of body systems. Earlier visits may have failed to identify a problem on account of the child's young age, so areas such as vision, hearing, and developmental milestones are always included.

TABLE 8–4 Routine Immunizations Recommended During Toddlerhood and Preschool Age

IMMUNIZATION	AGE RECOMMENDED
Hepatitis B	6–18 months: Administer dose #3 if series not completed during infancy (usually doses #1 and #2 are administered in early infancy, with dose #3 given from 6–18 months of age)
Hepatitis A	Series of 2 doses with first at 12 months and second at least 6 months later
Diphtheria, tetanus, acellular pertussis (DTaP)	15–18 months (#4) (first 3 administered in infancy) 4–6 years (#5)
Haemophilus influenzae type b	12–15 months (#4 or will be #3 for PRP-OMP type that requires only 3 doses for whole series) (first doses administered in infancy)
Inactivated poliovirus	4–6 years (#4) (first 3 doses administered in infancy)
Measles, mumps, rubella	12–15 months (#1)
Varicella	12–18 months (#1) 4–6 years (#2)
Pneumococcal	12–15 months (#4)
Influenza	Annually

Note: Schedule may need to be adapted if child did not receive all recommended immunizations during infancy. See Chapter 16 and the CDC and AAP websites for further information.

Recognize that the environment is a powerful influence on the health of children. Ask if parents or others in the home smoke. Discourage this practice and describe the health implications for the child. Is the neighborhood generally safe? Is there toxicity exposure from air, water, or other mediums? Ask about lead exposure in the home (see Chapter 17 for more information). How much television and other screen time is common in the home? Older siblings who allow the preschooler to play violent video games or watch many hours of inappropriate television can affect the mental health of the young child. Do parents watch the evening news, even when it involves violence, in front of young children? Do they discuss television shows with the child?

Ask if the child has had any diseases, whether common ones such as a middle ear infection, or less common ones such as a serious respiratory infection. Has the child been diagnosed with a chronic disorder such as cystic fibrosis or hemophilia? How has that affected the child's general health and family functioning?

Desired outcomes for disease prevention include integration of a healthy lifestyle into the family's daily life, prompt treatment of acute diseases, and individualization of all health supervision topics for the child with a chronic condition or special healthcare need.

Injury Prevention Strategies

Injuries remain a common healthcare problem for children during the toddler and preschooler years. Toddlers' and preschoolers' mobility, physical skills, and lack of understanding of the presence of hazards put them at particular risk. In addition, children are sometimes left to play alone for short periods, and toddlers and preschoolers can quickly get into dangerous situations. Every healthcare visit needs to include an assessment of risks and teaching to prevent injuries. Tables 8–5 and 8–6 list injury hazards and prevention measures to take during these age periods.

Ask parents what they think the most common hazards are for the age of the child, and add other hazards to their awareness. Car safety always needs reinforcing as the types of seats recommended change as the child matures. Children should be in a rear-facing car seat in the back seat until at least age 2 years, and preferably until 4 years or when the child has reached the top height or weight limit allowed by the car seat manufacturer. When the child has reached the highest height and weight allowed by the rear-facing seat, a forward-facing car seat with a harness should be placed in the back seat. Then, when the child has outgrown the recommendations for height and weight for the forward-facing car seat, a booster seat in the back seat is recommended (AAP, 2014).

TABLE 8–5 Injury Prevention in Toddlerhood

	HAZARD	DEVELOPMENTAL CHARACTERISTICS	PREVENTIVE MEASURES
	Falls	Gross motor skills improve: Toddler is able to move chairs to counters and can climb up ladders.	Supervise toddler closely. Provide safe climbing toys. Begin to teach acceptable places for climbing.
	Poisoning	Gross motor skills enable toddler to climb onto chairs and then cabinets. Medicines, cosmetics, and other poisonous substances are easily reached.	Keep medicines and other poisonous material locked away. Use child-resistant containers and cupboard closures. Post the Poison Control Center number (1-800-222-1222) by telephone and tape it on cell phones and program the cell phone with the number.
	Burns	Toddler is tall enough to reach stove top. Toddler can walk to fireplace and may reach into fire. Electrical cords may be placed in mouth.	Keep pot handles turned inward on stove. Do not burn fires without close supervision. Use a fire screen in fireplaces. Supervise child during play and keep electrical cords, power strips, and other hazards out of reach or covered securely.
	Drowning	Toddler can walk onto docks or pool decks. Toddler may stand on or climb seats on boat. Toddler may fall into buckets, toilets, and fish tanks and be unable to get top of body out.	Supervise any child near water. Swimming classes do not protect a toddler from drowning. Use child-resistant pool covers. Use approved child life jackets near water and on boats. Empty buckets when not in use.
	Motor vehicle crashes	Toddler may be able to undo seat belt, may resist using car seat, demonstrating characteristic negativism and autonomy.	Use approved safety seat only; toddler is not large enough to use car seat belts. Insist on safety seat use for all trips and position seat in rear seat of car. Verify that child is belted in properly before starting car. Keep the child in a rear-facing seat until at least 2 years of age and preferably longer, until achieving the highest weight or height recommended for the seat by the manufacturer; then a forward-facing car seat with harness should be used in the back seat.

TABLE 8–6 Injury Prevention in the Preschool Years

	HAZARD	DEVELOPMENTAL CHARACTERISTICS	PREVENTIVE MEASURES
Ruth Jenkinson/DK Images	Motor vehicle crashes	By about 4–5 years, the child independently gets into car and puts on seat belt. Child may forget to belt up or may do so incorrectly.	Verify that child is belted in properly before starting car. Keep the child in a rear-facing seat secured in the back seat until at least 2 years of age and preferably longer, until achieving the highest weight or height recommended for the seat by the manufacturer. Forward-facing seats with harness placed in the back seat are used next. Once the child has outgrown the car seat, a booster seat is used in the back seat.
	Motor vehicle and pedestrian accidents	Preschooler may play outside alone or with friends. Preschooler is unable to judge speed of moving car and assumes driver knows that he or she is present.	Teach child never to go into road. A safe, preferably enclosed, play yard is recommended. The child should be supervised by adults at all times.
	Drowning	Preschooler who has had swimming lessons may choose to go into a lake or pool.	Teach child never to go into water without an adult. Provide supervision whenever child is near water.
	Burns	Preschooler can understand the hazards of fire.	Teach child to stop, drop, and roll if clothes are on fire. Practice escapes from home are useful. A visit to a fire station can reinforce learning. Teach child how to call 9-1-1.
	Needlesticks in hospital and home	Preschooler can ambulate and is interested in new objects.	Keep needles out of reach. Remove from hospital unit immediately after use. Instruct families on safe disposal if a family member uses needles at home (e.g., a family member with diabetes).
	Electrical injury in hospital and home	Preschooler is mobile and may trip over cords and equipment or may choose to examine them.	Avoid use of electrical cords if possible. Keep equipment out of major traffic areas. Cover any electrical outlets not being used for equipment. Monitor child closely.

Recommend that parents have their child's car seat checked by a child safety seat inspector (Figure 8–3). Give them the addresses of the closest inspection stations. These can be located by going through the National Highway Traffic Safety Administration (2014) (www.nhtsa.dot.gov). Check your particular state laws regulating car safety seats for children.

Other common and serious safety hazards are falls and drowning. In addition to providing general guidelines about safety, these most common injuries should be directly addressed. Children often fall down stairs, from counters where they have been placed or crawled, and from grocery carts. Drowning episodes occur when toddlers and preschoolers are not watched every moment while in the bathtub, near a pool or spa, at a lake or ocean, or when they fall from boats without personal flotation devices on. All young children should begin to take swimming lessons, but this does not guarantee their safety around water.

Figure 8–3 **This police officer is certified to examine car seats for children and make recommendations for parents. He is examining a preschooler in a car seat for proper fit, alignment, and installation. Many car seats are improperly installed or not the proper type for a specific age/size of child, so centers that check seats provide an important service.**

The AAP (2013) recommends swimming lessons for all children by age 4 years and for children from 1 to 4 years if lessons are available and the parents believe the child is ready for lessons. Children also play with balls, and may follow them as they roll or are thrown into the street. Nursing interventions concentrate on relaying to parents the severity of the risk of falls, drowning, and other hazards for children. Teach them to be aware of the dangers and to avoid them, both at home and in other settings. Refer them to classes on first aid and cardiopulmonary resuscitation.

The child spends more time away from the parent than during earlier developmental stages. Childcare situations should provide the same supervision the child receives at home. Help parents to ask questions and feel confident in safety at other settings. For example, while parents may be cautious about gun safety at home, few of them inquire if a home the child is visiting has guns and how they are stored.

Preschool is a time when teaching can become directed both to the parents and to their children. Preschoolers are receptive to practicing street crossing and tricycle/bicycle riding skills. It may be helpful to have a place in the clinic or office where they can be taught basic skills such as hand washing or street crossing. Consider the time of year, climate, and geographic location and teach appropriately. Spring is often a good time to teach bicycle and water safety, while winter hazards may include teaching about the hazards of wood stoves or other heating devices. See Table 8–7 for further information about toddler and preschooler hazards and safety teaching needed.

SAFETY ALERT!

Young children die each year when they are left confined in parked vehicles and suffer heatstroke. Occasionally, children gain access to a vehicle and accidentally lock themselves inside. In most cases, however, parents leave a child unattended, either forgetting the child is in the car, or remembering but underestimating the danger of heat effects. Nurses can be effective in instructing families to keep cars locked so young children cannot gain access, and to never leave a child in a parked car, either in or out of a car seat, even for a few moments, no matter what the outside temperature (Safe Kids, 2014).

Desired outcomes for the child are integration of safe practices into car restraints and other daily activities, progression through toddlerhood and preschool with no serious injuries, prompt care for minor injuries, and understanding by child, parent, and other care providers of the common safety hazards at this age.

Nursing Management

For the Health Promotion and Maintenance of the Toddler and Preschooler

Nursing Assessment and Diagnosis

Nurses partner with other healthcare professionals such as physicians, nurse practitioners, and speech therapists to assess health promotion and health maintenance status of young children. The toddler and preschool years are characterized by much developmental progression, and strategies need to be constantly adapted to meet the particular needs of the child and family. It is important to realize that the parents are partners in the care of the child and that every health supervision visit should address their questions and concerns. Their observations of the child are an invaluable part of the process. As preschoolers become more verbal, they become partners with others in the healthcare team. Ask preschoolers what they want to learn, what questions they have about staying well, and other pertinent questions.

Toddlers and preschoolers are examined for growth, physical health status, and mental/social characteristics. Development is an area that many pediatricians feel ill prepared to address but which parents commonly want addressed. Additionally, developmental surveillance must occur at every healthcare visit, with standardized screening at 9, 18, and 24 to 30 months. Nurses are adept at describing normal developmental milestones, evaluating the progression of children, and using anticipatory guidance to address parental developmental concerns.

Based on a thorough assessment, the nurse will establish nursing diagnoses that are appropriate for the young child and family. Potential nursing diagnoses established during a health supervision of a toddler or preschooler might include the following (NANDA-I © 2014):

- ***Anxiety*** related to change of environment (new care provider)
- ***Role Conflict, Parental,*** related to lack of support from significant others
- ***Development: Delayed, Risk for,*** related to lead exposure
- ***Sleep Deprivation*** related to nightmares and night terrors
- ***Knowledge, Readiness for Enhanced,*** related to parental desire for safety information
- ***Skin Integrity, Impaired,*** related to hyperthermia (sunburn)

TABLE 8–7 Disease and Injury Prevention Topics by Age

AGE	INJURY PREVENTION	TEACHING TOPICS
15 months	Wash adult and toddler hands frequently. Clean toys with soap and water regularly. Provide child's own bedding for childcare setting and wash weekly. Use forward-facing car safety seat if child is 20 lb; install correctly and have installation checked; place in back seat and never in front seat with a passenger air bag. Empty containers of water immediately after use; be sure pools or other bodies of water are locked and not accessible. Use sunscreen, hat, and long sleeves in the sun. Keep heavy and sharp objects out of reach; check that all poisons are locked away including in homes visited; keep pet food and cosmetics out of reach.	Have poison control number by phones and taped onto and programmed into cell phones. Be alert for dangers of hot curling irons and other appliances. Have electrical cords out of reach and not hanging down. Keep water temperature no higher than 120°–125°F (49°–52°C). Have home environment checked for lead hazards; arrange for blood lead level testing when appropriate (see Chapter 17). Secure the child in shopping carts. Do not let child have access to alcoholic drinks. Remember that responsible adults—not other children—should always supervise your child. Know CPR, airway obstruction removal, and other first aid.
18 months	Follow the above. Bolt heavy objects securely to the wall to prevent them from being pulled down (such as bookcases and televisions). Be cautious of the toddler near machinery in the yard, such as lawn mowers and farm equipment.	Use a helmet on the child when taking the child on the back of a bicycle. Check batteries in home smoke alarms, CO or radon monitors, and check system monthly; change batteries on a scheduled basis as recommended by manufacturer. Ask care providers about discipline methods; do not allow corporal punishment.
2–3 years	Follow the above. When the child is 40 lb, switch to a belt-positioning booster seat, using vehicle lap and shoulder belt; continue to place booster seat in rear seat of the car. Teach hand hygiene after toileting and other activities. Clean potty chair thoroughly. Keep guns unloaded and locked away in a different locked place than ammunition; have trigger locks installed.	Teach how to cross streets. Provide a helmet for riding tricycles. Check playgrounds for safety hazards and hard surfaces under equipment; ensure cushioned surface.
3–4 years	Follow the above. Do not let child play unsupervised.	Know CPR, airway obstruction removal, and other first aid for the child who has become a preschooler.
4–5 years	Follow the above. Continue teaching safety skills to the child. Continue supervising when near streets or water sources.	Teach safety around strangers (never go with a stranger; find a trusted person such as a parent or police).

Source: Data from Hagan, J. F., Shaw, J. S., & Duncan, P. M. (Eds.). (2008). *Bright futures: Guidelines for health supervision of infants, children, and adolescents* (3rd ed.). Elk Grove Village, IL: American Academy of Pediatrics.

Planning and Implementation

Based on the nursing diagnoses, the nurse works with other partners to plan strategies to meet the needs of the family. Explain that assessment questions are asked to provide a picture of the child that can be helpful in partnering with parents to plan health care. Reinforce the importance of the family coming to health supervision visits with their own list of issues. See *Clinical Reasoning: Families Who Miss Scheduled Healthcare Visits*. Work with other healthcare professionals to be sure all needs of a particular child and family are addressed.

Some teaching takes place as the examination occurs. Explain the height and weight measurements and their meaning. Relate them to questions about dietary intake and family food patterns. During the physical examination, insert information about common infections such as otitis media (middle ear infection) and share immunization information.

Clinical Reasoning Families Who Miss Scheduled Healthcare Visits

Clarence is being seen at 15 months of age. He missed his 12-month visit and was last seen at 9 months. How can you ask the parents about the reasons they may have missed the 12-month visit? What immunizations must be "caught up" now that some were missed? (See Chapter 16 for immunization schedules.) What components of developmental surveillance are particularly important for you to perform at this visit?

If the family has been reluctant to ask questions, reflect on the child's development. "Many children have trouble sleeping through the night; is that the case for Cassandra? What helps her

to sleep? What is it like at her bedtime?" Developmental areas such as sleep, discipline, toilet training, and expected developmental milestones should be addressed. If the parents were provided in an earlier visit with a journal to record observations and questions, ask if they have brought it with them.

Health promotion activities are emphasized during the visit. Health promotion related to physical activity includes teaching about toys that encourage activity, such as balls, music, push toys, and tricycles. Review nutritional intake and encourage introduction of new foods, healthy snack and meal choices, and positive eating for busy families. Emphasize the importance of play to healthy child development. Provide ideas for incorporating free playtime each day. Apply concepts of anticipatory guidance as you address the child's approaching developmental progression. If the child will soon be toilet trained, provide information about possible approaches. If the child is learning to swim or has access to water, reinforce safety precautions near water. For the child going to a new childcare center, provide the parents with a list of questions they can ask the care provider, and tips to assist in the transition to a new setting.

Health maintenance activities are added to the visit as you give immunizations and screen for tuberculosis, lead screening, or problems with language, vision, or hearing. Provide instruction on use of nonprescription medications, including use of acetaminophen after immunizations. Precautions, safe dosing, and checking with the healthcare provider should be addressed. The focus of these activities is to prevent disease or to find it early before serious consequences arise. Whenever you find information that may indicate a problem, be sure to refer the child to the primary care provider, such as the physician or nurse practitioner. You may even recommend that another specialist, such as a speech pathologist or dentist, see the child. Other health maintenance activities that must be part of each visit with a toddler or preschooler involve teaching about common hazards and how to avoid them. Emergency care in case of injury is also helpful information for parents, so first aid classes can be recommended. Ask about daycare, preschool, or kindergarten attendance or future plans.

Healthy People 2020

(V-1) Increase the proportion of preschool children aged 5 years and under who receive vision screening

- While only 40% of preschool children receive vision screening presently, a goal of 44% has been set. Nurses should ensure that all preschool children receive vision screening in childcare centers and at health supervision visits.

(V-2) Reduce blindness and visual impairment in children and adolescents aged 17 years and under

- While 28% of children are blind or visually impaired, when more children are screened in their early years, fewer than 25% of children should experience visual impairment.

SAFETY ALERT!

Nearly 2000 children are injured annually by falls related to baby gates. Those under 2 years more commonly push over an expandable gate and fall down stairs with the gate. Children older than 2 years may climb the gate or open it and thus fall down stairs, often sustaining soft tissue injuries. Ask parents if their homes have stairs. If so, what type of protection is available for the child? Is an expandable gate used? If so, would the parents be able to change to one that is installed into the wall studs? Can a preschooler climb the gate? If so, it is safer to remove the gate and supervise the child more closely (Cheng, Fletcher, Roberts, et al., 2014).

Conclude the visit with some words of praise about both the parent's and child's accomplishments. Schedule the date for the next visit. List any resources helpful to the family, including the clinic/office contact information and emergency services.

Families Want to Know

Toy and Playground Safety

Play is essential to the physical and cognitive growth of toddlers and preschoolers. However, toys can present hazards for young children, and parents need guidelines to follow when selecting toys. These include (Safe Kids, 2011b):

- Select toys intended for the age of the child, as indicated on the label. Some toys have small parts or can break into small parts, and should not be given to children younger than 3 years. They should not be too heavy for the child to manipulate them appropriately. Toys with strings, straps, or cords longer than 7 in. pose strangulation hazards.
- Assemble toys as directed and check them frequently for breakage; remove all packing materials before providing toys for the child.
- Do not use older repainted toys unless the parent is certain that paint used contained no lead.
- Select cloth toys that are nonflammable, flame resistant, or flame retardant. Avoid electrical and battery-powered toys in children younger than 8 years.
- Do not allow latex balloons and especially noninflated balloons to be used as toys.

Playgrounds provide a location for healthy development of children, but can also be responsible for child injuries. Home playgrounds are the sites of most playground injuries. Falls, strangulation, and head impacts are examples of frequent playground injuries. Some tips can be provided to parents (Safe Kids, 2011a):

- Surfaces should be composed of soft and loose material such as mulch or fine sand. The surface should be 12 in. deep and extend 6 ft around equipment.
- Equipment should not allow the child to be more than 5 ft off the surface.
- Strangulation poses a high risk so be sure to remove ties, ribbons, drawstrings, and other hanging items from clothing and play areas.
- Ensure that the equipment is intended for the age of the child. Separate playgrounds for young and older children are recommended.
- Consult the U.S. Consumer Product Safety Commission for playground equipment standards. Inspect equipment regularly.
- Always supervise the young child on a playground at all times.

Evaluation

Parents should be asked occasionally to evaluate the care they are receiving at the health promotion and health maintenance site. Use these comments to monitor and adjust procedures as needed. The expected outcomes for nursing care of the toddler and preschooler include the following:

- The child demonstrates normal patterns of growth and progression in developmental milestones.
- The child remains free of disease and injury.
- Parents relay satisfaction with the pediatric healthcare home.
- The child manifests positive physical, social, and emotional adjustment.

Chapter Highlights

- General observations of physical ability and social interactions are made as the toddler and preschooler appear for the healthcare visit.
- Questions about growth and information related to physical health are integrated during the physical examination.
- The examination should include all areas on the American Academy of Pediatrics Recommendations for Preventive Pediatric Heath Care, with the approaches adapted to the young child.
- Developmental surveillance is integrated within each health promotion/health maintenance visit, and an appropriate developmental screening test is used.
- Toddlers and preschoolers gradually take on mature eating patterns; assessment of nutritional status involves growth, oral health and teeth, foods eaten, and family food patterns.
- Physical ability progresses steadily in young children; opportunities for daily active periods are necessary for healthy growth.
- Early years are essential to development of a positive sense of self, positive social interactions with others, and healthy lifestyle behaviors.
- Immunizations are administered to prevent infectious disease, and safety hazards are addressed at each healthcare visit, with suggestions provided to avoid disease and injury.

Clinical Reasoning in Action

Quinton and his mother have come into the office for his 2-year-old well-child checkup. During the visit you learn that his mother stays home with him during the day and his father often works overtime. His only significant medical history incident was when he had stitches placed in his forehead for falling on the edge of a table when he was 15 months old. There is a family history of attention deficit disorder and Crohn disease. Quinton's height is in the 75th percentile, weight is in the 50th percentile, and body mass index is between the 25th and 50th percentiles. His temperature is 98.9°F (37°C) and his pulse is 80. He is described by his parents as a picky eater and tends to eat the same foods frequently. They also say he tends to eat well on some days and other days will hardly eat anything. On the days he is not eating well, his mother will often resort to giving him soda or a sugary snack just so he is "getting something." Quinton sleeps about 7 hours per night, and his mother usually ends up sleeping with him because he continues to fight going to sleep after being put to bed. He does not have a regular bedtime or rest routine and he usually naps in the car during the day. His mother tells you that her only break during the day when she is at home with Quinton is when he is watching television in his bedroom, so he often watches 2 to 4 hours per day. Quinton has a soft stool every day and has not shown any interest in potty training at this time. He is developmentally able to go up and down stairs, kick a ball, scribble on paper, and is able to speak in 3- to 4-word sentences. During the visit at the office, it is obvious Quinton's parents have difficulty controlling him and frequently make threats and offer bribes to get him to behave properly. He starts screaming and kicking when his parents set limits on his behavior in the office, and his parents say they are frequently exhausted and do not know what to do about his high energy level. They also are concerned because they feel like the discipline methods they have been using are not working, and he is getting into so many things in the home that they are concerned he may hurt himself. They have used spanking and time-outs, but these methods do not seem to improve his behavior. The parents think their child may have some type of medical condition like attention deficit disorder considering it does run in their family.

1. At 2 years of age, a consistent routine will help a toddler behave more appropriately. What are some of the things you can tell Quinton's parents regarding his sleep and nutrition habits to help establish a better routine?
2. How can you advise Quinton's parents about positive approaches to disciplining him?
3. How can you advise Quinton's parents about disciplining him when it is needed?
4. What are some suggestions you can give Quinton's parents about handling his temper tantrums?

Chapter 9
Health Promotion and Maintenance for the School-Age Child and Adolescent

I know I should not be using chewing tobacco, but a lot of my friends use it, and I want to fit in with them. I would like to quit, but I really don't know how.

—Jeremy, 16 years old

Learning Outcomes

9.1 Identify the major health concerns of the school-age and adolescent years.

9.2 Describe the general observations made of school-age children, adolescents, and families as they come to the "pediatric healthcare home" for health supervision visits.

9.3 Apply communication skills in interactions with school-age children and adolescents.

9.4 Apply assessment skills to plan data-gathering methods for nutrition, physical activity, oral health, and mental health status of youth.

9.5 Synthesize data from history and examination of the school-age child and adolescent with knowledge of development to plan interventions appropriate during health supervision visits.

9.6 Plan with school-age children and adolescents to help them integrate activities to promote health and to prevent disease and injury.

Health Promotion and Maintenance for the School-Age Child

The older childhood years span the time when most children enter kindergarten at about 5 years of age and progress until adolescence begins at about 12 to 13 years of age. Even though health promotion and health maintenance remain important during this time, less frequent visits to the pediatric healthcare home are recommended. In addition, most children are relatively healthy and need few immunizations, which may lead to only sporadic visits for care. Whenever older school-age children are seen in health care, even for illness or emergency care, it is wise to ask when the last "well-child" or health supervision visit was scheduled. Encourage the parents to make an

appointment if the child is due for a visit. Visits are generally recommended at about 5 years of age, when most children are going to kindergarten, and then at 6, 7, 8, 9, 10, 11, and 12 years of age. The visits during this time will focus on monitoring physical and developmental changes, establishing good health habits related to important issues such as nutrition, physical activity, and mental health; learning the importance of avoiding tobacco, alcohol, and drugs; ensuring success in school, family, and extracurricular activities; and fostering good decision-making and problem-solving skills.

General Observations

The first school-age health supervision visit usually occurs just before entry into kindergarten. During this visit the child has a thorough examination to be certain that physical development is normal, developmental milestones have been met for fine and gross motor skills, school readiness is displayed in social skills and language, and final sets of basic immunizations are completed. The child is often excited about the visit because it is associated with beginning school; some anxiety is often felt, as it may be the first time the child is aware of getting "shots." As with earlier visits, the nurse's observations begin as the child is called in for the visit. It is wise to speak to the child first, introducing yourself and welcoming the child and parents to the office or clinic. Many children of this age actively participate in conversations, making teaching and gathering data easy. For children who are quiet or look to the parents, allow more time for them to get to know the healthcare provider, directing most initial questions to parents. This may be the first visit where the child is old enough to be a partner in the healthcare visit. Establishing positive rapport with the child will be more likely to enhance efforts designed to teach about health. At the same time, family-centered care, or a partnership to include decision making jointly by the family and the healthcare provider, is important for school-age health (Kuo et al., 2011).

Notice whether the child brought a book, toy, or some other object to the visit. How are the parents interacting with the child? What types of speech tones are used? Is there mutual respect or are parents and child ignoring each other or having disagreements? The child should walk with symmetry and ease of movement, follow instructions about where to go and taking off shoes for weighing, and demonstrate clear language skills with parent or healthcare personnel.

By the time children come for visits at age 6 to 8 years, they are expected to be increasingly active in sports, school activities, music, or other interests. Look for clues about their interests as they arrive. Did they bring books or an electronic device? What are the reading topics or favorite types of music? Ask what they are doing during the summer or about their two favorite afterschool activities. Have them describe a typical day to obtain clues about their life.

Some children do not commonly come to clinics, offices, or other settings for health supervision visits. School nurses or nurse practitioners in school-based clinics sometimes offer health promotion/health maintenance activities in the school setting. A major focus of school nurses is making the environment conducive to health for groups of children. School nurses may:

- Offer some parts of examination to individual children, such as growth and developmental surveillance.
- Conduct health screenings, such as vision, hearing, lipids, or scoliosis.
- Work with food service personnel and administration to improve meal and snack quality and minimize unhealthy choices in vending machines.
- Work with teachers to integrate concepts such as physical activity and self-esteem into classroom activities.

The nurse often links children with healthcare needs to other community services.

During health supervision visits, watch the parents' responses as children answer questions. Be alert for the parent who interrupts the child or constantly "corrects" what is said. Comments by the parent should involve praise of the child or looking to the child for opinions on certain topics. This indicates that a partnership is developing in the family and that family members work together and value each other. Also direct some questions to the parents. Ask if they came with specific questions or concerns that should be addressed. If the child has an individualized education or health plan (see Chapter 10), ask if the parent brought a copy, if the plan is still appropriate, or if it needs updating; facilitate a meeting with the school district about the plan if indicated. Allow the parent an opportunity to meet with the physician, nurse practitioner, or other professional in a private place and without the child present if desired. Be alert for family dynamics that can influence mental health status. Ask if there have been any important changes in the family and how they have influenced the child. During conversations, be alert for reports of separation; divorce; remarriages; ill parents, siblings, or grandparents; recent or upcoming moves; parent job changes; substance abuse; incarceration of family members; custody disputes; or other issues. Integrate a family history of diseases into the examination. Such topics can be followed up with further questions, as described later in the mental health section, to learn how they influence the child.

Growth and Developmental Surveillance

When the child first comes into the health supervision site, take height and weight measurements. Be sure to have the child remove shoes and coats. Ask the child and parents if they know the child's current height and weight, and if they have any questions. Plot the percentiles for these measurements, calculate body mass index (BMI) and its percentile, and explain the meaning of these findings later in the visit. Recognize that children do not grow uniformly; they have periods of slow growth followed by fast spurts. Similar to earlier ages, watch for children who have changed channels on a growth grid, and for those above the 85th percentile or below the 5th percentile for BMI, and gather additional nutritional data in these cases (see Chapter 14).

School-age children have begun to learn about their bodies, and so they should be active participants in the physical examination. Explain what you are doing and why. Carry out a head-to-toe examination, paying particular attention to systems and skills that influence performance in school, such as vision, hearing, muscular strength, and coordination. See Chapter 5 for detailed information about the physical examination. Remember to provide feedback about the findings; families appreciate knowing that the child's vision is normal and strength is well developed. Tell them what findings are normal as well as areas that may need more assessment or intervention. Inquire about the child's sleep patterns. During the examination, ask for a description of any illnesses the

child has had. Children of school age are generally healthy, with only a few upper respiratory infections or other minor illnesses annually. Unusual complaints may indicate a need for further testing, as discussed in the disease prevention section later in this chapter. Specific screenings for school-age visits include vision, hearing, hematocrit/hemoglobin, and lipid screening (10-year visit recommended for lipids) (American Academy of Pediatrics Committee on Practice and Ambulatory Medicine, 2014).

School-age children frequently have minor injuries. These might include falls from bicycles, skin rashes from exposure to plants on a hiking trip, bruises from a ball sport, and other minor mishaps. Be alert for more serious problems that may indicate a need for additional detailed data gathering and teaching (see *Injury Prevention Strategies* later in this chapter for examples).

Developmental surveillance continues to be an important part of the examination for school-age children. Some milestones can be observed during the visit, while other information is obtained by report of parent and child. This information is combined with reports about school and other activities in order to establish that the child is developing as expected.

Desired outcomes for growth and developmental surveillance include normal progression with developmental tasks, absence of physical and psychosocial abnormalities or trauma, and integration of safe practices into daily life.

Nutrition

Key concepts related to nutrition in school-age children are independence and formation of habits that influence the future. First, children are increasingly independent in food choices. They usually have strong likes and dislikes for certain foods. They may arrive home from school each day to an empty house and prepare their own snacks. During school, they choose what to eat from the school lunch, or the sack lunch sent by family. They may have access to vending machines or sales of snacks during school hours. While independence in food choices is growing, the child is greatly influenced in those choices by friends and the media. Foods that may be rejected often include fresh vegetables and fruits, since they get little media attention, and friends may not prefer them.

At a time when the child chooses many of the foods in the daily diet, habits are being formed that will affect nutrition and health in general in the years to come. Good choices will help promote health—to maintain weight at a recommended level, provide nutrients for adequate growth and activity, and prevent onset of some chronic diseases. Conversely, poor choices can lead to overweight and its accompanying problems, lack of adequate calcium and resultant osteoporosis, eating disorders, or lack of energy for brain growth and optimal performance in school. The patterns established during this period are often influential in later nutritional status. Knowledge about foods, family participation in good nutritional practices, and access to healthy foods can all be enhanced by nursing intervention during this critical formative period.

Continue to perform height and weight measurements, body mass index calculations, and examination of percentiles for growth grid measurements. Slow, steady growth is the norm during the early school-age years; it will be followed by a growth spurt when the child nears puberty.

During the visit, observations provide information about nutritional status. What is the condition of the nails, skin, and hair? What is the energy level and reported physical activity? Does the child look lean or overweight? As the child nears puberty, there may be an increase in fat stores as a preparation for the pubertal growth spurt. Integrate some questions for the parent and child into the visit that provide clues about diet. While observing the child and family and asking dietary questions, list risks and protective factors related to nutrition. Examples of protective factors include adequate access to nutritious foods, a family garden, and weight and height within normal limits; risk factors may include inadequate access to nutritious foods, excess intake of calories during television viewing, and lack of vegetables in the daily diet. Reinforce the positive practices of the family and inform the child of how food choices relate to energy level, school performance, and general health. Risk factors become the basis for teaching and planning with the family for necessary change. It is difficult to tackle several nutritional changes at one time, so concentrate on those most needing attention, and on those the family agrees are important. Provide information about healthy snacks to keep at home, ways to improve calcium intake, the importance of getting at least five fruit/vegetable servings daily, limitation of soft drinks to one serving daily, and the importance of family meals (Figure 9–1). Desired outcomes for health maintenance include absence of overweight and other potential chronic diseases, adequate intake of all nutrients, and increasing child and family knowledge about nutrition.

Figure 9–1 **This school-age child is receiving teaching from the nurse about food choices. What benefit do the food models provide in this situation? What other teaching techniques can you suggest?**

Physical Activity

Just as food choices during the school-age years are likely to influence the child's future nutrition, physical activity during these years is often crucial to development of lifelong exercise habits. During these years, the child who is physically active continues to refine skills such as eye–hand coordination, muscular strength, agility, and speed. Some children become skilled at ball sports such as basketball, football, soccer, or baseball. Others focus on gymnastics, wrestling, horseback riding, or hockey (Figure 9–2). Some do not like team or organized sports but choose rollerblading, skateboarding, skiing, or biking. Whatever the interest, it is important that children identify some physical

Figure 9–2 **Everyone needs to be physically active. Some children participate in school sports. Others, such as these boys playing hockey, choose a sport that is available in the community. Other children prefer to walk, ride a bike, or engage in other more solitary activities. Determine what is enjoyable for a particular child and provide assistance in integrating desired activity into daily routines.**

SOURCE: Ruth Bindler.

activity and continue to develop motor skills. The benefits include socialization, positive sense of accomplishment and self-esteem, weight control, and increasing physical ability (Figure 9–3). Children who do not have an activity of importance often fall behind their peers in agility and skill, making future attempts at an activity very difficult and less likely to be successful.

As in earlier periods in life, the nurse lists risk and protective factors related to school-age physical activity (Table 9–1). Families are often significant in promoting physical activity for children. Find out what the parents do for physical activity and how often. Do they attend a sports club after work or does the child see them engaging in exercise? Most families can include some walking, yard work, or other activity that is done together in order to engage the child. Do they walk to a neighbor's house or a nearby store rather than drive? Do they always take elevators, or choose the stairs in buildings? What is the activity level of siblings? When older siblings are involved in sports, the younger child often is encouraged to develop skills in the same sport.

The child spends much of the day in school, and so this setting is important to consider. In an effort to conserve financial resources, some schools have decreased physical education (PE) programs. Children may not have regular PE classes, and there may be few standards of performance. In addition, many states and provinces have established tests and standards for performance in certain cognitive areas. In an attempt to increase teaching time to meet standards, some schools have cut out recess and other breaks. Some schools are located in unsafe areas and outside recreation is not advisable.

It is unrealistic to expect children to sit for long periods without physical activity, and such practice reinforces the poor habits of inadequate exercise among children. Schools that offer a

TABLE 9–1 Risk and Protective Factors Regarding Physical Activity in School-Age Children

RISK FACTORS	PROTECTIVE FACTORS
• Developmental delay and special needs	• Expected developmental skill level
• Limited role modeling of daily physical activity by parents and other family members	• Parents exercise daily and exercise with the child some of this time in a setting the child can see • Parents set expectation that everyone in the family will choose a physical activity and engage in it regularly
• Limited facilities in the neighborhood to encourage activity, such as parks, skateboard facilities, rinks, ball courts	• Neighborhood provides access to parks, skateboard facilities, rinks, ball courts, and other facilities
• Inadequate financial resources to join clubs or pay for organized sports	• Family has adequate financial resources to pay for health club or organized sports
• Safety gear for activities chosen is not available due to cost, or child is reluctant to use the gear	• Recommended safety gear that properly fits child is available • The child understands importance of safety gear and accepts using such equipment
• School cuts to physical education programs and recess	• Schools provide physical education each day with a variety of offerings; student gets to choose and set goals for some activities • Schools schedule recess or physical activity breaks twice daily
• School tryouts for sports that eliminate all but the best players in certain sports	• Sports teams are leveled so that all students desiring to play a particular sport, such as soccer, are able to do so
• Reluctance to try new activity	• Willing to try new activities
• Worry about competence and physical appearance	• Feels self-confident in ability and physical appearance • Sets goals for learning physical skills
• Television viewing or other screen activities for more than 2 hr daily	• Television viewing and other screen activities are limited to no more than 2 hr daily

Figure 9–3 Benefits of physical activity. School-age children often enjoy hikes with family, clubs, or other groups. What are the physical and mental health benefits from this activity?

SOURCE: Ruth Bindler

variety of activities, including intramural (rather than only organized competitive) sports, are more likely to encourage a wide variety of children to be active. At least half of the recommended 60 minutes of daily vigorous physical activity should be provided in school, along with an adequate amount of unstructured playtime during recess (Centers for Disease Control and Prevention [CDC], 2011a). Nurses are influential members of school committees and can encourage the integration of activity in the school day. They may be able to serve on a school or community committee, informing other committee members of the benefits of exercise to enhance cognitive performance and general health. Teachers and school administrators can be supplied with models of successful school activity programs. Nurses can often be influential in finding community volunteers to work with teams of students. Student nurses, physical education students, senior citizens, and others in the community may be able to help young children play baseball, tennis, or soccer. Other volunteers may teach stretching or warm-up activities. Community partners such as businesses may provide protective gear or uniforms for school sports, especially if the business name can be displayed. In addition, schools can offer alternative activities that some children might prefer to traditional organized sports.

It is essential to consider physical activity for the child who has special healthcare needs. It may be difficult for schools to plan an activity for the child with cerebral palsy, visual impairment, or developmental delay. Search for other community resources and help the family access them. There may be programs for children to ride horses, swim, ski, and engage in other physical activities. Learn about the Special Olympics for children with disabilities. Imagine the thrill that awaits a child who has rarely moved quickly when riding a sled or sliding on skis.

To summarize, health promotion activities for the nurse include teaching about activities that parents can do with their children, becoming active in fostering physical education programs in schools, acting as a positive role model, and helping interested children to partner with community resources for activity. Health maintenance outcomes include encouragement for use of safety gear and correct techniques to prevent injury from sport participation.

Oral Health

Many changes occur in the mouth during the school-age years, necessitating periodic examination. At about 6 years of age, most children lose a tooth, usually in the front. Following that, all 20 of the deciduous or primary teeth will be lost, and the permanent teeth will simultaneously begin to erupt. See Chapter 5 for the schedule of deciduous tooth loss and permanent tooth eruption. In addition, the jaw line elongates and teeth move into new positions. Periodic dental visits focus on both the placement of teeth and oral hygiene.

During the health promotion visit, examine the teeth. Look to see how many deciduous and permanent teeth are present. Describe the child's oral hygiene. Ask how often the child brushes, flosses, and visits the dentist. The child should have learned how to brush and floss during preschool years and now be performing the skills independently. If dental caries or poor oral hygiene is apparent, ask the child to demonstrate brushing and flossing. Reinforce the need for brushing twice daily and flossing once daily. Provide toothpaste and toothbrushes as gifts during health supervision visits. Local dentists will often provide these supplies to encourage oral hygiene.

Dental visits are recommended every 6 months. If the child is not visiting on that schedule, ask if finances or transportation is an issue, if the family needs a referral to a dentist, or if there is some other reason. If caries or malocclusion is present, stress the need for a dental appointment soon. Inquire about use of fluoride if the water supply is not fluoridated. Ask if the child has had sealants applied to the permanent teeth; most dentists believe these will help to prevent future caries (American Academy of Pediatric Dentistry [AAPD], 2012). Offer to help parents locate resources to assist with dental care expenses if needed. State and community programs are often available to assist families, and nurses should search out resources in their own communities and regions.

Many children have a high intake of sugared foods and snacks. If this is apparent from the nutritional assessment, discuss the importance of limiting these foods and brushing after their consumption. Frequent brushing is needed when the child has braces. Ask how they are caring for the braces and what the orthodontist has recommended.

The nurse's health promotion activities include positive reinforcement of good hygiene habits, and health maintenance involves teaching about the need for improved care and limiting food that furthers the formation of caries. Desired outcomes include recommended oral hygiene, attendance at recommended dental visits, and absence of dental caries.

Clinical Reasoning Dental Health

The family of 7-year-old Mario just moved to your city. You learn in a healthcare visit that Mario has never been to a dentist. You notice that several of his teeth are decayed. He has started to lose his primary teeth and has two permanent teeth in place. A dietary recall demonstrates that he drinks two to three sweetened beverages daily and likes to eat candy whenever possible.

Describe the daily dental hygiene that Mario should be practicing. Plan a teaching session for Mario and his parents. What other cues will you look for in his dietary recall in order to identify risk and protective factors for oral health? How will you locate resources in the community to recommend for the family so that Mario can receive dental care?

Mental and Spiritual Health

SELF-ESTEEM AND SELF-CONCEPT

The school-age years are marked by the emergence of new cognitive skills and the development of self-esteem. **Self-esteem** reflects feelings of self-worth or value. **Self-concept** refers to evaluations of the self in certain specific areas, such as those related to academic achievement, athletic ability, physical appearance, and social interactions (Santrock, 2012). A child with a positive self-concept feels competent, is able to meet challenges, and applies lessons from successes and failures. Specific facets of self-concept include **body image**, the idea that one forms about one's body, and **sexuality**, the person's view of self as a sexual being. Together, self-concept and self-esteem include all of the cognitive, emotional, spiritual, sexual, and physical aspects of the individual.

The child who believes in his or her ability to face good times and bad has a lowered chance of mental illness such as depression, eating disorder, and anxiety. Parents are encouraged to evaluate and help to build the child's sense of self-esteem (see *Families Want to Know: Evaluating and Fostering Self-Esteem*).

Many of the areas discussed already in this chapter provide clues to the child's self-concept. Does the child take part in sports or other physical activities? Such activity may reflect a positive self-concept and body image. However, if the child is forced to do these sports by parents and feels inadequate in their performance, these activities may promote a negative self-concept and body image. Ask about children's activities and how they feel about them. Do they enjoy them? How do they rate their performance?

Is the child increasingly independent and responsible for self? Success in achieving developmental milestones leads to a positive sense of self-esteem in the child. Parents are encouraged to evaluate and help to build the child's sense of self-esteem. A low sense of self-esteem is noted when the child states a disinterest in exercise, school clubs, and family activities. This can lead to loneliness, depression, and mental health problems such as eating disorders. When these feelings are noted during a health supervision visit, the nurse should recommend that the child see a counselor at school or another setting, and should recommend that parents be included in the sessions so that they can best help the child.

It is obvious that the family plays a critical part in the child's developing self-esteem and mental health. To understand the child, it is necessary to ask questions about and explore dynamics in the family. Several protective factors have been identified for families (U.S. Department of Health and Human Services, 2011):

- Nurturing bonds and attachment are formed.
- Parents have knowledge about parenting skills and child development.
- Parents demonstrate resilience by recognizing their own stress and enhancing their problem-solving abilities.
- Parents have a wide array of support systems to provide social connections.
- Caregivers are available who provide resources to meet basic needs, such as finances, housing, and food.

School-age children continue to develop their abilities to self-regulate activities and responses to situations. At this age, the abilities to solve problems and assume more responsibility for self are important. Encourage parents to discuss issues with the child and to seek solutions together when appropriate. The child assumes more responsibility for assisting with meal preparation and home chores, coming home alone after school, and caring for younger siblings. Encourage the parents to praise the child for assuming more family responsibilities and recognize that the child will need some guidance when taking on new tasks.

Families Want to Know

Evaluating and Fostering Self-Esteem

Parents play an important part in fostering a child's self-esteem. The nurse can ask parents to evaluate the child and provide suggestions about positive actions.

Evaluation Questions	Positive Actions
What does your child do well?	Build on the child's strengths and talents; affectionately point out the child's abilities.
How does your child respond to failure?	Assist children to assess their own performance; help them to see lessons that mistakes can teach.
Does your child have close friends?	Arrange structured playtimes such as going to a movie or cooking with a friend.
How does your child respond to new challenges?	Give the child responsibilities at home; encourage your child to try new experiences; help the child feel a sense of control over outcomes.
How does your own personality compare to your child's?	Recognize differences in style; appreciate the unique qualities of each child; tailor expectations to the child and not to self or other children.
Are you setting reasonable and attainable expectations for your child?	Be a positive role model; establish goals for behaviors together.

Source: Data from KidsHealth. (2011). *Developing your child's self-esteem.* Retrieved from http://kidshealth.org/parent/emotions/feelings/self_esteem.html

Ask about and observe the family's relationships. Evaluate the effect of family interactions on the child. Model respectful interchanges by listening carefully to the child, as well as the parent. Gently speak directly to the child if parents answer for the child or seem to put the child down. Provide brochures and examples of ways to show children their importance. Encourage both parents to come to child healthcare visits and support the involvement of both parents in childrearing. Ask about family stressors such as job changes, financial concerns, illness, substance abuse, and domestic violence. About one half of marriages end in divorce, so be prepared to offer suggestions to deal with this situation. Ask about and identify risk factors and protective factors. The child's strengths are used to assist the family functioning and will, in turn, give the child a sense of accomplishment. Some examples include the following:

- A child who is able to act independently can be given responsibility for parts of the home or family function, such as planning the menu for dinner two evenings weekly, caring for a family pet, or completing household chores.
- A creative child can be given the task of planning book readings and other activities for a younger sibling.
- A child with a talent for design can be asked to set the table for dinner guests.

SEXUALITY AND SEXUALITY EDUCATION

The school-age child is developing a sense of body image and sexuality. Be aware of the child's appearance and dress. Some children may have poor posture, display a sense of insecurity, and seem uncomfortable with themselves. Others may dress as if they were much older, seem sophisticated, and are clearly assuming the role identification with their gender group. Ask the parents in a private setting what observations they have about the child's body image and sexuality. Inquire about friends in whom the child seems romantically or sexually interested, and whether the parent has concerns.

Questions related to sexuality will emerge during school years. They should be answered truthfully and fully. Even children who do not ask questions usually need information related to sexuality education. They may get information in school beginning in about fourth grade, but often still have misconceptions about the bodies of men and women, sexual intercourse, how babies are born, and other topics. Suggest that parents read books with their children that deal with these issues at a level that children understand. If books are available at home, children will be likely to look at them and ask questions. They should be in the home from third grade on since many young girls have body changes as early as 9 or 10 years of age (see Chapter 5). This can often put both the parent and child at ease and open the door to discussion. Parents should be advised to talk with teachers to learn what is presented in school and be able to supplement and clarify this information. Having discussions at a young age will help lead to further discussion as the child gets older. Nurses often perform sexuality education in schools or work with school districts in establishing policies regarding sexuality education plans. Help the parents plan to discuss appropriate and inappropriate touch so that the child understands and states those who can help in situations that lead to discomfort. (See Chapter 17 for a thorough discussion of child abuse.)

Suggest to parents that computers and other media provide information that can confuse children. Encourage them to watch movies with their children, engage in frank discussions related to sexuality observed, and answer questions truthfully. Children generally learn about topics such as sexual intercourse, homosexuality, and childbirth from school discussions and the media. It is better to learn from parents than from friends or the media. A few moments alone with parents and the child separately at healthcare visits may help to identify the concerns of each related to sexuality.

By approximately 9 to 12 years (fourth to sixth grades), most girls have started to have prepubertal body changes and have had their first menses. This is another opening for discussions about mature bodies of men and women and the transformation from childhood to greater maturity. Boys mature about 2 years later than girls. Without an event such as menstruation, parents may be less likely to start discussions with male children. Suggest that parents consciously begin conversations with boys periodically to explain changes they see in themselves and their peers. See Chapter 5 for further discussion of the body changes seen in the prepubertal period and during puberty.

SLEEP

Sleep is important for children because it helps provide the energy they will need to perform well in school and other activities. They generally take charge of bedtime routines with reminders about the time to go to sleep, and they sleep through the night. Sleep time varies from 8 to 12 hours, depending on the child and activity level. Busy schedules may interrupt this pattern, leading to irritability, lack of concentration, or even hyperactive behavior. Help children and families plan for healthy practices of **sleep hygiene**, or behaviors that foster a regular and sufficient sleep pattern, as well as daytime alertness (Mayo Clinic, 2013).

Sleepwalking and sleep talking sometimes occur at this age, but usually decrease as the child nears adolescence. Children who have stress at home, such as parental fighting, ill family members, or inadequate food or shelter, may not get enough sleep and fall asleep at school. Ask children if they fall asleep in class, and seek additional information about family stressors. This can lead to interventions such as recommending family counseling or referring to resources to obtain better housing or more stable food sources.

SCHOOL

School is a major microsystem that influences the lives of children and plays a role in self-concept and mental health formation. The child is usually ready for kindergarten when (Hagan, Shaw, & Duncan, 2008):

- Communication and cognitive skills are sufficient to support learning.
- The child can successfully separate from parents.
- Experiences with other children show ability to make friends and regulate own behavior.
- The child can follow rules and directions.

Help parents learn ways that they can facilitate a healthy transition to school, such as ensuring good sleep and eating routines, reading with the child, showing interest in school activities, and finding a space in the home for the child's school-related work.

When examining a school-age child, ask for a description of a best friend. If the child is unable to provide this, isolation may be occurring. Inquire about what the three best and three worst things are about school. Children with low self-concepts often have trouble talking about and evaluating school. Find out where

Families Want to Know

Sleep Hygiene

Nurses should inquire about the sleep patterns and amount of sleep that children receive. Ask if they are frequently tired or have trouble sleeping. Some simple behaviors help promote sleep and are referred to as *sleep hygiene.* They include (Mayo Clinic, 2013):

- Go to bed and get up at approximately the same time each day, including weekends.
- Follow a bedtime routine to prepare for sleep.
- Recognize that we do not "make up" sleep that is "lost" by sleeping in.
- Avoid caffeine, including tea, coffee, and carbonated beverages, for several hours before sleep.
- Gradually slow down activity about an hour or two before bedtime.
- Do not watch television, play games, text on the phone, or conduct other activities in the sleep location.
- Avoid naps in the late afternoon or evening.
- Darken the room for sleep.

the child attends school, if the area is generally safe, and how the child gets to school. Encourage the parents to meet the child's teachers, to become active in school activities, and to be available to solve problems with school personnel when needed. Partner with the parents and child when interventions are needed. An office nurse may contact a school nurse when the child needs support in the school environment. This may occur if the child has become ill and missed school, has family stressors, does not get along well with a teacher, or has a condition such as attention deficit disorder. Identify the risk and protective factors in the school environment and plan interventions to support the child when risks are present.

EVALUATING MENTAL HEALTH AND SPIRITUAL HEALTH

Certain mental health disorders are commonly seen during the school years. One example is anxiety problems that result in worries, fears, physical symptoms, stress, and sleep disorders without significantly impairing daily functioning. However, some anxiety disorders affect functioning and have more striking characteristics such as clinging, abdominal pain and headache, and refusal to attend school. Posttraumatic stress syndrome and depression may also be seen. See Chapter 28 for further description of these disorders. Anxiety disorder, posttraumatic stress, and depression should be referred to a mental health specialist for treatment. However, all children worry at times, and this type of anxiety can be helped by learning coping skills and relaxation techniques.

Spiritual health is the ability to develop a spiritual nature, including awareness of a life purpose or meaning, a sustaining power during times of stress, a feeling of harmony with the universe, and a sense of fulfillment (Pender, Murdaugh, & Parsons, 2015). School age is a time when children learn more about the people and the world around them, and begin to find their place in that world. Connection with faith-based groups assists some children and families in defining the purpose of life, while others may do so through social activity or a strong moral sense of responsibility. Ask children what brings happiness, how they help other people, or if they are members of a church, synagogue, or mosque. If families seem to have little purpose, parents are withdrawn or depressed, or the child has difficulty answering questions about meaningful activities, suggest methods of engagement in the community. Strategies might include providing contacts at local religious events, posting flyers about community events designed to bring unity to various cultural groups, or suggesting services needing volunteers in the community. Families who spend time together and find meaning in supporting each other nurture the spiritual health of their members. Suggest that every family plan a "family night" weekly when they play games, talk, eat, or engage in other activities together.

The nurse has an important role in fostering the mental and spiritual health of school-age children. Health promotion fosters the strengths of families and children, leading to healthy self-concept and positive self-esteem. Health maintenance seeks to prevent mental health disruptions. Be alert for risk factors in families since they represent the need for intervention. Expected outcomes for health promotion and health maintenance activities with school-age children include formation of a positive sense of self-esteem and healthy body image, use of coping skills to deal with stress, sleep patterns that meet needs for rest, and a growing purpose and meaning in life.

Relationships

Although the school-age child is gradually moving away from the family as the center of life, the family remains an important anchor. Ask about siblings, grandparents, and other extended family members. Sometimes these persons assist in the child's formation of a self-concept. Peers are increasingly important to the school-age child's self-identity. School age is a time of cooperative engagement with others. All children need to learn how to make and maintain friendships and work with others on projects and in recreation.

Inquire about the child's friends and activities at school. In private, ask parents if they are comfortable with the child's selection of friends. Find out if the parents facilitate friendships by allowing other children to come to the home and providing transportation as needed. When the child experiences a risk factor such as a move to a new town or school, role-play how to meet new children and how to make friends. If the child feels like an outcast or outsider among peers at school, explore how the family can create a safe and secure place for the child through extracurricular activities with children who have similar interests. When children are home schooled, the family should encourage social events and contacts after usual school hours.

Since peers are important to the school-age child, the child may feel pressure to appear like others, to fit in, and to do what others encourage. Although such pressures are often associated with teen years, they usually begin earlier, at least by 8 or 9 years of age. Ask children what kinds of things their friends try to get

them to do that they know they should not do, or if friends have tried to get them to smoke. Middle school years are the most common age for beginning to smoke, so always ask if the child has tried smoking, being careful to do this when the parent is not present and the child is more likely to be honest. When parents are not in the room they may also tell you about other activities, such as playing with guns, trying alcohol or other substances, or other risky behavior. It is best to ask children what they do in these situations, what they want to do, and who they can talk to about these events. Offer information about the risks connected with behaviors that are described, and suggest people such as parents, teachers, counselors, or clergy who are possible resources. If the child's health is at risk, be sure to report the activity to the physician or other healthcare provider so that it can be pursued and the child's safety can be assured. Activities such as playing with firearms or visiting a friend whose parents are making methamphetamine, for example, place children in extreme danger.

Parents often need guidance to help them in setting limits for their school-age children. The child is becoming more independent but unacceptable behaviors must still be managed by successful discipline techniques. Some guidelines that can help families include talking calmly about behaviors that are unacceptable, using techniques such as natural consequences or withholding privileges, modeling, and suggesting stress relief such as physical activity (American Academy of Pediatrics [AAP], 2011a).

School age is often a time when children first experience violence in relationships with others. Some children are bullied, while others are the bullies. Anger and aggression can occur, and children may engage in violence with each other. Ask children to describe when they last had a disagreement with someone and how the problem was solved. Suggest people who can help, such as school nurses, teachers, and counselors, and be sure that children feel safe in schools, neighborhoods, and homes. Ask parents how they resolve arguments between children at home and what help they need to help children learn problem-solving skills. Find out what policies the local schools have to assist in decreasing harassment of and by children. Become active on school committees that help children learn how to solve problems peacefully and how to respond to episodes of violence. See Chapter 17 for further discussion of violence in children and a detailed discussion of bullying.

The child's temperament (see Chapter 4) still plays a part in response to situations and the ability to self-regulate. The "difficult" child may have trouble getting to sleep or being quiet in the classroom. Have parents plan more physical activity for this child. Teach the child that bedtime routines are helpful and that sitting near the front of the class can help with concentration. The "slow to warm up" child may need ideas about what to say when meeting new people. Parents can help the child prepare for a new school by visiting the school with the child, talking about it, and meeting with the teacher so that a warm welcome can occur. The "easy" child is usually adaptable in most situations and is regular in activities. However, this child may object when other children interrupt, fail to take turns, or otherwise "break the rules" of behavior. They might need help in understanding differences in temperament in order to be more tolerant of classmates and their behaviors. Often nurses in schools address the issue of individual differences by speaking with classes or small groups of children.

The nurse takes an active role in promoting the child's health by anticipating developmental issues and preparing the parents and child to deal with them. Health maintenance outcomes include prevention of problems such as bullying.

Figure 9–4 School nurse's role in managing health problems. A student with diabetes is showing the school nurse how she programs her insulin pump. The nurse has partnered with nurses in the endocrinology office to learn about the type of pump the student is using. Such collaboration contributes to the monitoring and management of diabetes.

Disease Prevention Strategies

School-age children are generally healthy. The immune system is mature (see Chapter 22), personal hygiene practices are more developed than at earlier ages, and immunizations are usually complete. Engage school-age children in active pursuit of their own health. Teach strategies that can enhance the prevention of diseases. Nurses in offices and schools can teach children how to wash hands effectively, how respiratory infections are transmitted, what can cause gastrointestinal illness, and how to best manage their own health problems (Figure 9–4). Ask children in your settings what topics are of most interest to them and be prepared to suggest common areas of concern such as safety, skin care, athletics, and illnesses. Children can understand the connection between eating well and avoiding illness, maintaining normal weight and preventing type 2 diabetes, avoiding smoking to prevent cancer and other respiratory diseases, maintaining oral hygiene to promote oral health, and exercising to prevent hypertension.

School-age children are in the concrete stage of intellectual development, according to Piaget (see Chapter 4). This means that teaching is most effective when opportunities are provided to touch, feel, and otherwise become actively engaged in learning. When teaching about smoking, provide models of lungs and have the students breathe through a straw to demonstrate the effects of airway narrowing. These concrete activities will teach them concepts better than simple lecture or reading (Figure 9–5). Concepts of health promotion tend to be abstract since they deal with supporting one's highest potential for wellness. Thus it becomes even more important to provide concrete methods of learning.

Immunizations are generally up-to-date for school-age children. However, some children may have missed earlier doses because of illness or missed healthcare visits. Evaluate the immunization record to be sure it meets all recommendations. The most common immunization needs at this time include the following:

- Hepatitis B (whole series or a missed third dose)
- Hepatitis A (two doses if not previously administered)

Figure 9–5 Concrete experiences for health teaching. This boy is learning about the effects of smoking on the body through the concrete experience of examining a model of the lungs. Why does this type of hands-on technique help school-age children to learn concepts?

- Poliomyelitis, and measles-mumps-rubella (if booster doses of each were not given prior to school entry)
- Tetanus-diphtheria-acellular pertussis (Tdap) at the 11- to 12-year visit
- Varicella if not given earlier and the child has not had the disease
- Human papillomavirus (HPV) three-dose series at 9 years or older
- Meningococcal conjugate vaccine at 11 years with booster at 16 years
- Influenza annually
- Certain vaccines for children at high risk, such as meningococcal and pneumococcal (see Chapter 16 for further information on immunizations)

Screenings for health risks should occur during the visit. These include hearing and vision screening, blood pressure monitoring, tuberculin skin test, and, in some cases, screening for hyperlipidemia and lead exposure (American Academy of Pediatrics Committee on Practice and Ambulatory Medicine, 2016). Unusual complaints may indicate a need for further testing. Examples include the following:

- Pain other than brief discomfort after an injury
- Headaches
- Bruising
- Lack of coordination
- Repeated infections
- Decreasing vision or hearing
- Problems or changes in school performance or behavior

Children who have an identified health problem or developmental disability may have additional needs for screening and for interventions to assist with health maintenance. For example, the child with cystic fibrosis will need information to reduce the risk of respiratory infection, and the child with diabetes may need additional blood studies. The child who has difficulty reading will need alternative approaches to teaching correct hand hygiene; demonstration with explanation may be the best approach.

Inquire about any medications the child takes, including vitamins, fluoride, and nonprescription medications. Some families use complementary therapy for common conditions such as respiratory infections or gastrointestinal complaints. Complementary therapy is quite common in families where children have chronic conditions such as attention deficit hyperactivity disorder, autism, and skin conditions (Ben-Arye et al., 2011).

Parents should receive explanations about the screening tests performed and the results obtained. Inform them about vision and hearing results. Send home or call about results of blood tests when available. Be sure they understand the findings and have resources to assist in preventing or treating the specific disease in their children. Have them call with questions about health problems the child develops, and provide information about lowering risks of diseases. Be sure that families know when to keep children home from school (elevated temperature, active vomiting or diarrhea, coughing up brown or green mucus). Assist schools in setting guidelines for management of infectious diseases in that setting. Contact the local county and state health department for infectious disease guidelines for schools. Desired outcomes for the school-age child include prevention of infectious diseases, prompt treatment for acute infections, and careful management of existing health conditions in order to maximize health potential.

Injury Prevention Strategies

Injuries are a common cause of morbidity and mortality among school-age children, and each health maintenance encounter should include injury prevention strategies. Children of this age have more independence and may be harmed by activities they engage in without adults present, such as playing with fire or firearms. They participate in many sports and other physical activities and may sustain related injuries. Some children unfortunately suffer from harm due to physical abuse or other forms of violence (see Chapter 17).

Many common injuries are preventable with simple use of protective gear and the following safety guidelines. About 7% to 8% of youth rarely or never wear seat belts in automobiles, and in some states, up to 16% do not use seat belts (CDC, 2014). Certain groups of children are more at risk than others of not taking protective measures. Many children ride bicycles, but only a fraction of them use helmets. Strategies to make helmet use more attractive and to ensure correct wearing of helmets are needed (see *Evidence-Based Practice: Bicycle Helmet Effectiveness and Use*).

Identify youth engaging in risky activities and teach them safe practices. Join with schools and community groups to establish education programs. Provide information about adequate conditioning for sports in order to decrease chance of overuse injury. Each visit should contain basic history questions related to injury prevention. Pursue topics that appear to indicate problems. After information has been collected during the visit, plan two or three health maintenance topics that seem most important for injury prevention in the family. When there is a history of injury in the child, partner with the family to plan ways to avoid repeated harm. Table 9–2 lists some common injury hazards during the school years, and Table 9–3 offers suggestions for injury prevention teaching.

EVIDENCE-BASED PRACTICE | Bicycle Helmet Effectiveness and Use

Clinical Question

About 800 people die of bicycle-related injuries annually in the United States and there are over 500,000 emergency room visits for bicycle injuries, 60% of which involve children. Youth from 15 to 24 years old have the highest rate of bicycle injuries (CDC, 2013). Although helmets can reduce injury, many times they are not worn or are worn incorrectly. What are the factors that foster helmet use, and how can nurses contribute to efforts for use of bicycle helmets?

The Evidence

Wearing bicycle helmets is associated with higher household incomes, living in a state with a bicycle helmet law, younger ages, and having health insurance (Devoe, Tillotson, Wallace, et al., 2012). Bicycle helmets are often the wrong size or incorrectly adjusted so that they fit children improperly (Thai, McIntosh, & Pang, 2014).

Best Practice

Nurses should provide information about helmet use for bicycles and other vehicles. Engage children at community events and in schools. Inquire about helmet use at every healthcare visit. Reinforce proper fit and maintenance of helmets.

Clinical Reasoning

Where will you find information about helmet safety? What educational programs are available in your schools and communities? Are helmets made available for families that might not be able to buy them? How do you determine if a child is wearing a helmet correctly? Plan educational materials and programs for children who bicycle, ride skateboards, or use scooters.

TABLE 9–2 Injury Prevention in the School-Age Years

	HAZARD	DEVELOPMENTAL CHARACTERISTICS	PREVENTIVE MEASURES
	Motor vehicle/pedestrian/biking crashes	Child plays outside; may follow ball into road; rides two-wheeler.	Teach child safe outside play, especially near streets. Reinforce use of bike helmet. Teach biking safety rules and provide safe places for riding.
	Firearms	Child may have been shown location of guns; is interested in showing them to friends.	Teach child never to touch guns without parent present. Guns should be kept unloaded and locked away. Guns and ammunition should be stored in different locations. Be sure guns have trigger locks.
	Burns	Child may perform experiments with flames or toxic substances.	Teach child what to do in case of fire or if toxic substances touch skin or eyes. Reinforce teaching about 9–1-1.
	Assault	Child may be left alone after school and may walk, bike, or take public transportation alone.	Provide telephone numbers of people to contact in case of an emergency or if child feels lonely. Leave child alone for brief periods initially, and evaluate child's success in managing time. Teach child not to accept rides from, talk to, or open doors to strangers. Teach child how to answer the phone.

TABLE 9–3 Injury Prevention Topics by Age

AGE (YEARS)	INJURY PREVENTION	TEACHING TOPICS
5–8	Use a booster seat, properly positioned in the back seat of the car; when the child is large enough for the vehicle seat belt, use both lap and shoulder belts. Never place a child in the front seat of a car with a passenger air bag. Restrain all children younger than 13 years in the rear seat. Be sure the child knows how to swim and works on these skills regularly. Protect the child with sunscreen when outside. Check smoke alarms and keep them functioning properly. Have an escape plan in case of fire in the home. Keep poisons, electrical appliances, and fire starters locked. Keep firearms unloaded and locked; store ammunition in a separate locked location; have trigger locks installed on guns; keep dangerous knives locked. Provide protective gear for bicycling and other activities and insist that it be worn. Teach safety precautions for bicycling and other activities.	Teach safety with strangers. Provide a list of people a child can approach if feeling threatened by touch or other experience. Choose care providers carefully; occasionally pick up child earlier than expected; ask about policies regarding discipline and do not leave child with someone who uses corporal punishment. Be sure the child knows emergency numbers, names, and plans. Review carefully any hazardous event that has occurred with the child and summarize what was done correctly and how response could be improved. Limit screen time to 2 hr daily; do not allow violent games or viewing. Review behavior with strangers regularly such as not getting in cars and not engaging in phone or Internet conversations.
8–10	Use car booster seat until child sits upright against back seat with bent knees over edge of seat; insist on use of lap and shoulder belts. Do not place child in front seat of car with a passenger air bag.	Do not allow child to operate power tools or machinery. Continue to reinforce other teaching described above, include child more fully, and expand responsibility to the child with increasing age.
10–12	Continue to reinforce teaching described above. Parents and child should attend class on cardiopulmonary resuscitation and airway obstruction removal.	Avoid high noise levels such as when listening to music through earphones.

Source: Data from Hagan, J. F., Shaw, J. S., & Duncan, P. M. (Eds.). (2008). *Bright futures: Guidelines for health supervision of infants, children, and adolescents* (3rd ed.). Elk Grove Village, IL: American Academy of Pediatrics.

Developing Cultural Competence Use of Safety Protection

There are marked differences in behaviors that influence unintentional injuries. Although about 8% of children rarely or never wear a seat belt in the car, Black males are most at risk, with almost 12% not using seat belts. In addition, 88% of youth who ride bicycles rarely or never wear a bicycle helmet, but the rates vary, with 94% of Black and 92% of Hispanic youth not wearing helmets, while 86% of White youth do not wear bicycle helmets (CDC, 2013, 2014). How will you inquire about seat belt and bicycle helmet use in an open-ended manner during health promotion visits? Consider asking these questions:

- Where do you sit when you ride in the car?
- Who do you usually ride with?
- Do you drive? If so, how often do you text or hold and talk on your phone while you drive?
- Are there seat belts? How often do you use them?
- Do you ride a bike?
- Do you have a bicycle helmet? How often do you wear the helmet?

Plan strategies to include all children and families, especially those at high risk of not using seat belts or bicycle helmets.

Nursing Management

For the Health Promotion and Maintenance of the School-Age Child

Nursing Assessment and Diagnosis

Assessment of health promotion and health maintenance topics occurs in many settings with school-age children. They may be seen in offices, clinics, or other settings designed to provide such care. They may come for episodic care for a fracture or infection when health promotion and health maintenance can be easily integrated. They may be seen in the home or neighborhood center, and are frequently encountered by nurses in schools. Opportunities for assessment and intervention should be used whenever they occur. The individual child is examined, and the family, friends, school, and community are addressed. In addition, these visits provide an opportunity to identify early and intervene for health-related problems that emerge or become apparent in school age.

Assessment can be considered on two levels with school-age children. Individual children may be assessed for height and weight, for immunization status, and for use of protective gear during sports. Populations of children may also be assessed since school age is the first time that large numbers of children are together in certain settings. The findings from such assessments will become the basis of an **individualized approach** or a **population-based approach** to health promotion and health maintenance. For example, nurses commonly measure height and weight, calculate body mass index (BMI) for *individual* children

seen in a clinic, share results with the family, and address appropriate teaching about weight control and nutritious intake. In other settings, nurses may measure a *classroom* of children and use the collective data to plan appropriate interventions. If 40% of children in a school are classified as overweight by BMI percentile, much emphasis should be placed on teaching about dietary intake, physical activity, and the relationship of recommended weight levels to chronic disease risk. However, if only a small number of children are overweight, interventions may not be as extensive about this topic.

Nurses perform assessment of growth in school-age children, look for achievement of developmental tasks, assess physical and mental health, and assess social characteristics. Based on the assessment of the individual child or populations of children, nursing diagnoses for children and families are established. Possible nursing diagnoses include the following (NANDA-I © 2014):

- ***Development: Delayed, Risk for,*** related to abuse
- ***Parenting, Impaired,*** related to lack of knowledge about child health maintenance
- ***Sleep Deprivation*** related to sleep terrors
- ***Violence: Other-Directed, Risk for,*** related to history of witnessing family violence
- ***Loneliness, Risk for,*** related to long periods alone after school

Planning and Implementation

The nurse is instrumental in planning interventions to promote and maintain health in school-age children. These interventions may take place in offices, homes, or clinics with an individual child, or in schools and other community settings with groups of children.

When working with individuals, summarize the strengths and needs identified during the visit, and ask the child and family if they concur. Plan together with them to provide the needed information for topics developed during the visit. Be sure to emphasize those areas where the family excels. For example, positively reinforce use of car seat belts (see *Families Want to Know: Car Safety for the School-Age Child*), use of protective sports gear, and being current with immunizations. Summarize the next expected developmental tasks, such as increasing independence and growing self-responsibility for choosing snacks and television shows. Then provide anticipatory guidance to assist with the child's growing independence. As peers are becoming more important, always focus some discussion on maintaining healthy social relationships through school peers, religious or community events, and sibling contacts.

Most families welcome a combination of discussion and reading material or pertinent websites for later exploration. Provide telephone numbers of resources for questions and community contacts. Tell the parents when the next health promotion/maintenance visit is recommended. If working with school children for episodic care, ask when the last health maintenance visit occurred. If a child is seen for health care after a bicycling accident, the family may be receptive to teaching about safety precautions. When the child is exposed to skin injuries, a review of the last tetanus booster may reevaluate health maintenance needs. Use every opportunity to work with individual children and insert appropriate health promotion/health maintenance topics.

When working with groups of children, health promotion focuses on known needs, interests, and risk areas. Nurses in school settings have used a variety of creative approaches to promote the health of youth. Nurses in schools can set up a program to train students in health topics; these students then become peer coaches or health advocates in working with other students. Another activity is evaluating the components of school health programs and making recommendations for additions as needed. In school settings, nurses have used a variety of creative approaches to promote the health of youth. Nurses in this setting can establish programs to train students in health topics; these students then become coaches or health advocates who can work with other students, especially those of younger ages. Nurses may also evaluate components of school health programs and offer recommendations for additions as needed. Bulletin boards, community newspapers, television, and community group membership may all be as effective as teaching in school classrooms. Stress reduction teaching should be provided on group and individual levels. Nurses can teach or assist in development of progressive relaxation, deep breathing, biofeedback, yoga, or meditation. Interventions will be most effective if they begin with an understanding of the population served.

Evaluation

Seek evaluation from parents during visits for care. Were their questions answered? Do they know where to turn for advice? Do they know when the child should be seen again for health promotion/maintenance?

Families Want to Know

Car Safety for the School-Age Child

Even though parents may have been diligent about car seat and seat belt use when children were younger, guidelines change and they need teaching about current requirements for the school-age child. Recommendations include the following:

- The child should be kept in a rear-facing seat as long as possible. Generally, by 4 years of age, the child has outgrown the rear-facing seat and should be in a forward-facing car seat with a harness in the back seat. This type of seat is recommended for children 4–7 years of age.
- Once the child outgrows the largest height and weight recommended by the manufacturer for the forward-facing seat (usually by 8 years of age), a booster seat is used in the back seat.
- Once the child is large enough for the regular seat belt, the lap belt must lie snugly across the upper thighs and the shoulder belt should be snug across the shoulder and chest.
- Keep all children in the back seat until 13 years of age; this is the safest location for them in the car (American Academy of Pediatrics, 2011b, 2014; National Highway Traffic Safety Administration, 2012).

The expected outcomes for nursing care of individual school-age children include the following:

- The child demonstrates normal patterns of growth and development.
- The child, family, and community provide a supportive and nurturing environment for the child.
- The child shows growing independence in directing own health promotion activities.

Expected outcomes of nursing care for groups of children include the following:

- The children identify lifestyle decisions that influence their health status.
- The school and community offer resources that help to lessen risk factors related to health and disease/injury prevention.

Health Promotion and Maintenance for the Adolescent

Adolescents are often seen only sporadically for health care, even though visits are recommended annually. They are usually healthy, may not need immunizations, and consequently do not often come for health care, although annual visits are recommended (American Academy of Pediatrics Committee on Practice and Ambulatory Medicine, 2016). If adolescents seek care for a minor illness, birth control, or a sports examination, the visit should be viewed as a health supervision opportunity.

Professionalism in Practice Adolescent Healthcare International Guidelines

The World Health Organization (WHO) realizes that adolescents are neither young children, nor young adults, and therefore have unique healthcare needs. The WHO made several recommendations for adolescent health care (WHO, 2014):

- Adolescent care should evolve from being "adolescent friendly" to "adolescent responsive" in order to be meaningful to youth.
- Universal healthcare coverage should be available for all adolescents.
- E-health, m-health (electronic and mobile, respectively), and in-school delivery of care should be offered for adolescents.
- An adolescent-competent workforce should be trained.

Nurses play a role in establishing adolescent-responsive health care in schools, community centers, and via electronic venues. A full range of services can be developed, with input from adolescents themselves about their needs and delivery choices. All nurses working with adolescents must have a thorough understanding of development, best approaches, and common healthcare needs.

While all components of the usual visit may not be performed, at least those parts most important are inserted into care. If time is limited, the nurse has to decide which topics to address during a healthcare visit. It is advisable to start with the topic of most interest to the teen and then to include injury prevention teaching, since injury is the greatest risk to teens. Health promotion topics such as dietary and exercise habits could be discussed.

Lifestyle behaviors are responsible for most of the preventable diseases, and all typically have origins in adolescent years, including sedentary lifestyle, unhealthy diet, tobacco and other substance use, and risk taking. Mental health assessment and teaching are other areas of prime importance. If the teen is at immediate risk, such as considering suicide in response to depression, this must be dealt with immediately by collaborating with a mental health specialist.

What general principles can guide programs to promote health in adolescents? Some researchers have analyzed theory application and approaches of programs, and others have suggested key elements of programs (see *Clinical Reasoning: Applying Theory to Plan for Adolescent Health*). Programs assist adolescents in taking on health promotion behaviors by fostering a sense of competence, promoting decision making, and increasing motivation for change toward healthy behaviors (Pender et al., 2015). When establishing youth programs, whether with individual adolescents or with groups, the nurse includes evaluation of the effectiveness of the plan, and uses methods to expand and sustain successful approaches.

Clinical Reasoning Applying Theory to Plan for Adolescent Health

Several theories guide healthcare professionals in establishing health promotion programs for adolescents. These theories provide an organized approach to planning and suggest the strategies that will be most successful, based on the person's motivation and developmental age (Pender et al., 2015). One such theory that is commonly used in adolescent care is the social cognitive theory.

This theory was developed by Albert Bandura, whose work is described in Chapter 4, and is frequently used in health research (Bandura, 1986, 1997a, 1997b; Connor, George, Gullo, et al., 2011; Davies, Terhorst, Nakonechny, et al., 2014). The key components of his theory involve **self-efficacy** (the person's belief in the ability to perform a behavior) and **outcome expectancy** (what the person expects to get from performing a certain behavior). Learning a new behavior occurs through **modeling**, or imitating the behavior of someone else. Bandura believes that individuals make decisions about health behaviors based on thoughts about the consequences and outcomes of those behaviors. The person's characteristics, such as self-efficacy and outcome expectancy, interact with the external environment and the behavioral choices available. All of these components together determine health behaviors, and all can be influenced to promote health.

When seeking to promote physical activity behaviors in youth, essential components include the following:

- Encourage the youth to believe they can perform the activity (self-efficacy).
- Point out the positive aspects of the behavior (outcome expectancy).
- Show the youth how to do the activity (modeling).
- Provide a physical setting and opportunity for performing the behavior (environment).
- Allow trial and error, choice in time, and extent of activity (behavioral choices).

Compose a teaching plan to encourage increased physical activity for a teen, using all components of the social cognitive theory. List the outcome measures or goals for the teaching, the interventions, and methods of evaluation.

Figure 9–6 **Healthcare visit with a teen. Parents often accompany teens with a healthcare problem when they come in for the examination. Provide an opportunity to see both the teen and parent privately and integrate general health promotion and health maintenance into the visit. What questions can you ask this teen? What teaching might be needed?**

General Observations

The beginning of the visit with an adolescent can be an important time to gather information, just as it is with younger children. However, the observations you make will relate to the adolescent's more advanced stage of development.

Ideally the facility has a waiting area that is designed for adolescents. Teens often dislike waiting for health care with either young children or older adults. Teen waiting areas are popular because they provide a special place, thereby relaying that the adolescent is important, and can use video kiosks and other contemporary methods to impart health information while the teen waits (Figure 9–6). As you call the adolescent back for care, observe if parents or friends are present, or if the teen is alone. Young adolescents often come with parents to the facility, and parents often then wait in the waiting room during the examination. If the young adolescent comes in for a special problem, such as a skin lesion or other health concern, the parent may accompany the adolescent into the examination room. If someone comes with the teen, it may be necessary to provide some private time by asking the other person to wait outside for a moment. Reassure parents that there will be time to talk with them about any of their concerns and questions, and provide them with an opportunity to ask questions and obtain information.

Some teens are comfortable in healthcare settings and actively engage in conversation, while others are nervous and will need more explanations and reassurance during the first steps of measurement and blood pressure. By adolescence, boys and girls should be assuming more of a partnership role in their own health care. As the visit begins, greet adolescents warmly, ask what concerns and questions they have, and ask for their opinions and reactions throughout the visit. This will show that their thoughts are important and that they play an important role in guiding the healthcare visits. When adolescents are visiting the same office or clinic that they came to during childhood, they usually know and feel comfortable with the care providers. If the setting is new to them, explain procedures and introduce personnel so they feel more at ease.

Growth and Developmental Surveillance

Adolescence spans several years, and growth and developmental issues vary throughout the period. For young adolescents, or those from about 12 to 13 years of age, growth measurement remains important. These youth are still growing, and use of percentile grids continues to be an important part of care. Growth should remain in the same percentile channel as during childhood, with girls reaching nearly adult height at this age, and boys still continuing to grow. As always, be alert for youth who have either increased or decreased percentiles, or are above the 85th percentile or below the 5th percentile for body mass index. They will need additional assessment of nutritional intake and physical activity.

By middle (14 to 16 years) and late adolescence (17 to 19 years), adult growth is nearly achieved, earlier for girls than boys. While measurement continues to be performed, nurses assess the BMI carefully to be sure the height and weight indicate appropriate intake and exercise. Overweight at this age is likely to continue into adulthood, particularly if parents are overweight, so early intervention will be needed to decrease this potential. Other youth may have eating disorders and should be referred to a specialist for care. Children from homes without sufficient financial resources may be hungry and lack adequate food of high quality (known as *food insecurity*). Parents who were eligible for the Special Supplemental Nutrition Program for Women, Infants, and Children (WIC) services when children were younger may not receive them once the child is an adolescent, so the increasing dietary intake needs of their teens cannot be met. If an adolescent is thin and has little energy, consider administering a food security questionnaire such as the one provided by the U.S. Department of Agriculture (www.ers.usda.gov). Even the child who is overweight may live in a family with insufficient resources since foods with high fat and caloric content are often less expensive than those with greater nutrient value. For example, a "dollar menu" at a fast-food restaurant meets hunger needs faster and with less expense than a home-prepared meal of fresh fruits, vegetables, and grains. In addition, people who have experienced periods of hunger from inadequate food resources may overeat when food is available, a pattern that promotes weight gain (see Chapter 14).

Few options exist for measuring the developmental competence of adolescents, but observations and questions during care provide information about the meeting of developmental milestones. Key tasks for adolescents involve separating from the parents and establishing positive relationships with peers. The young teen may come to an appointment with a parent and still rely on that parent to answer some questions during the examination. However, middle and late teens should be increasingly able to come alone, answer questions themselves, and assume responsibility for healthcare decisions. Offer older teens the

option of coming into the room alone, stating, "Your mom can wait here and we can come and get her later. Does that sound all right?" During time with the adolescent, ask questions to learn about peer interactions and activities.

The adolescent may receive a physical examination from a nurse practitioner or a physician. See Chapter 5 for components of the examination. Some particular parts of the examination to include for teens are scoliosis screening, sexual maturity rating (Tanner stages), breast examination, testicular examination, testing for sexually transmitted infections (among those sexually active), pelvic examination, and Pap smear (for sexually active females), hematocrit/hemoglobin for anemia when risk assessment warrants, hearing and vision screening when needed, annual blood pressure, lipid screening for those with family history of early heart disease or other risk factors, and tuberculosis screening for those in high-risk areas (American Academy of Pediatrics Committee on Practice and Ambulatory Medicine, 2016).

Most adolescents do not want their parents present during the examination, but occasionally will want a parent present for something like a first pelvic examination or a blood draw. Ask them their wishes in a confidential setting so they can freely make the choice. They also may choose to have a same-gender healthcare provider complete the genitourinary examination. Expected outcomes of care include screening and early identification for common health problems, normal patterns of growth, and meeting of developmental milestones.

Nutrition

The young adolescent needs a well-balanced diet to support the growth of this period, and the late adolescent requires intake that supports physical activity and provides nutrients for metabolism and to promote the immune system. While nutritional intake is important, teens often do not eat well. They may be busy and do not want to plan meals, they like to eat foods that are popular with other teens (so high fat and sugar intake can be common), they may be dieting to achieve weight loss, and some do not have enough financial resources to access healthy foods.

Combine the information from measurement of the adolescent with the answers to questions about diet to identify possible areas for intervention. Find out what questions the teen has about foods, diet, maintaining desired weight, and topics such as vegetarianism or supplements to enhance athletic performance. See Chapter 14 for further detail about these special nutritional topics. Health promotion plans focus on practices that lead to healthy growth and development. They may include teaching about:

- Getting five fruits and vegetables daily
- Including whole-grain products to replace refined products whenever possible
- The importance of eating three meals each day, including breakfast and lunch
- Eating together as a family several times weekly, which enhances quality food intake
- How to plan menus and prepare foods for balanced intake

Health maintenance plans center on those practices that prevent disease, including:

- Limiting refined sugar and high-fat intake (such as soft drinks and fried foods) to maintain weight at recommended level
- Including two to three servings of dairy products daily to enhance bone formation and decrease chance of osteoporosis as an adult
- Using resources for treatment of eating disorders if they are identified

While much of nutrition teaching should be aimed directly at the adolescent, parents are also included. They can be effective contributors to healthy intake by providing plenty of fruits and vegetables for snacks, having foods attractively prepared and ready for consumption when the teen is hungry, planning several meals together as a family each week, encouraging milk or other forms of calcium intake, and setting a good example for food intake. Help parents identify the youth with an eating disorder and provide resources for intervention in these cases. Consider as well the teen with a baby. The adolescent who is pregnant or breastfeeding has even more need for nutritional teaching and may need financial resources to access sufficient food. How can the nurse combine in the teaching plan the growth and developmental needs of an adolescent with those of her new baby?

Physical Activity

Many adolescents suffer from the effects of inadequate physical activity. As children get older and enter the teenage years, physical activity decreases, particularly in girls. Sixty minutes daily of moderate or vigorous activity is recommended for teens, but 15% do not get this level of exercise even 1 day a week, and 53% do not achieve this activity 5 out of 7 days of the week (CDC, 2014). The percentage is lower among some groups, such as females, Blacks, and Hispanics, with wide state variation (CDC, 2014). At a time when teens are not very active as a group, physical education requirements in school are also decreasing. Only 24% of 12th-grade male and 16% of 12th-grade female students regularly attend a physical education class (CDC, 2014). Physical activity levels must therefore be assessed at each health supervision visit or in other contacts with adolescents. Apply resilience theory as discussed in Chapter 4, and assess youth, family, and community for risk and protective factors regarding physical activity (Table 9–4).

Some youth have established regular physical activity programs, and their behaviors should be encouraged (Figure 9–7). Be alert for adolescents who exercise but have other health problems. Some athletes try to eat very little to remain a certain weight for wrestling, running, or other sports. Integrate nutritional teaching that includes the importance of adequate intake for sports performance. Other athletes use nutritional supplements to enhance performance. While most are not harmful, few have proven benefits and their cost is not warranted. Some may actually be harmful to adolescents, such as prolonged use of creatinine and any use of steroids.

Some youth have very little physical activity and feel incompetent in performing many sports. Work with them to find at least one thing they can do on a daily basis—walking their dog in the neighborhood, riding a bike to the store, using stairs instead of elevators when possible, parking on the far side of the school lot and walking farther, swimming at a club their parents belong to or at a local YMCA or YWCA, or saving money to take lessons for something they have always dreamed of doing, such as horseback riding or golf. The community health nurse can form interest groups at schools and community centers that provide an outlet for adolescents who cannot "make the team" for school sports. Encourage parents and adolescents to set goals together to integrate some physical activity daily.

TABLE 9–4 Risk and Protective Factors Regarding Physical Activity in Adolescence

RISK FACTORS	PROTECTIVE FACTORS
• Lives in rural or other isolated setting with little opportunity for contact with other teens • Lives in urban area that is unsafe or provides little opportunity for outside physical activity • Presence of neighborhood hazards and unsafe areas • Lack of neighborhood programs for physical activity promotion	• Has opportunities for participation in physical activity at home, at school, and in the community • School provides daily physical education classes • Neighborhood and community provide physical activity options • Has many friends living close who participate in physical activity • Public policies maintain parks, green spaces, biking trails, playgrounds
• Has a developmental disability that impairs physical movement	• Programs are available for adolescents with developmental disabilities or other healthcare needs
• Does not like physical activity	• Likes physical activity
• Has a pattern and history of low activity levels • Is overweight • Does not feel competent in most sports	• Has exercised during all of childhood, often with parents
• Limited financial resources to pay registration fees or buy protective gear for sports	• Availability of financial and other resources for sports gear and protective equipment
• Family members who have little physical activity • Parents who are not active in school sports and committees • Parents who do not like physical activity and have had low levels while their teen was growing up • Parents who have little time or facilities for exercise, or always exercise at a club—out of view of their family	• Parents participate in regular physical activity and encourage the adolescent to do so also • Youth and parents agree to a limit of 2 hours daily of screen time
• Lack of youth and parent knowledge about physical activity needs and benefits	• Knowledgeable about benefits of activity; committed to maintaining exercise patterns

Source: Data from Hagan, J. F., Shaw, J. S., & Duncan, P. M. (Eds.). (2008). *Bright futures: Guidelines for health supervision of infants, children, and adolescents* (3rd ed.). Elk Grove Village, IL: American Academy of Pediatrics.

Figure 9–7 Teen use of safety measures. This teen girl is an avid "skater." How can you encourage and praise her for this activity? What clues do you have that she is using adequate safety measures?

What risk and protective factors for physical activity exist in your community? Go to www.activelivingbydesign.org to examine the positive effect community planning can have on its members' exercise levels.

The nurse's activities for health promotion concentrate on teaching the health and mental benefits of physical activity such as increased energy, weight control, and a feeling of control and success. Health maintenance focuses on viewing physical activity as a method to prevent disease such as cardiovascular disease and diabetes. Youth who have family members with these diseases or meet adults who have them are more likely to understand the importance of their own activity. Desired outcomes include maintenance of weight within recommended level, daily exercise of 60 minutes, and establishment of lifetime exercise routines.

Oral Health

Continued dental care during the adolescent years can ensure oral health. The recommendations remain the same as those for young children. The adolescent should floss daily, brush twice daily with a small amount of fluoridated toothpaste, and visit a dental care provider every 6 months. By about 14 years of age, those adolescents who do not have fluoridated water and have been taking fluoride can stop this supplement. Even the molars have been formed by that age so fluoride tablets are no longer needed. Continue to examine the condition of the teeth and the number of erupted permanent teeth present. Be alert for any unusual growths and ulcers in the mouth and refer for care as needed.

Unavailability of dental insurance for the adolescent is a potential concern. The teen whose family does not have dental insurance needs referrals for care to affordable resources. Dental specialists clean off plaque that has formed, apply sealants to erupting molars, examine the teeth for caries, and perform restorative care. Certain groups are more at risk for inadequate dental care (see *Developing Cultural Competence: Dental Care*).

When working with these populations, nurses can question access to care and make recommendations that foster regular checkups.

Developing Cultural Competence Dental Care

Analysis of several national surveys, such as the National Center for Health Statistics and the National Health Interview Survey, shows marked disparity in oral health. The major factor in disparity of dental care is lack of dental insurance. While 42% of youth from families without insurance did not have a dental visit in the previous year and 27% of them had unmet dental needs, only 11% of youth from families with insurance lacked a previous year visit and only 4% had unmet dental needs. Poverty and immigrant status are two risk factors associated with lack of dental insurance (Child Trends, 2013).

When working with adolescent populations from groups at high risk for lack of dental coverage or high incidence of caries, include dental assessment in health supervision visits, and have resources for care readily available to carry out referrals as needed. The Affordable Care Act provides for two dental visits annually, so assist families to participate in their state or employment healthcare plan.

Evaluate risk factors for threats to oral health such as tobacco use, particularly chewing tobacco (see quote from Jeremy in the chapter-opening scenario). A risk for oral injury exists with engagement in certain sports. Ask about physical activity and recommend that a mouth guard be worn if the youth engages in hockey, football, or some other sports. Some teens may wish to whiten the teeth or obtain orthodontia to improve appearance. The nurse can help the youth and parents to find resources for needed care.

Expected outcomes for oral health include dental visits twice annually; daily positive oral health habits; absence of risk factors for poor oral health, injury, or tobacco use; and obtaining recommended follow-up care for problems.

Mental and Spiritual Health

Adolescents have many challenges to their mental health and need support to emerge from adolescence with mental and spiritual strengths. Mental health topics must be addressed at each health supervision opportunity to promote mental health among teens. Mental health is closely linked to developmental tasks such as growing independence, formation of close relationships with peers, becoming confident in accomplishments, and setting goals for the future. Some chronic mental health disorders such as schizophrenia can emerge during adolescence, so mental health screening is important to perform with this age group.

As during other developmental stages, the self-concept continues to evolve, influencing how the adolescent reacts to the environment. Self-regulation—making decisions to govern oneself—becomes critically important. Self-esteem, or a positive feeling about the self, is key to meeting life's challenges. Ask what the teen is proud of and has accomplished and what disappointments have occurred as well. Provide resources to deal with disappointments and praise the teen's accomplishments.

The adolescent's self-esteem is connected to perception of body image. Factors such as early or late maturation, overweight or underweight, or the role of the media can influence the teen's body image. A healthy image includes the realization that the body has positive and less positive attributes and that the individual can influence the body by healthy eating and physical activity. Be alert for the teen whose wish for a different body leads to eating disorders and excessive exercise or intake of nutritional supplements.

Sexuality involves both body changes that signal mature sexual development, and the mental concept of oneself as a sexual being. Body changes and mental concepts do not necessarily mature at the same time, and adolescents may not be ready for sexual maturity; decisions about sexual behavior are not necessarily equivalent to achieving sexual maturation. Most young adolescent girls have begun menstruating, and by early to middle adolescence, boys are having nocturnal emissions and ejaculations. Ask teens if they have received information about puberty, body changes, and sexuality. Tell young adolescents that most teens have questions and that they may ask about any areas of interest, including contraception and sexually transmitted infections. Ask older adolescents directly if they have had sexual intercourse and if so, what they are doing to protect against pregnancy and sexually transmitted infections. Provide support for adolescents who have decided not to have sexual intercourse, encouraging them to continue this plan, telling them that sexual feelings are normal, but that decisions about sexual intercourse are their right and privilege. Ask if the adolescent has ever experienced unwanted pressure for intercourse and if there has been help and support to deal with the situation. Intimate partner violence, date rape, and other trauma signal a need for referral to a mental health specialist. See Chapter 17 for further information.

Ask if teens have confusion about their sexuality. If teens have self-identified as being gay, let them know they are welcome and ask about decisions regarding sexual practices, reinforcing the need for protection against sexually transmitted infections. Provide community resources to support gay or lesbian teens so that they can develop a social group in which they feel comfortable. Some adolescents are seen for health care at the time they become sexually active. Use this opportunity to reinforce and correct prior knowledge about the body and protection against pregnancy and sexually transmitted infections.

Clinical Tip

The nurse who works with adolescents dealing with sexuality issues may find that the values of some teens are very different from one's personal values. How do you react when a teen decides to have sexual intercourse or has become pregnant? Can you help teens make wise decisions without telling them what they should do?

It is important for adolescents to learn the significance of sexual intercourse and the meaning of close relationships. Teaching them early about this will enable them to respect others at the time they do have intimate relations. Respect is also the key to working with teens. Nurses should treat them with respect, expecting them to consider options and make wise decisions. Nurses who cannot work with certain groups of teens because of moral values differing from their own have the obligation to refer the teens for care to resources where they can receive the information and services they are requesting.

Most adolescents still need discipline or guidance from parents at certain times. Rather than a constant battle over daily events, it is best if there are just a few important rules that parents have to enforce only rarely. When working with parents, nurses can assist them to set useful boundaries for

teens and offer resources such as parenting groups and websites for assistance.

Sleep is necessary for anyone to function safely and at a level of one's potential. Unfortunately, many youth do not get the sleep needed for healthy functioning. Teens have an increased need for sleep due to their growth rates and activity levels. At the same time, their internal clocks change, making it more difficult to get to sleep at the usual time. It is thought that a decrease in secretion of melatonin occurs, so the teen does not feel tired in the late evening. However, they often do not have the number of hours of sleep needed by the time they wake up for school or work. The problem may be worsened if the student participates in sports or other activities. They may need to get to school before normal starting hours for music, sports, or other activities, or perhaps stay late into the evening for practices. Some adolescents work weekends or evenings as well. And of course social activities usually fill much of their time. Although about 9 hours of sleep is needed, most adolescents get about 6 hours (Mayo Clinic, 2013). The effects of sleep deprivation can be serious. Teens cannot perform to their potential in school or at work. Many parents state that adolescents are moody and difficult to communicate with when they are tired. There may be a connection between lack of sleep and substance abuse, and teens commonly use caffeinated beverages to stay awake. Some people tend to eat more when they are tired, and get less physical activity. Perhaps one of the most serious consequences deals with the danger of driving while sleepy; this is a common cause of accidents. Ask adolescents about what time they go to bed, when they awaken, and whether they are frequently tired. Provide suggestions for regular sleep schedules, avoiding caffeine products in the evening, making screen technology unavailable during sleep time, and planning a day of relaxation into every week.

Healthy People 2020

(SH-3) Increase the proportion of students in grades 9 through 12 who get sufficient sleep on school nights

- Less than 31% of adolescents have 8 hours of sleep on school nights. *Healthy People 2020* has set a modest goal to increase this percentage to 33% who achieve at least 8 hours of sleep on school nights.

School plays an increasingly important role in adolescent mental health. School provides peer support, meaningful activities, and a forum for learning time management and other skills. At the same time, some youth become stressed because of inability to fit in, worry about grades and their futures, and violent or unsupportive school situations. Discuss the elements of school that adolescents like and those they do not like. Determine what support is available in the schools. Ask the adolescent about future plans and how those are influencing choices for courses and friends in school.

Temperament or personality characteristics continue into adolescence and generally do not change from earlier years. For example, the active infant and young child is usually an active teenager. The slow-to-warm-up baby may be the adolescent who needs more time to adjust to a new school or teachers. If the adolescent or parent has trouble with personality characteristics, it may be helpful to talk about these traits, help them establish a positive sense about the attributes, and discuss ways to adapt the environment as needed. For example, parents should not expect a slow-to-warm-up teen to be interested in running for a class office. Someone with irregular sleep and eating habits will find it difficult to have a job at a set time and will need to set alarms and other reminders.

Figure 9–8 Spiritual health for teens. Teens often become associated with causes. This helps them to feel part of a social group and also provides opportunities for examining belief systems and making decisions about meaningful activities.

Spirituality offers comfort and support for the adolescent. Being a member of a teen group in a faith-based home can offer a peer group with similar values and bring meaning to life. Some adolescents reject the faith of their parents and seek a different group; others seek to leave religious practices totally, while others become more committed to them. Ask them if they have the resources they need to bring meaning to their lives; provide them if needed. Realize that participation in community food kitchens, raising money for causes, and other activities also provide meaning for many adolescents (Figure 9–8).

The nurse actively promotes the mental health of youth by understanding their developmental needs and providing information and resources. Gentle guidance and active partnership with youth help to provide the resources to ensure healthy self-concept, sexuality, and personality development. While most teenagers have many protective factors that can be identified and fostered, a few have risks that can harm mental health. It is important to identify the risks, and to use health maintenance techniques to lessen the risk factors. Depression and substance use are two common risks to mental health. Depression is discussed in Chapter 28, and substance abuse is discussed in Chapter 17. See the quick checklists in Table 9–5 to help in identifying these problems during health supervision visits.

Although health promotion and health maintenance activities commonly occur in office or clinic settings, there are many other settings where nurses work with adolescents, and mental health activities are often integrated into these settings. Consider offering health promotion/maintenance wherever students might be found. Some nontraditional settings include correctional facilities, school-based health centers, and programs for pregnant teens. Adolescents in these facilities can benefit from services to improve diet, physical activity, and lifestyle behaviors that influence mental health.

The desired outcomes for mental and spiritual health promotion and maintenance include meaningful activities in the adolescent's life, emerging independence, good choices about lifestyle behaviors, and development of successful coping skills.

TABLE 9–5 Signs of Depression and Substance Abuse

DEPRESSION	SUBSTANCE ABUSE
Changes in appetite and weight	Changes in school performance, sleep, and appetite
Changes in sleep schedules and patterns	Unusual behavior, such as getting into trouble at school
Changes in school performance	Accidents and other unexplained events
Physical complaints	Lack of responsibility for actions
Loss of interest and pleasure in usual activities and friends	Increased mood changes
Depression, irritability, poor concentration	Inability to set goals
Feelings of worthlessness, helplessness	A variety of physical changes depending on the substance used
Thoughts of death or suicide	

Source: Adapted from Tanski, S., Garfunkel, L. C., Duncan, P. M., & Weitzman, M. (2011). *Performing preventive services*. Elk Grove Village, Il: American Academy of Pediatrics.

Relationships

Adolescents form stronger bonds with friends than at any time earlier in development; at the same time, they need their parents for guidance and reassurance as they become more independent. As teenagers strive for independence, they frequently strike out at parents, test limits, and have conflicts with parents. Interactions in the family provide consistent and important ties at the same time that social interactions become a central part of life. Health promotion helps teens to form strong friendships with peers and to continue to value and participate in the family. It helps parents to understand the developmental needs and their role in establishing a new type of relationship with the emerging young adult in the family. Partnerships with healthcare providers are important to help families work together to achieve these outcomes.

When adolescents are seen for healthcare visits, assess relationships with others. Provide time alone with both the adolescent and the parents (if they are present) so that everyone has time to talk freely and to ask questions. Some areas already discussed, such as school performance and activities, provide information about the adolescent's friends and how time is spent. Ask teens to describe their best friends and what they do together. Ask parents their opinions of the youth's friends. Inquire about the youth's roles in the family. Does the teen have jobs and responsibilities? What freedom is allowed? What are relationships like with siblings and extended family members such as grandparents and cousins? What activities are done together as a family? Are there differences in the teen's and the parents' answers to these questions? What are the teen's and parents' desires for how the family unit functions?

Provide an opportunity to talk with the teen alone about issues such as domestic violence. Is the youth abused or is there violence between adults in the family? Are there stressors such as lack of sufficient finances, an ill parent, or a lost job? How have these occurrences affected the adolescent? Minor adjustments can be helped by discussion, whereas some major problems will need referral to mental health specialists.

In their relationships with peers, adolescents often have many of the same issues that emerge with parents. They may have disagreements with friends or feel hurt by things that are said or done. Ask teens about how things are going with friends and what problems they have. Talk about negotiating, joining groups to form new friendships, and the importance of respecting and not making fun of others. Give them strategies for living up to their own standards even when friends are enticing them to do other things. Suggest that having friends one can trust and who have the same ideals can be very supportive and fun in adolescent years. Expected outcomes are the formation of strong relationships both within and outside of the family, along with independence in decision making.

Disease Prevention Strategies

Teenagers typically do not have many diseases and most are minor illnesses like respiratory and gastrointestinal illness. However, there are some diseases that occur and nurses must always be aware of signs of potential disease. Some common health issues that are described throughout this book include the following:

- Acne and skin infections (see Chapter 31)
- Body piercing and tattooing (see Chapter 17)
- Sports overuse injuries (see Chapter 29)
- Constipation and diarrhea (see Chapter 25)

Other observations may signal more serious health concerns and need to be referred for further evaluation. Examples include the following:

- Scoliosis (see Chapter 29)
- Anemia (see Chapter 23)
- Excessive tiredness (see Chapter 24)
- Bruising (see Chapter 23)
- Depression, suicidal thoughts, other mental health issues (see Chapter 28)
- Sexually transmitted infections (see Chapter 26)
- Eating disorders (see Chapter 14)
- Abuse or severe bullying (see Chapter 17)

Several screening tests should be performed during health supervision visits with adolescents, including vision, hearing, smoking, depression, stress, alcohol or other substance use, blood pressure, urinalysis, sexually transmitted infection risk, and, in some cases, Pap smears and breast examinations. Screening tests with abnormal results require follow-up and intervention. For example, if the adolescent is anemic, iron tablets may be needed and teaching about high-iron foods should be done. Vision impairment requires referral to an eye specialist. Presence of sexually transmitted infections requires teaching and medication treatment. History of sexual activity will guide the nurse to tests that should be included in the examination (see *Clinical Tip*).

Clinical Tip

Sexually active teens should be screened annually for the following:

- Chlamydial infection
- Gonorrhea
- Trichomoniasis
- Human papillomavirus
- Herpes simplex virus
- Bacterial vaginosis
- Human immunodeficiency virus

Individuals should be screened for syphilis and HIV/AIDS if requesting testing or meeting any of these criteria:

- History of sexually transmitted infection
- More than one sexual partner in past 6 months
- Intravenous drug use
- Sexual intercourse with a partner at risk
- Sex in exchange for drugs or money
- Homelessness
- Males—sex with other males
- Syphilis—residence in areas where disease is prevalent

See Chapter 26 for further information on screening procedures.

Source: Data from Hagan, J. F., Shaw, J. S., & Duncan, P. M. (2008). *Bright futures: Guidelines for health supervision of infants, children, and adolescents* (3rd ed.). Elk Grove Village, IL: American Academy of Pediatrics.

The adolescent should receive extensive information about ways to protect health and prevent disease. The hazardous outcomes of smoking are discussed, and smoking cessation programs are encouraged for smokers. Unprotected sexual activity is presented as a serious health threat. Use of sunscreens to prevent burns and future skin cancer is encouraged. Females are taught breast self-examination, and males are taught testicular examination. For youth who are overweight and sedentary, the possible outcomes such as type 2 diabetes and cardiovascular disease are mentioned. While it would not be advisable to threaten or frighten an adolescent with descriptions of diseases, an understanding of the potential serious outcomes can be motivators for behavior change.

In addition to teaching to prevent disease, the nurse also administers any needed immunizations. Many adolescents have not had immunizations since about school entry time, so their record should be carefully reviewed (see Chapter 16). When checking the adolescent's record, consider the following questions about some common immunizations that are needed:

- *When was the last tetanus-diphtheria (Td) booster?* It is recommended every 10 years if no wounds have required an update in the interim. If the child received it at age 5 years, a booster is needed at 15 years. A Tdap (tetanus-diphtheria-acellular pertussis) booster is given, with the preferred age of 11 to 12 years.
- *Was a second measles-mumps-rubella administered?* A second dose may not have been routine when teens were younger so they may need it now.
- *Is hepatitis A common in your state?* If so, the teen needs to get that vaccine.
- *Has the youth had hepatitis B vaccine?* This is important for all youth, and some may not have received it as infants.
- *Did the youth have a documented history of varicella disease?* If not, two doses of the vaccine are needed.
- *Has the youth received meningococcal vaccine?* Meningococcal vaccine is now recommended for all youth.
- *Have the adolescent female and male received the human papillomavirus vaccine?* Human papillomavirus vaccine (three-dose series) is recommended for females and males from 11 to 12 years, or for those 13 to 26 years not previously immunized. The vaccine can be given as early as 9 years of age.
- *Has the youth received the annual influenza vaccine?* Annual influenza vaccine is now recommended for all children and adolescents.

The results of health screening are shared with the teen and with the parent as appropriate. Teaching and other interventions for disease prevention are examples of health maintenance activities. Expected outcomes are increasing knowledge of common diseases and methods of prevention among teen and parent, use of screening tests by the healthcare provider, and use of the healthcare home by the adolescent for treatment of diseases.

Injury Prevention Strategies

Injury is the greatest health hazard for adolescents, so injury prevention must be integrated into every health contact with youth. The major hazard is automobile crashes (see Chapter 1). Many teens learn to drive and have a license by 16 years of age. They often transport friends, get distracted by social interactions in the car, have little experience about what to do if a car slides or has mechanical problems, may drink and drive, talk or text on cell phones while driving, and are often tired when driving (Figure 9–9). Many states have instituted graduated driving licensing to help decrease some risks. Know the graduated driver license laws in your state and reinforce them with youth

Figure 9–9 Injury prevention for teens. Adolescents often drive motorized vehicles and may be at risk for injury if not properly prepared or protected. What teaching and experience do these youth need for safe enjoyment of the experience of driving and riding with friends? Do schools in your area offer driver education classes? What are the state requirements for youth driver licensure?

SOURCE: wrangler/Shutterstock

and families. Driving should always be presented as a privilege and a responsibility. Suggest that parents consider enforcing serious consequences such as losing the ability to drive for a time after any infraction. Because of the great risk of injury and death from motor vehicle crashes, ask at each health visit if the teen drives, rides with other teens, what rules parents have established about driving, and whether the teen ever drinks and drives or rides with someone who does. Reinforce the need to wear a lap and shoulder belt at all times and to never drink and drive.

SAFETY ALERT!

Major risk factors for teen drivers include inexperience (especially vulnerable time is the first 6 months of driving), transporting other teens, night driving, non-use of seat belt, and distractions such as texting and playing music. Graduated driver licensing is an approach used to decrease motor vehicle crashes among novice teen drivers. The CDC recommends that no learners' permits be allowed before 16 years of age, that permits must be held for at least 6 months, that driving from 10 p.m. to 5 a.m. not be allowed except with adult chaperone, that other youth not be transported, and that regular licenses (without youth restrictions) not be allowed until 18 years of age. Zero-tolerance policies for drinking, texting or cell phone use, and non-use of seat belts should be enforced (CDC, 2011b). How can nurses be active in political discussions to promote graduated driver licensing and support parents of novice teen drivers?

Youth are at risk for injury with other motorized vehicles. Motorcycles, four-wheelers, boats, jet skis, farm machinery, and tools are other sources of injury. Ask about the youth's exposure to various machines and teach about avoiding alcohol and drug use and safety gear and precautions to be used. Every health visit should include other questions that help identify a wide variety of injury hazards. Be sure to discuss and provide written material to perform injury prevention teaching. Such measures are important health maintenance activities (Tables 9–6 and 9–7). Desired outcomes for nursing care include absence of serious injury, the ability to state sources of risk for injury, and emergency plans for assistance when engaging in any risky activities.

Nursing Management

For the Health Promotion and Maintenance of the Adolescent

Nursing Assessment and Diagnosis

Nurses assess adolescents in a variety of settings, including offices, clinics, schools, homes, correctional facilities, extended care facilities, sports-related facilities, and family planning clinics. A wide array of health concerns should be included in these assessments:

- Measurement of growth
- Presence of any unusual findings on physical examination
- Lifestyle choices related to dietary intake, physical activity, and oral hygiene
- Assessment of mental status, family interactions, and social connections with peers
- Any risky behaviors the adolescent engages in such as smoking, unprotected sexual relations, alcohol or drug use, or unsafe driving practices

The people and organizations around the adolescent such as family, school, and neighborhood are all assessed. Remember to list both risks and protective factors. The protective factors can be used during implementation to enhance the youth's resilience.

Based on a thorough assessment, you will establish nursing diagnoses that are appropriate for the adolescent and family. Some possible nursing diagnoses might include the following (NANDA-I © 2014):

- ***Rape-Trauma Syndrome*** related to date rape
- ***Dentition, Impaired,*** related to ineffective oral hygiene
- ***Obesity*** related to lack of basic nutritional knowledge and obesity in both parents
- ***Nutrition, Readiness for Enhanced,*** related to increasing interest in nutritional knowledge
- ***Sleep Pattern, Disturbed,*** related to frequently changing sleep—wake schedule
- ***Self-Esteem, Situational Low,*** related to situational crisis of friends making fun of adolescent
- ***Injury, Risk for,*** related to psychomotor and cognitive factors

Planning and Implementation

Whatever the setting, the nurse partners with the adolescent, the parents, and other persons such as teachers or school counselors to plan appropriate goals and related interventions. Nurses work with individual adolescents in offices, schools, and other settings, and often work with groups of adolescents to perform teaching. Apply communication skills that are effective with teens, such as listening to concerns, allowing for discussion, and bringing in peers who have had experiences related to the topic being discussed.

Many nursing interventions involve teaching, so it is wise to develop a number of resources for working with teens. Consult the resources on this textbook's companion website, and visit agencies in your community to gather appropriate materials. Teaching topics should be directed both at health promotion (providing information to enhance the adolescent's state of health) and health maintenance (sharing tips about how to avoid disease and injury). A good starting point is to have the adolescent identify a personal health goal and begin teaching there. In addition to teaching, direct care is provided when administering immunizations, performing vision screening, and examining the spine and posture for scoliosis.

One of the challenges during health supervision for adolescents is including the right mix of teen and parent decision making and involvement. It is again important to apply communication skills by tactfully allowing time for both parent and adolescent to be seen alone. Realize that health supervision provides support and information for parents, such as useful discipline techniques, recognition of common parental feelings about teens, and the need for growing independence by their youth. When providing teaching to groups of teens in schools, there may be policies about what needs to be sent home to parents. For topics such as sexually transmitted infections or substance use, some schools require that an outline be sent home for parents to read. Parents may call with

TABLE 9–6 Injury Prevention in Adolescence

	HAZARD	DEVELOPMENTAL CHARACTERISTICS	PREVENTIVE MEASURES
	Motor vehicle crashes	Adolescents learn to drive, enjoy new independence, and often feel invulnerable.	Insist on driver's education classes. Enforce rules about safe driving. Seat belts should be used for every trip. Discourage drug and alcohol use. Get treatment for teenagers who are known substance abusers.
	Sporting injuries	Adolescents may participate in physically challenging sports such as soccer, gymnastics, or football. They may be allowed to drive motorboats.	Encourage use of protective sporting gear. Teach safe boating practices. Perform teaching related to hazards of drug and alcohol use, especially when using motorized equipment.
	Drowning	Adolescents overestimate endurance when swimming. They take risks diving.	Encourage swimming only with friends. Reinforce rules and teach them about risks.

questions about content and approach, or some may choose to attend the presentation. To create an effective presentation, the nurse must partner with the school administration, teachers, parents, and others. The ability to collaborate successfully with many individuals and agencies is an important skill for the nurse.

Wherever adolescents are seen, whether in offices or other private settings, schools, correction facilities, or other places with groups present, it is important to leave information about how to contact the nurse or another care provider. Provide brochures, referral numbers, names, and e-mails related to the topics discussed. Encourage annual visits for health supervision and suggest a variety of places to obtain this care. For example, if a youth will soon graduate from high school, find out if the youth will be working or attending college and provide links to health insurance or care providers in the new location.

Evaluation

Expected outcomes for care of adolescents and their families during health promotion and health maintenance include the following:

- Normal growth patterns and healthy weight are maintained.
- The adolescent is physically active for 60 minutes daily.
- Debris and plaque are absent on dental surfaces.
- The adolescent establishes a positive self-concept.
- The adolescent establishes positive relationships with peers, family members, teachers, and others.
- Healthy lifestyle habits are maintained that promote prevention of disease and injury.

TABLE 9–7 Injury Prevention Topics for Adolescents

TOPIC	INJURY PREVENTION TEACHING
Driving	Always wear seat and shoulder belts. Do not drink alcohol or take drugs and drive or ride with others who do. Do not talk or text on a cell phone as you drive. Do not drive when you are tired. Drive with parents or other adults for several months in winter driving conditions if you live where there is snow, ice, or heavy rains. Keep your car in good repair.
Sun	Wear sunscreen. Limit direct exposure to the sun, especially early in the summer when the skin is most sensitive to burns. This can be achieved by wearing sunscreen, hats, and clothing that prevent sunburns.
Machinery	Learn how to use power tools correctly. Always have someone near when you use tools or machinery. Follow guidelines for agricultural safety (CDC, 2011c).
Emergency care	Learn first aid, CPR, and airway obstruction removal.
Water safety	Learn to swim well. If you supervise younger children near water, never leave them alone, even for a minute.
Fires	Do not play with fire. Follow guidelines to avoid igniting gasoline. Test smoke alarms in your house every 6 months and change batteries annually.
Firearms	Know and follow rules to keep firearms locked, with ammunition locked in a separate place. Never take out a gun to show a friend unless your parent is also present. Take firearm safety classes if you hunt or target shoot.
Hearing	Avoid loud music especially for long periods and through earphones.
Sports	Wear protective gear recommended for your sport.
Abuse	Report any abuse to an adult you trust. Date with other couples whenever possible and report date rape. Do not drink or take drugs.

Source: Data from Hagan, J. F., Shaw, J. S., & Duncan, P. M. (2008). *Bright futures: Guidelines for health supervision of infants, children, and adolescents* (3rd ed.). Elk Grove Village, IL: American Academy of Pediatrics.

Chapter Highlights

- Health promotion visits are recommended annually and should take place in any setting where the child is seen, even for episodic or emergency care.
- Developmental surveillance, growth measurement, and physical examination provide the basis for establishing risk and protective factors for each child and adolescent.
- School-age children and adolescents are increasingly independent in making choices about nutrition and physical activity, while peer influence continues to grow.
- Establishment of affirmative self-esteem is important for school-age children and adolescents in order to develop positive mental health.
- Injury and disease prevention for school-age children and adolescents focuses on common causes of morbidity and mortality, such as firearms, abuse, motor vehicle crashes, alcohol and substance use, lack of immunizations, and sports-related injuries.
- The nurse integrates information from the health supervision visit to plan appropriate interventions for school-age children, adolescents, and their families.

Clinical Reasoning in Action

Tammy is a 13-year-old coming into the office for her yearly checkup and she has never been in the hospital or had surgery. She is a good student and is excited to start seventh grade next year. She has not had any immunizations since going into kindergarten. Tammy arrives with her mother, with whom she lives; she has no contact with her biologic father. Her mother decides to stay in the waiting room, but did note on the written history form that there is a family history of high cholesterol and heart disease in family members under 50 years old. Tammy's mother is a single parent working full time with two other children at home. Tammy's body mass index is in the 85th percentile and she passed her hearing and vision tests. Her blood pressure is 115/70 and her urinalysis shows blood, but Tammy has her menses today. Tammy has a period every month and menarche started at 10 years old. Her menses lasts 5 to 7 days and she denies experiencing cramping or excessively heavy menses. Tammy enjoys being a member of the volleyball team and is involved in a church youth group. She does not get to spend much time with her friends because she watches her two younger siblings in the afternoons while her mother is at work. When her mother is away, she admits to sitting and playing video games or watching TV most of the day. Tammy says she has had a boyfriend, but denies sexual activity. She also denies any experimentation with substance use.

1. What vaccines is Tammy due for at this age if she has not already had them?
2. A dietary assessment demonstrates that Tammy frequently skips meals and eats fast food almost daily. What are some of the suggestions you can give Tammy to improve her nutritional status?
3. What are some of the injury prevention topics you can discuss with Tammy?
4. Based on the additional information you collected about Tammy, what are some of the areas of recommended health teaching?
5. Develop a concept map for Tammy that includes all of the health promotion areas important to all youth, such as nutrition, oral health, physical activity, social interactions, family relationships, and disease/injury prevention. How can her development be enhanced to draw on strengths and improve areas of need? What part does the healthcare provider play in promoting her health?

Chapter 10
Nursing Considerations for the Child in the Community

Ryan McVay/Getty Images

Sometimes Lani's asthma attacks really frighten me because she struggles so hard to breathe. She has a lot of trouble with asthma in the summertime with all the heat. I'm afraid to let her play outside with her friends for fear that she will have another attack. I'd really like to know how to keep Lani's asthma under control.

—Mother of Lani, 8 years old

Learning Outcomes

10.1 Discuss the community healthcare settings where nurses provide health services to children.

10.2 Compare the roles of the nurse in each identified community healthcare setting.

10.3 Assemble a list of family support services that might be available in a community.

10.4 Develop a nursing care plan for a child in the school setting who has short-term mobility limitations.

10.5 Examine five ways in which nurses assist families in the home care setting.

10.6 Summarize the special developmental needs of children to consider in disaster preparedness planning.

Children receive most of their health care in community settings. Depending on the community, healthcare resources, and age of the child, nurses have an important role related to the care provided in each of these settings. When providing health care to the child and family, it is important for the nurse to assess the family's strengths, be aware of community resources, help families manage the complex health care that is often provided in the home, and prepare for emergencies and disasters.

Community-Based Health Care

Health plans and healthcare providers continue to explore options to provide safe, high-quality care in the community with fewer hospitalizations or shorter stays when hospitalization is needed. Patterns of healthcare delivery have changed due to technologic developments and efforts to reduce healthcare costs. For example:

- Surgery and invasive diagnostic procedures are performed in ambulatory settings.
- Short-stay or observation units in hospital settings reduce the number of hospital admissions.
- Long-term intravenous antibiotic therapy can be provided in the home.
- Pediatric hospice and palliative care services occur in the home setting.

The trend in out-of-hospital care continues to increase for children with chronic health conditions and advanced disease states. Families are often willing to care for their child who is

medically fragile (having complex chronic health conditions that require skilled nursing and often technology support for vital functions) in the home because of their desire to have the child integrated into the family and community (Spratling, 2012). Technologic advances, such as portable medical equipment, enable families to provide complex healthcare services in the home and other community settings, and such care in the community is less costly. Home care services and other support services have been developed to support these families.

Pediatric health care in the community occurs along a continuum that covers the entire child healthcare system. This continuum is reflected in the Bindler-Ball Continuum of Pediatric Health, including health promotion and health maintenance services, care for chronic conditions, acute illnesses and injuries, and end-of-life care (see Chapter 1 for this model). Health care for individual children is improved when there is continuity of care and communication between healthcare settings.

The nurse working with families in a community setting uses knowledge of how the larger environment influences the child's health and development and the family's functioning, and integrates that information into the nursing care plan. To work effectively in the community, the nurse needs to gain experience and skills in:

- Conducting a child and family assessment and collaborating with the family to plan, implement, and evaluate healthcare strategies that fit the family's economic, cultural, and social situation
- Working with community agencies (schools, faith-based groups, military-based groups, and other community-based resources) to assess, plan strategies, and implement and evaluate approaches addressed to the healthcare needs of the community's children

Community Healthcare Settings

Children receive most of their health care (health promotion and episodic health care for acute illnesses and injuries) in community settings. Depending on the community, healthcare resources, and age of the child, care may be received in all or only a few of the following settings:

- A healthcare center or a physician's office is the usual site for health promotion, health maintenance, episodic acute care, and health management of children with chronic conditions.
- A public health clinic may provide health promotion and health maintenance services as well as treatment for specific health conditions. A homeless shelter may also have the capacity to offer such services.
- A hospital outpatient center may provide specialized services to children with chronic conditions or the full range of services offered in a healthcare center.
- Schools usually provide health promotion and health maintenance services, plus first aid and emergency care as needed. School-based healthcare centers exist in some schools to provide health care, counseling, health education, and care for acute conditions. Some school settings also offer preschool and after-school childcare services.
- Childcare centers provide first aid for emergencies and some health promotion services.
- The home is where the family provides care for minor illnesses and injuries and for chronic and complex health conditions, including end-of-life care when the child's family is supported by home health services.

A nurse may serve as a community health nurse, home health nurse, school nurse, pediatric nurse in an office setting, and nurse practitioner or advanced practice nurse in these settings. The nurse in any of the above settings has an important role in promoting the health and safety of the child, being a leader in setting policies in the healthcare center, and using the nursing process to help families meet the healthcare needs of their children. The nurse may assume the role of direct care provider, educator, advocate, or planner.

Nursing Roles in the Office or Healthcare Center Setting

The nursing process is used when providing care for children in the healthcare center. The range of assessment responsibilities may vary by setting as well as the nurse's preparation and experience (Figure 10–1). Specific functions of the pediatric nurse in this setting include the following:

- Identifying children in need of urgent care or isolation
- Performing nursing assessments, including the health history, vital signs, growth and development, nutritional status, immunization status, family strengths and challenges
- Conducting physical examinations
- Performing age-appropriate screening tests to detect health problems such as vision or hearing loss, anemia, and lead poisoning to ensure that the child has access to all needed health services
- Assisting with health examinations, diagnostic tests, and procedures
- Developing nursing diagnoses and implementing a plan of care
- Providing immunizations
- Providing information about procedures and offering reassurance
- Providing family and client education for health promotion or management of the health condition
- Linking families with community resources

Figure 10–1 **Nurses carefully assess children in the office setting who present with an acute care illness to identify how serious the child's illness is. Monitor the child for symptom changes during the visit. Gather information about the child's illness, and identify the education needed for the family to care for the child at home.**

- Ensuring a safe healthcare setting and adherence to infection control guidelines (See the *Clinical Skills Manual* SKILLS for infection control methods.)
- Participating in the healthcare center's performance improvement program to identify ways to enhance services provided to children and their families

An important goal is to develop a positive relationship with the child and family so that optimal health care is provided. This relationship is strengthened during future healthcare visits.

Clinical Tip

Developing a relationship with the child and family in a community setting is equally as important as it is in the hospital. The initial interaction often sets the stage for a long-term relationship with the family that returns to the same setting for health care over many years. Remember to put aside the stressors you may be feeling before you approach the child and family. Take a few moments to play with the infant or child and to comment on a positive attribute of the child to the parents. This should help reduce the parents', and perhaps the child's, stress level, which helps set the stage for a long-term partnership with the child and family.

EDUCATING THE CHILD AND FAMILY

Family and client education regarding injury prevention, growth and development, nutrition, healthy lifestyles, and the home care of episodic illnesses and injuries are important nursing roles. The nurse may be responsible for selecting client education materials for the waiting area and those specifically used to teach families about various conditions. Knowledge of the community and population served by the healthcare center enables the nurse to select appropriate education materials for the culture and literacy level served.

Nurses teach families to provide the condition-specific care for the child at home. Examples of information provided include:

- Signs that the condition is not improving as expected and when to return to the healthcare provider
- How and when to administer prescribed medications and their potential side effects
- Recommended diet and activity
- Other supportive care for the child's condition
- Education to help the child and family recognize when to initiate care for a new episode of a chronic condition (e.g., asthma and sickle cell disease) to avoid a healthcare visit or reduce the episode severity

IDENTIFYING SEVERELY ILL AND INJURED CHILDREN

Each child with an episodic illness or injury presenting to the healthcare center must be assessed on arrival to determine the urgency of care needed. Quickly assess for changes in mental status, airway patency, labored breathing, or poor circulation to identify a child who needs immediate medical attention. The child with an urgent condition must be monitored frequently to detect any worsening of condition and need for emergency care.

EMERGENCY RESPONSE PLANNING

The nurse collaborates with all health professionals and the office manager to develop an emergency response plan for the healthcare center. The nurse teaches office staff to recognize a child needing immediate assessment by the nurse. The nurse is often responsible for ensuring that all emergency care equipment, supplies, and medications are organized and readily available in a central treatment room. The nurse may also coordinate mock drills so that all health professionals and support staff know and perform their designated role when a true emergency occurs.

SAFETY ALERT!

Required emergency equipment for managing a pediatric emergency in a healthcare center includes the following in various pediatric sizes (Wright & Krug, 2016):

- Oxygen delivery system (bag-valve masks in 450- and 1000-mL sizes, clear oxygen face masks with and without reservoir)
- Airway equipment (oral and nasopharyngeal airways, Magill forceps, suction devices, laryngoscope handle and blades, endotracheal tubes and stylet, end-tidal CO_2 detector, nasogastric tubes)
- Pulse oximeter, automated external defibrillator with pediatric capabilities
- Intravenous (IV) and intraosseous needles, IV tubing and microdrip, and 500 mL bags of normal saline, lactated Ringer, and 5% dextrose 0.45 normal saline IV solution
- A length-based resuscitation tape and preprinted drug dosage chart to quickly identify equipment sizes and drug dosages by the length or weight of the child
- Essential drugs, including oxygen, epinephrine 1:1000, and albuterol for inhalation; suggested drugs, including activated charcoal, naloxone, 25% dextrose, diphenhydramine, antibiotics, oral and parenteral corticosteroids, atropine, and sodium bicarbonate

Locate the emergency equipment in every clinical setting where you have assignments so that you can quickly take the child to it or bring the equipment to the child if an emergency occurs.

IDENTIFYING COMMUNITY RESOURCES

Nurses are often involved in identifying community resources needed by the child and family to help promote the child's health. Compiling a manual of community resources and regularly updating names, phone numbers, and websites of contacts will make it easier to provide information efficiently. Examples of community resources that might be included are early intervention programs, support groups, translation services, food banks, lead paint abatement services, social services, and mental health services.

ENSURING A SAFE ENVIRONMENT FOR CHILDREN

The healthcare center has many potential hazards such as equipment, cleaning supplies, sharps, medications, and laboratory chemicals and supplies from which the child needs to be protected. The child must be attended at all times when in the examination area. Develop and implement infection control guidelines to reduce the transmission of infectious diseases among child patients and among the healthcare providers and children.

Nursing Roles in the Specialty Healthcare Setting

Pediatric nurses also provide care for children with acute and chronic conditions within hospital outpatient or specialty care ambulatory settings. Children may be referred to physician specialists for diagnostic workups or for the long-term management

Figure 10–2 **Nurses often assume a larger role in working with children and families with a chronic health condition in the hospital ambulatory setting. Developing a plan of care and educating the family to manage type 1 diabetes is an important role of this pediatric nurse who is also a nationally certified diabetic educator.**

of their chronic conditions. In some cases, health promotion, health maintenance, and episodic illness care are provided to children with chronic conditions in these settings. With experience, pediatric nurses working in a hospital ambulatory setting develop specialized knowledge and skill to meet the specific needs of the children cared for in that setting (Figure 10–2). The roles for nurses in these settings are similar to those described for the healthcare center.

Nursing Roles in the School Setting

School nursing is a specialized practice of professional nursing in the education setting that advances the well-being, academic success, and lifelong achievement of students. School nurses care for children and youth with a wide range of physical and mental health challenges. They advocate for the children as policies are developed for the school community, such as nutritious school breakfasts and lunches or recess and physical education classes for all students. Because of their role in the education system, they are able to educate teachers and administrators about how health conditions affect student functioning and ways to integrate children with special healthcare needs into the school setting (Taras, 2014).

Healthy People 2020

(EMC-4) Increase the proportion of elementary, middle, and senior high schools that require school health education

(NWS-2) Increase the percentage of schools with a school breakfast program and offer nutritious foods and beverages outside of school meals

In 2013, 61.7 million children and adolescents attended public and private elementary and secondary schools in the United States. An estimated 12.9% of the enrolled children had a known medical condition or disability for which they received Individuals with Disabilities Education Act services (U.S. Department of Education, National Center for Education Statistics, 2014). Approximately 11% to 13% of children and adolescents require daily medication administered at school for at least 3 months for conditions such as asthma, diabetes, and seizures. Additional children need medications for a shorter interval for an acute health problem (Center for Health and Healthcare in Schools, 2013). Children who have complex health conditions (e.g., dependent on medical technology, such as peritoneal dialysis, tracheostomies, and ventilators) need school nurses to develop and coordinate the plan for their care during school. These include children who are medically fragile. (See Chapter 12 for a discussion of children with chronic conditions and planning for their care in the school setting.)

The breadth of school health issues addressed by school nurses is illustrated in national health objectives published in *Healthy People 2020*. Additional examples of objectives addressing children and youth in the school setting include (U.S. Department of Health and Human Services, 2015):

- (ECBP-2) Increase the proportion of elementary, middle, and senior high schools that provide comprehensive school health education to prevent health problems in the following areas: unintentional injury, violence, suicide, tobacco use and addiction, alcohol or other drug use, unintended pregnancy, HIV/AIDS and sexually transmitted infections, unhealthy dietary patterns, and inadequate physical activity
- (PA-4) Increase the proportion of the nation's public and private schools that require daily physical education for all students
- (IVP-27) Increase the proportion of public and private schools that require students to wear appropriate protective gear when engaged in school-sponsored physical activities
- (DH-14) Increase the proportion of children and youth with disabilities who spend at least 80% of their time in regular education programs
- (ECBP-5) Increase the proportion of elementary, middle, and senior high schools that have a full-time registered school nurse-to-student ratio of at least 1:750

The school nurse plans, develops, manages, and evaluates healthcare services to all children in the educational setting. Other roles of the nurse in the school setting include the following: maintaining infection control, participating on teams to develop student individualized education plans (IEPs) and individualized health plans (IHPs), updating health records, collecting data on services provided to students, consulting with health teachers about educational topics, investigating environmental safety hazards, developing an emergency preparedness plan, and planning for crisis intervention and support services. The traditional tasks of screening, first aid, and monitoring immunization status are still performed (Figure 10–3). In many cases, the nurse works with families of the students to ensure that needed care is provided. See Chapter 12 for more information on IEPs and IHPs.

Collaboration with the other health professionals in the community is also important to promote health in the school setting, as the following examples illustrate:

- Partnering with the school physician consultant to discuss and update standing orders for the care of children. These standing orders usually address urgent and emergency care potentially needed by students and the variety of student healthcare problems that may occur.
- Working with the parent–teacher association and other community organizations to organize health fairs and injury prevention programs for students.

Figure 10–3 **The school is often the setting for screening tests of large groups of students to identify those who may have a health problem that could interfere with learning. Screening tests are often organized so all children in a particular grade are assessed, such as scoliosis screening for children in fifth grade.**

- Communicating with the child's primary healthcare provider or pediatric specialist about a child's specific health condition that needs to be effectively managed in the school setting. Obtain the parent's permission to request confidential client information. The school nurse has regular opportunities to monitor the child's health status and to provide information that may help the primary healthcare providers with the child's ongoing management.

In some communities, school-based healthcare centers provide comprehensive physical, dental, reproductive, and mental health services plus health education to students. They provide service coordination and collaboration to address the health needs of youth with health problems or poor access to healthcare services, especially those not readily available in the community (American Academy of Pediatrics [AAP], 2012). A multidisciplinary team of nurse practitioners, physicians, physician assistants, mental health providers, and other supporting staff often provides care.

PREPARATION FOR EMERGENCIES

Because children spend so much of their day in school, this setting is a common location of injury and acute illnesses. The school nurse often works with school administrators, the physician consultant, and the local emergency medical services (EMS) agency to develop a response plan for true emergencies. School personnel (administrators, secretaries, and health aides) also need training to identify an emergency that requires activation of the local EMS system and to provide emergency care until the EMS providers arrive.

Other potential emergencies can occur during school hours, such as natural and man-made disasters, and behavioral crises (e.g., school shootings). Nurses may participate in planning committees to develop an **emergency preparedness plan**, a community-based coordinated response plan for the incident (see information later in the chapter). Children experiencing a traumatic event may need psychologic support (see Chapter 17).

Clinical Reasoning **Acute Asthma Episode at School**

Lani, 8 years old, is at school and is getting anxious because she is having more trouble breathing than usual. Her teacher notices her breathing difficulty and sends Lani to the school nurse for treatment. Lani has a rescue inhaler at school, and this treatment often relieves her symptoms and allows her to return to classes. In this case, Lani's acute asthma episode does not respond to the treatment, so the school contacts her mother. Because it will take Lani's mother at least 45 minutes to reach the school, the school nurse and mother decide that 9-1-1 should be called to get Lani to the emergency department more quickly.

What special arrangements are needed to permit a child to receive care for asthma or another chronic condition while at school? See Chapter 20 and *Evidence-Based Practice: Improving Asthma Management at School* for more information about asthma management.

FACILITATING A CHILD'S RETURN TO SCHOOL

The school nurse also helps the child return to the classroom following an acute illness or injury. Examples include making environmental adaptations, creating an IHP when a new health condition is diagnosed, or revising the IHP when a significant change in the status of the child's chronic condition has occurred (see Chapter 12). The child's parents or the pediatric nurse in the hospital or community setting may initiate the request to coordinate the child's return to school. Educational materials about the child's condition can be recommended to educate students, faculty, and staff. The school nurse then begins to work with the family to prepare teachers and school administrators for the child's special needs, such as limited mobility or medications. The child's teacher and classmates can be prepared for the child's physical changes if appropriate. Sometimes the teacher's expectations of the child need to be modified, such as a child with a mild brain injury who may have decreased ability to concentrate for several weeks during recovery.

Nursing Roles in the Childcare Setting

An estimated 12.5 million children under 5 years of age receive care in out-of-home childcare settings while parents are at work (U.S. Census Bureau, 2011). Many types of childcare arrangements exist, such as in-home care by a family member or nanny, a babysitter cooperative, a licensed childcare family home setting for up to five children, or a licensed childcare center for six or more children.

States establish minimum licensure requirements and guidelines for the safe operation of childcare settings that address the staff qualifications, staff-to-child ratio, staff training requirements, safe food handling, safe health practices, and environmental safety. Guidelines for the safe operation of childcare centers are available through the National Resource Center for Health and Safety in Child Care.

EVIDENCE-BASED PRACTICE | Improving Asthma Management at School

Clinical Question

Because of the potential for frequent absences and the need to manage their condition at school, what are some strategies for helping children with asthma to decrease their episodes during the school day?

The Evidence

A study recruited 530 children with persistent asthma, ages 3 to 10 years, from 67 schools for a randomized controlled trial with school daily-observed therapy compared to parent-administered therapy. Families of all children received a diary to track the child's symptoms, which were retrieved by a monthly telephone interview. Children in the school treatment group had more symptom-free days, significantly fewer nights with symptoms, fewer days with activity limitations, and fewer school absences than the children in the control group. Children in the school treatment group were also less likely to have an asthma episode requiring oral prednisone treatment (Halterman et al., 2011).

A subsequent study recruited 100 children with persistent asthma, ages 3 to 10 years, from 19 schools to participate in a pilot study to compare a web-based screening process and school daily-administered therapy to parent-administered therapy. Parents were expected to administer therapy on nonschool days for children in the intervention group. The web-based screening tool integrated national guidelines for assessment of asthma severity, selected prescribed medications for severity level, and sent information to the child's primary care provider. At the end of the school year, children in the school treatment group had fewer school absences related to asthma, fewer nighttime symptoms, and fewer days needing rescue medications compared to the comparison group. Primary care providers and school nurses reported support for the school-observed therapy program after learning study outcomes (Halterman et al., 2012).

A questionnaire was used to investigate the knowledge of 38 elementary school teachers from two schools about the care of children with asthma. More than 50% of teachers missed questions about characteristics of children with severe asthma, signs that asthma is under good control, signs of a life-threatening asthma episode, proper technique for medication administration, and the common symptoms after rescue inhaler medication (Lucas, Anderson, & Hill, 2012).

Best Practice

Children with persistent asthma are often unable to perform their best in school. Teachers also need increased awareness of asthma symptoms to help identify children who need rescue medications during the school day. School health programs can offer effective strategies to help manage asthma, such as identifying children needing daily asthma medications, offering supervised medication administration, and educating children to manage their asthma. Prior research revealed a relationship between how well the children self-manage their asthma and the children's asthmatic symptoms and morbidity (Kaul, 2011).

Clinical Reasoning

During a school clinical experience, identify the number of children with asthma and how many children report to the school nurse with asthma episodes in a month. What strategies has the school nurse used to work with children who have persistent asthma (e.g., educating students about self-management, providing medication at school, or seeking an asthma action plan)? Have those strategies helped to reduce the number of asthma episodes?

Healthy People 2020

(NWS-1) Increase the number of States with nutrition standards for foods and beverages provided to preschool-aged children in child care

(PA-9) Increase the number of States with licensing regulations for physical activity provided in child care

Nurses can assume an important consultant role in the establishment of a childcare center's policies for healthcare practices, teaching staff about safe healthcare practices, and monitoring and promoting healthcare practices in the setting. The nurse consultant can also teach staff to identify children with illnesses and to provide first aid for injured children. Nurses may provide health screening and direct care in childcare centers that care for ill children.

REDUCING DISEASE TRANSMISSION

Children attending childcare centers are at increased risk for infectious diseases. Children are close together in large numbers, put things in their mouths, may be contagious before symptoms occur, and are susceptible to most infectious agents. The nurse can educate and work with the childcare center manager and staff to reduce disease transmission in the following ways (American Academy of Pediatrics, American Public Health Association, & National Resource Center for Health and Safety in Child Care, 2013):

- Teach staff when and how to perform hand hygiene, manage a child's secretions, sanitize toys and surfaces, and treat a child's cuts and scrapes.
- Develop guidelines for diapering infants and toddlers to reduce disease transmission.
- Check each child's health daily for signs of acute illness (e.g., behavior changes, rashes, fever, vomiting, diarrhea, or eye drainage). Isolate and care for ill children until they return home.
- Monitor the immunization status of children and plan for the exclusion of unimmunized children and children with immune deficiencies and disorders when a vaccine-preventable disease occurs in a child attending the facility (see Chapter 16).
- Develop and follow guidelines for safe food preparation and handling.

HEALTH PROMOTION AND HEALTH MAINTENANCE

Health promotion activities within a childcare center promote the child's highest level of functioning and development, such as activities to stimulate physical, cognitive, and emotional development, and nutritious food to foster growth. Health maintenance

activities are those that prevent injury or disease, such as immunization monitoring, infection control, and practices like putting infants on their backs to sleep. See the *Sudden Infant Death Syndrome* section in Chapter 20 for additional information.

Health Promotion

Nurses working with a childcare center can design and offer health education programs for the children (such as toothbrushing, hand hygiene, blowing the nose into a tissue, and coughing or sneezing into the elbow or shirt sleeve if a tissue is not available) to promote healthy habits.

Growth and Development Childcare Outcomes

When children receive quality child care that addresses their health and developmental needs, there are numerous benefits in cognitive development, language, math proficiency, social skills, interpersonal relationships, and self-regulation of behavior. These benefits lead to improved school readiness (Hillemeier, Morgan, Farkas, et al., 2013).

ENVIRONMENTAL SAFETY

To prevent child abduction, ensure that the childcare center maintains a current list of family members who may take a child from the facility and has guidelines for verifying identity when necessary.

The nurse should inspect the childcare environment to identify hazards that could cause injury to the children. Cleaning supplies and other toxins must be stored in a locked cabinet to prevent exposure. Inspect toys used by children to ensure that there are no sharp edges or points, small parts, or pinching parts. Check the safety of playground equipment (Figure 10–4).

EMERGENCY CARE PLANNING

As in the school setting, guidelines for assessing and identifying the child with an emergency health condition and the development of an emergency care plan for an acutely ill or injured child is essential. This plan should include giving first aid, calling EMS to transport the child to the emergency department, notifying the parent, and accompanying the child to the emergency department until the parent arrives.

Nursing Roles in the Home Healthcare Setting

Home health care is a component of the continuum of comprehensive health care provided to children and families. Children with episodic or long-term health conditions can benefit from home healthcare services to promote their optimal function and participation in the family. Home healthcare services may be provided to children with complex health conditions, short-term acute care conditions, and even for hospice care.

Pediatric in-home healthcare services for children with complex healthcare conditions or who are medically fragile have increased because of the increased survival of preterm infants, infants with complex congenital conditions, children with severe trauma, and children with life-limiting or life-threatening conditions (Mendes, 2013). Technologies now used in the home include ventilators, suction, peritoneal dialysis, enteral feeding tubes, pumps for feeding tubes, intravenous fluids, and medications.

The home environment is believed to improve the long-term care of these children by integrating them into the family, promoting their growth and development, and minimizing the number of hospitalizations. The family may feel as if some control over family life is achieved by having the child in the home. However, the health and well-being of parents is affected by limited sleep, chronic distress, and less time to engage in social and personal health-oriented activities (Murphy, Carbone, & the Council on Children with Disabilities, 2011). Many families feel like they were offered no choice about assuming responsibility for the nursing and technologic care of their child who is medically fragile (Mendes, 2013). This causes stress as the family attempts to balance the child's constant care requirements and needs of the entire family. Healthcare providers and insurers are challenged to simultaneously address the child's illness and developmental needs while supporting families when these children are transitioned to care at home.

Home health care is considered by health payers to be a cost-effective alternative to hospital inpatient care. Many different options for health insurance payment exist, such as family health insurance, the Child Health Insurance Program (CHIP), Social Security, and state Medicaid programs. The family also has a financial burden because of paying some costs out of pocket—for medications, supplies, and transportation. A parent may need to give up employment to care for the child and to qualify for Medicaid.

Figure 10–4 **Assess the childcare center's environment for safety hazards. Check the area around playground equipment, making sure there are wood chips or cushioned tiles under the equipment. Inspect the playground equipment for protruding screws, loose nuts and bolts, and instability at least monthly.**

Figure 10–5 **Nurses provide both short-term and long-term services to families in the home setting. In some cases, families need support for a short time after the child is discharged from the hospital following an acute illness. In other cases, families need assistance with complex nursing care for the child assisted by technology.**

SOURCE: Paula Solloway/Alamy

Nurses need a variety of skills, knowledge, and experience to work in the pediatric home care setting, such as:

- Knowledge and experience in pediatric assessment and acute care practice using various medical technologies. These skills enable nurses to provide direct care, teach the family and child self-care practices, and monitor the child's progress.
- The ability to adapt, be creative, and be prepared to deal with the unexpected, such as equipment malfunctions.
- An understanding of community resources, financing mechanisms, and multiagency collaboration; and good communication skills.
- Knowledge of the community's health resources to help families obtain services that match the child's and family's needs.
- An understanding of the community's cultural diversity and the cultural values of the families served.
- Skill in collaborating with other healthcare team members.

Home care nursing is focused on assisting a family to gain a greater ability to more independently manage the child's care related to a chronic condition or an acute condition following hospital discharge. Nurses also work with the family in the home care setting to promote or restore the child's health while attempting to minimize the effects of the disability and illness, including life-limiting illness (Figure 10–5).

Nursing Management

For the Child in the Home Healthcare Setting

Nursing Assessment and Diagnosis

Home health nurses assess the home, the child, and the family during intermittent skilled nursing visits. Assessment of the home is focused on environmental safety, adapting the environment for the child's care, and identifying needed resources. When working with the hospital discharge planner or case manager to initiate home health services, the following aspects of the home are assessed:

- Home readiness (safe sleeping arrangements, adequate supplies, ability to meet nutritional and fluid needs, telephone access, heat, electricity, refrigeration, lack of any communicable diseases in the home, and safe access into and out of the home)
- Potential hazards related to the child's age, condition, and requirements for technology-assisted care (e.g., extension cords used to plug equipment into electrical outlets and inadequate space for a wheelchair or walker)
- Features of the home environment that could cause an acute illness (e.g., use of a woodstove or fireplace for heating that could cause respiratory distress, active renovation of a house releasing lead dust, and family members who smoke)

Assessment of the child is focused on the current health status, growth, developmental progress, and social interaction with family members and healthcare providers. The potential for abuse and neglect is assessed in children with complex health conditions who are at higher risk.

Family strengths and coping abilities are evaluated along with parenting methods. Parents' skills in giving the child needed medications, performing care procedures, and detecting signs of an urgent change in the child's health status are assessed. The presence of siblings, their developmental and physical status, and their needs should also be assessed.

Developing Cultural Competence Assessment

When assessing the child and family in the home, recognize when any potential conflicts might exist between recommended medical care and the family's preferences. Identify which family member is most influential in decisions about the child's care. Use open-ended questions to talk with families and understand the issue from their point of view. Ask family members to identify the issue, why it is a concern, and the impact on their lives. Information gained can be used to educate the family, communicate with healthcare providers about potential alternate care options, and develop a nursing care plan that integrates the family's preferences.

Examples of nursing diagnoses that could apply to the family as the child transitions from the hospital to home setting include the following (NANDA-I © 2014):

- ***Home Maintenance, Impaired,*** related to insufficient family organization and planning
- ***Coping: Family, Compromised,*** related to multiple stressors in caring for a child with a complex health condition
- ***Health Management, Family, Ineffective,*** related to complexity of medical interventions
- ***Social Interaction, Impaired,*** related to therapeutic isolation

Planning and Implementation

Nursing care should focus on promoting an environment within the home for the child to develop, learn social skills, and gain a

sense of identity based on family values. Nurses help families in the home setting in the following ways:

- Ensuring that the child will be safe at home
- Providing competent nursing care to the child
- Educating parents about the child's condition and signs that may indicate an urgent change in health status
- Educating family members to safely administer medications and feedings, and perform medical procedures
- Demonstrating methods to promote the child's development
- Linking families to community resources, including support groups, respite care, and therapeutic recreation
- Assisting families in time management skills
- Advocating for increased health insurance coverage or locating other sources of financial assistance

COLLABORATING WITH THE FAMILY

The nurse works in partnership with the family in the home to promote the health of the child and of the family unit. The nurse must develop a respectful and trusting relationship with the family, remembering that the family maintains control in the home care setting. Open communication is essential so the nurse can learn what is important to the child and family, and then modify the nursing care plan when appropriate.

Role expectations of the nurse, especially when in the home for extended hours, must be clearly understood to reduce stress in the family. House rules for such things as parking, private areas in the home, door to use, where to store belongings, and routines need to be negotiated, and then those rules need to be followed. The success of home care is also based on effective cultural communication. For example, some Jewish families follow strict dietary guidelines that do not permit dairy products and meat to be served together in the same dishes or during the same meal. The nurse needs to abide by the dietary guidelines and observe the family's food preparation practices.

The range of nursing care that may be included in a child's home care plan may include sensory stimulation, routines of daily living, positioning and skin care with gentle handling, respiratory care, nutrition and elimination, medications, and other supportive therapies. Other providers, such as physical therapists, speech-language therapists, occupational therapists, and social workers, may provide other healthcare services in collaboration with the home health nurse.

A parent or guardian should be present when nurses provide home care. Informed consent is needed for invasive treatments and decisions for provision of needed emergency care to prevent serious consequences. A plan for communication about key client-care information (e.g., daily notes written by both the family members and nurse) and scheduled meetings with family members are important to ensure that needed information is shared. This also helps the family members evaluate how well the nurse meets their expectations for care of the child.

SUPPORTING THE FAMILY

When home health nursing is episodic, parents of children with complex conditions often feel stressed by the constant care demands. They may be sleep deprived when caring for the child 24 hours a day and need some assistance in identifying alternative care options, such as **respite care**, short-term home care to relieve the primary caregiver and allow time away from home (see Chapter 12 for more information). Families often need support in identifying and advocating for potential services that may be of value to their child and financial resources for which they may be eligible.

EMERGENCY PREPAREDNESS

The nurse should help the family develop an emergency care plan for any child whose condition could worsen rapidly and become life threatening (e.g., severe congenital heart defect, tracheostomy, or apnea), or be more than the parents or home health nurse can provide with resources available. The plan should provide guidelines for when to call 9-1-1. The emergency care plan should include an essential medical history that provides the emergency care providers with enough information to understand the child's health condition, to prevent delays in disease-specific treatment, and to minimize unnecessary interventions until the child's personal physician can be consulted. Refer to the American Academy of Pediatrics website for an emergency information form.

Families should develop a plan for safe evacuation of the home in case of fire or other emergency. This is very challenging when the child cannot mobilize independently and requires equipment for continued survival or quality of life. See *Families Want to Know: Home Evacuation Plan* for information to help families develop a plan for safe evacuation of the home.

Families Want to Know

Home Evacuation Plan

Developing a home evacuation plan is important when the family has one or more children with special healthcare needs. Important steps to have families take in developing the plan include:

- Have working smoke and carbon monoxide detectors in the home and teach children what the alarm means. Make sure batteries are changed twice a year.
- Draw a diagram of your house. Mark all windows and doors. Plan two routes out of every room. Think about an escape plan if the fire starts in the kitchen, bedroom, or basement.
- Figure out the best way to get infants and young children out of the house. Will you carry them? Is there more than one small child, and if so, how will you get all the small children out if you are the only adult?
- Teach preschool and school-age children to follow the escape plan by crawling, touching doors, and going to the window if the door is hot. Show children how to cover their nose and mouth to reduce smoke inhalation.
- Prepare an alternate fire escape plan in case you are alone with the child when the fire begins.
- Keep home exits clear of toys and debris.
- Select a safe meeting place outside the home. Teach children not to go back inside the burning home.

When the child is dependent on technology, the family should notify the power company so that the home is on the high-priority list for service after power outages. Backup generators may be needed if electrical power for life-sustaining equipment is essential. The child should also be registered for a disaster shelter that can accommodate the healthcare needs of the child and at least one caregiver when major power outages occur.

Evaluation

Expected outcomes of nursing care include the following:

- Care of the child's medical needs is integrated into the family's routines when possible.
- The family has an emergency care plan for the child in the event of a disaster, a weather emergency, or if the child's condition suddenly worsens.
- The home health nurse and family work in partnership to promote the child's health and growth and development.

Assessment of Community Needs and Resources

Community Assessment

Community assessment is a process of compiling data about a community's health status and resources to develop a public health plan to address the priority health needs of a target population within that community. For example, the target population could be all children, a specific age group, or even a special group of children (such as those with a chronic condition). The assessment process involves community partners but follows the nursing process format. Analysis of information gained about the number of individuals with the health need and existing resources helps healthcare professionals determine if additional programs or resources are needed. An overview of the community assessment process is described, but additional resources such as a community health nursing textbook are needed to complete a full assessment.

Community assessments may be conducted for the following reasons:

- A request is made by interested community advocates or the local health department.
- Justification is needed to fund a new or expanded healthcare program.
- Evaluation of responses to healthcare programs or interventions (such as immunizations, injury prevention programs, or services targeted to new immigrants in the community) may provide the data to determine if the children with the greatest needs have been appropriately targeted and are benefiting equally from the intervention.

The focus of a community assessment is on the target population. For example, the focus might be on ensuring that all children in the community, regardless of socioeconomic status and racial group, are considered when trying to ensure access to care or specific interventions—such as injury prevention programs, immunizations, school health services, or suicide prevention programs.

A community assessment is often initiated because one or more individuals (i.e., concerned parents, school nurse, or community leader) are concerned about a health or social issue, such as a child who is severely injured in a pedestrian crossing on the way to school. The concerned individuals partner with other **stakeholders** (all community residents, policy makers, health providers, and funders concerned with the outcome of the assessment) to investigate if this is an isolated event, or if similar incidents have happened at other locations and to identify ways to protect other children. Community partners for this investigation and community assessment may include nurses, family members, local organizations (e.g., Kiwanis, Safe Kids, parent-teacher association), the faith community, the local trauma center, an epidemiologist, elected officials, and health department representatives.

Developing Cultural Competence **Integrating Cultural Groups Into Community Assessments**

Community assessment leaders should invite community members representing different cultural groups to participate in the process. They help provide an important perspective of the community's needs and help identify culturally appropriate and acceptable strategies to address the health problem.

Family members, a pediatric nurse, and a school nurse are important members of the group when pediatric health issues are being addressed.

The first step in beginning a community assessment is to clearly define its purpose and scope to keep the process focused. The purpose is often associated with a specific problem that an advocate or community leader would like to have addressed by the community. Example issues could be one of the following:

- Several child pedestrians and bicyclists have been injured or killed by motor vehicles over the past 3 months in the same neighborhood.
- Two children drowned at the local lake in a boating incident.
- Three teens from a local high school have committed suicide in the past 2 months.
- The number of children who are fully immunized on school entry has decreased in the last year.

Once the purpose and scope of the assessment are determined, various factors that influence the health of a community should be considered when collecting assessment data (Clark, 2015, pp. 356–370), such as the following:

- Demographic characteristics such as age composition of the community, birth statistics, age-specific and cause-specific mortality rates, racial composition, and **morbidity** (incidence and prevalence of certain diseases), as well as the immunization status of children
- Community prospects for continuing growth or economic challenges, cohesion of the community in dealing with past health problems or crises, existing tensions between various community groups, adequacy of personal safety services, communication networks, stresses in the community, and incidence of crime, homicide, and suicide
- Type of community (rural, urban, suburban), size, climate, topographical features, housing adequacy, water supply, waste disposal, and potential hazards that could lead to a disaster
- Sociocultural characteristics such as local government and community leadership, transportation, income and education levels, employment rates, occupations, family composition, faith communities, cultural groups represented, language barriers to health care, number of homeless families and children, recreation, shopping, and social service agencies

- Behavioral characteristics such as nutrition and specific dietary patterns, use of harmful substances, exercise and recreational opportunities, and population use of safety practices
- Health services available to children in the community covered by health insurance, Medicaid, or the State Children's Health Insurance Program (SCHIP); services available to uninsured children; and barriers to healthcare access

Stakeholders next make plans for data collection (types of data to be gathered, sources of data, and methods for obtaining the data) and data analysis. Some of the best data to use are those calculated as rates, such as the following:

- $\text{Birth rate} = \dfrac{\text{number of births in a state in a year}}{\text{total state population (same year)}} \times 1000$
- $\text{Mortality rate} = \dfrac{\text{number of deaths in a state in a year}}{\text{total state population (same year)}} \times 100{,}000$
- $\text{Age-specific mortality rate} = \dfrac{\text{number of deaths in children aged (e.g., 1 to 4 years) in a year}}{\text{total population of children aged 1 to 4 years (same year)}} \times 10{,}000$
- $\text{Cause-specific mortality rate} = \dfrac{\text{number of deaths due to (e.g., injury) in a year}}{\text{total state population (same year)}} \times 100{,}000$
- $\text{Incidence rate} = \dfrac{\text{number of new cases of a disease (e.g., type 2 diabetes) in a year}}{\text{total population at risk at the midyear}} \times 1000$
- $\text{Prevalence rate} = \dfrac{\text{number of children with a disease (e.g., asthma) in a year}}{\text{total population at risk at the midyear}} \times 1000$

National, neighboring state, and state data can be compared with community data using rates to determine how similar or different the community statistics are for the health problem.

Data may be collected from many sources. For example, the Centers for Disease Control and Prevention collects state data and calculates birth rates and death rates for all types of conditions. Population data are available on the Internet from the U.S. Census. Other potential sources of data include a state or local trauma registry; an immunization registry; community surveys; a telephone book for numbers of healthcare providers and faith communities; and local health agencies for such information as the number of child abuse incidents, trauma centers for injuries requiring hospitalization, clinics for specific services, and infants served by the WIC program. Law enforcement agencies may provide information on motor vehicle crashes, assaults, or homicides. In many cases databases include specific locations of where events occurred with geographic information systems (GIS) coding. Focus groups or interviews with key community representatives may provide information on perceptions of health needs.

An **epidemiologist**, a specialist with training in the study of patterns of diseases or health risks in a population, is often responsible for analyzing the data. Data trends are analyzed over several years to determine if the identified problem is a cluster of events that is part of a larger significant pattern. For example, the timing and clustering of events, such as the number of child pedestrians and bicyclists killed or injured, provide a clue to explore recent changes in the community. Have traffic patterns changed because of construction? Does this happen every year as school sessions begin? Is it related to children enjoying spring weather after school? Once the data are collected and analyzed, the community group can then develop a plan to address the problem and have baseline data for evaluation of the planned community intervention.

Key community assets should also be identified during the data collection stage. A **windshield survey**, a walking or driving tour around a neighborhood or community for the purpose of identifying resources and characteristics of the community, often provides important information needed to plan interventions. What could be collected during a windshield survey to study child pedestrian injuries and deaths?

A community assets map can be developed to help identify the presence of some community resources such as its healthcare facilities, local library, grocery stores, recreation facilities, schools, and so on.

Planning and Evaluation

An intervention is planned and implemented after the collected data have been analyzed and the community health problem is more clearly described. The planning involves a collaborative effort with all the stakeholders contributing ideas, developing strategies, considering funding sources, and ultimately promoting and advertising the plan in the community. The collaboration often includes persons with specific skill sets who can take leadership roles with different aspects of the interventions. The planning group's knowledge of the cultural beliefs, primary language, income levels, reading level, sources of community health education, and potential community partners is valuable in designing the intervention. Knowledge about potential community funding resources or barriers helps in determining potential strategies that may be approved and endorsed by community decision makers.

The plan and interventions for the health problem need to be evaluated. Data collected before the intervention can serve as one comparison for the evaluation. Evaluation should also focus on the intervention and how well the target population received it, as well as the outcome, such as reduced injuries and deaths.

Preparation for Disasters

Disasters are serious and massive events that impact many people in a community and cause extensive damage, hardship, deaths, injuries, and psychologic trauma. Natural disasters include floods, ice storms, hurricanes, earthquakes, volcanic eruptions, tornados, and wild fires. Trains or trucks carrying toxic chemicals and nuclear waste that crash or explode may also cause a disaster. Terrorism is another potential cause of disasters and may involve the use of bombs, infectious organisms, toxic chemicals, or radioactive agents. (See Chapter 16 for information about infectious agents used for bioterrorism.) Disasters may cause death, injury, physical damage, psychologic trauma, and economic disruption.

State and federal agencies, hospitals, and health professionals are participating in **disaster preparedness**, community planning for responses to natural and man-made disasters that involve multiple casualties. Special planning for the needs of infants, children, and adolescents must be integrated into these efforts. Health services are needed to treat injuries and potential illnesses caused by contaminated water and other exposures.

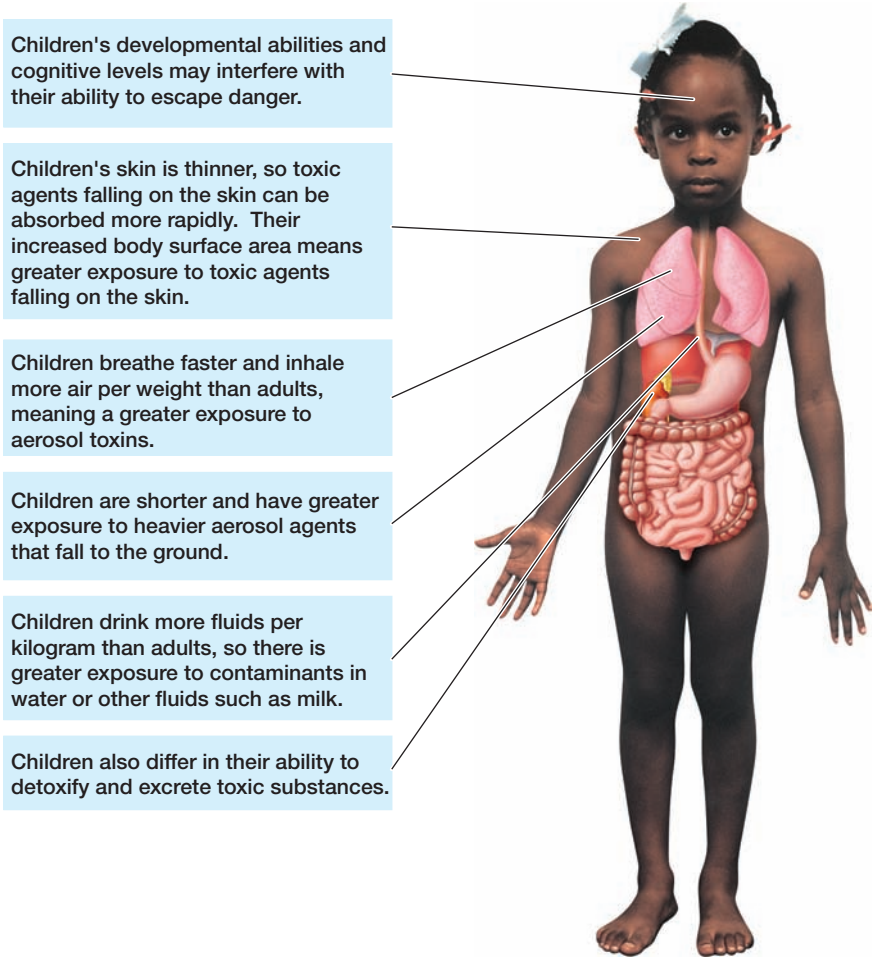
Children have special vulnerabilities during a disaster. Disasters are very traumatic for the children involved, and there may be immediate and delayed responses. Disbelief, fright, and grief reactions are among immediate responses (Jones & Schmidt, 2013). Children may lose their homes and personal possessions. They may be separated from their families. Friends, pets, and family members may be injured or dead. They may also have problems expressing their feelings about the disaster.

Growth and Development

Developmental considerations must be considered during disaster planning because young children may be unable to do the following (AAP, 2013a):

- Walk or mobilize to escape danger.
- Understand what is happening.
- Understand the need to flee or take evasive action.
- Follow the instructions regarding evacuation or safe actions.
- Tell others they need help.
- Distinguish between reality and fantasy.

As Children Grow: **Response to Terrorism Agents**



The child's size, physiology, and cognitive vulnerabilities lead to special considerations when the child is exposed to chemical, radiologic, or biologic agents of terrorism.

Clinical Manifestations

Injuries caused by explosions or falling debris may affect any part of the body. Exposures to various chemicals and toxins may cause burning sensations in the respiratory tract, increased secretions, coughing, respiratory distress, tearing, blurred vision, eye pain, sweating, nausea and vomiting, bradycardia or tachycardia, seizures, muscle weakness, and burns to the skin. Few signs of radiation exposure are seen initially, but nausea, vomiting, and immunosuppression may develop.

Fear, anxiety, sadness, and confusion are some common initial responses to a disaster, whether it is natural or man-made. The responses of children may be even greater if parents are also anxious or overwhelmed. Developmental stage, prior life experience, and the ability of the primary caregiver to meet safety and security needs will determine a child's response to disaster. Support for early responses to the disaster include the following (Jones & Schmidt, 2013):

- *Infants:* Disrupted routine such as changes in sleeping and eating patterns, crying, and irritability associated with family responses to the disaster. Support involves providing a consistent caregiver and maintaining normal routines as much as possible.
- *Toddlers:* Disrupted sleep, nightmares, night terrors, regressive behaviors such as clinging behaviors, withdrawal, and temper tantrums. Support involves reestablishing routines for sleep, meals, and play as much as possible as well as a comfort item and storytelling.
- *Preschoolers:* Similar to toddlers, regressive behaviors (bed wetting, thumb sucking, fear of the dark), disrupted sleep, anxiety, and complaints of stomachaches or headache. Support involves reestablishing routines, allowing regression during stress, and promoting play and storytelling to express feelings.
- *School-age children:* Preoccupation with the disaster details and anxiety about consequences, fear of more harm for themselves and their family. Support involves restricting media exposure, explanations of the event in age-appropriate terms, opportunities to express their feelings, and play therapies.
- *Adolescents:* More awareness of the disaster's severity and its significance that may complicate responses, anxiety, unrealistic fears, anger, changes in mood, stomachaches, and headaches. Support involves engaging adolescents in disaster response efforts when it is safe, encouraging them to talk with peers and teachers about their feelings, relaxation techniques, exercise, and journal writing.

Clinical Therapy

Children have different physiologic responses to emergencies because of their smaller anatomy and developing organ systems. As a result they require special management considerations when exposed to chemical or radiologic agents used by terrorists or to toxins released during another type of exposure, such as a train crash (see *As Children Grow* for more information).

The initial response to the scene of a disaster is to get victims to fresh air and to quickly identify the level of injury or illness severity of all individuals. Emergency care and transportation to facilities that can provide needed care are initiated. Clinical therapy is focused on determining the type of exposure and providing immediate care to reduce the agent's effects.

Decontamination, the removal of chemicals and nerve agents from the skin, should be performed as soon as possible. Clothing is removed, and the child is washed with soap and water. Eye irrigation may be needed to reduce pain and eye damage. Decontamination reduces the child's exposure to the toxin and helps protect medical personnel who will care for the child.

Some children need fresh air, oxygen supplementation, a secured airway with an endotracheal tube, eye irrigation, fluids, and other symptomatic care. Burns and other injuries are cleaned and treated. Antidotes may be administered, such as potassium iodide for radiation exposure or atropine for nerve agent exposure.

Nursing Management

DISASTER PREPARATION

Pediatric nurses in schools and other community settings play an important role in preparing families for a disaster. They can guide families to developmentally appropriate resources for talking with their children about disaster planning and disasters that occur. Families who discuss disaster planning with health professionals are more likely to follow disaster preparedness recommendations, and children may cope better if involved in the family's disaster planning (Jones & Schmidt, 2013). Children need to know what to do in case of a disaster and that police officers, firefighters, and emergency medical personnel are available to help them. They should be taught areas that are safest in the home, how to respond to smoke detector alarms and community alerts, when to call the emergency number, and how to contact the family members when separated (AAP, 2013b).

Help the family develop a disaster plan for staying at home or for evacuation. Families must prepare to manage for 72 hours within their own home following a major disaster or epidemic. The family needs a 3-day supply of nonperishable food and bottled water, flashlights and batteries, a battery-powered radio, over-the-counter medications, and many other resources. Remember to have formula, diapers, bottles, powdered milk, moist towelettes, and diaper rash ointment for infants and children if needed. A plan for family pets should also be made. Refer to the Federal Emergency Management Agency (FEMA) website for the most current recommendations for family supplies to have on hand.

Parents should also carry phone numbers of out-of-town contacts, schools, and neighbors at all times. Developing a list of each family member's medications, clothing, food, water, and other essentials is important so the family can quickly pack and respond to an evacuation order.

Advance planning is needed to ensure that children assisted by technology have the resources needed in the event of a disaster. Help the family register with the designated community shelter caring for individuals needing electrical power for their medical equipment. Batteries for medical equipment should be fully charged at all times. Additionally, parents need to arrange for a durable power of attorney so that consent for emergency medical care can be available should the child and parents become separated during a disaster.

Professionalism in Practice Pediatric Nursing Role in Disaster Planning

Pediatric nurses have an important role in helping community organizations plan and implement emergency preparedness plans for disasters. Each of the community settings where nurses work should have a disaster plan in which pediatric nurses advocate for children and their families. Children and their families may experience adverse outcomes if emergency preparedness plans do not integrate the special needs of children (Society of Pediatric Nurses, 2014).

EMERGENCY RESPONSE

Nurses are important first responders during disasters. They provide emergency health care for rescued victims and first aid for the walking wounded, work in disaster shelters, and perform general public health interventions (e.g., vaccines, sanitation, food and water). Nurses can provide a safe place for children, away from media and unfolding traumatic events, such as the rescue of dead and injured. Do not allow children to leave a scene unaccompanied by a parent or other responsible adult. Assess for panic reactions, unexpected behaviors, and changing conditions.

Clinical Tip

A 12-volt inverter is an inexpensive device that can be plugged into a car's cigarette lighter and delivers 110 to 120 volts of alternating-current power. This device can be powered with the car's battery or by turning on the engine and can be used to keep a patient's life-support device working.

PSYCHOLOGIC SUPPORT

Nurses with knowledge of child and adolescent development can meet the psychologic needs of youth after a disaster. Respond to families in a compassionate and supportive manner, comfort and console children, and provide information and some guidelines for positive coping.

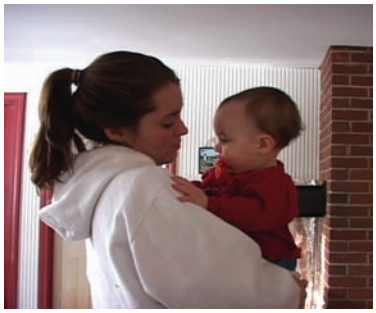
Once the initial disaster is managed and children return to home or other settings, children may need extra time with their parents. Parents should attempt to reestablish daily routines for school, meals, play, and rest as soon as possible. Encourage parents to listen and answer the child's questions about the disaster honestly and in language the child can understand. If they cannot answer a question, it is better to be honest and say so. Reassure the child that they are trying to do everything to keep the child safe. Encourage older children and adolescents to discuss the disaster with family members and peers if desired.

Because disasters may cause disruption for extended periods, the child may have prolonged periods of emotional distress. Identify children and families who do not return to normal life patterns. Worrisome signs include persistently reliving the event in dreams or memories, hypervigilance, difficulty sleeping, irritability, difficulty concentrating, and avoiding stimuli associated with the event. Children who may be more vulnerable to posttraumatic stress reactions (PTSD) include those who change schools, witness destruction, lose a parent or a sibling, lose a home, or remain in a shelter (Jones & Schmidt, 2013). (See Chapter 28 for a discussion of PTSD.) Use these signs to identify children for whom more psychologic help is needed and to promote access to those services.

Chapter Highlights

- Pediatric care in the community occurs in many settings such as physician offices, mobile vans, healthcare centers, hospital outpatient clinics, schools, childcare centers, the home, and disaster shelters.
- Working with the child and family in the community setting requires an understanding of how the larger environment influences the child's health and development.
- Nurses working in many community healthcare settings develop a long-term relationship with the child and family over time that helps promote the provision of optimal health care.
- Examples of community family support services include Head Start education programs, before- and after-school programs, peer support groups, faith community social service programs, crisis care, and respite care programs.
- Pediatric nurses in community settings assist with diagnostic workups and management of children with chronic health problems, including family and client assessment, health education, health promotion, and linking families with community resources.
- School nursing focuses on removing or minimizing health barriers to learning so children can perform academically. Services include prevention, health promotion, health education, emergency care, and managing chronic health problems.
- Nurse consultants to childcare settings assist the administrators in the establishment of the childcare center's policies for healthcare practices, teach staff about safe healthcare practices, and monitor healthcare practices.
- Home care nursing goals include promoting or restoring the health of the child while attempting to minimize the effects of the disability and illness.
- Pediatric nurses help families prepare for a disaster by helping them develop a disaster plan, use developmentally appropriate information to talk with children about what to do when disasters occur, provide direct care in a disaster shelter, and provide psychosocial support to families and children.

Clinical Reasoning in Action



Gavin is a 1-year-old coming into the clinic for his well-child checkup. The clinic is set up to see teen mothers and their babies for well-child visits and immunizations. Tanika, his mother, has been bringing him there since he was born. Gavin qualifies for healthcare coverage through the Medicaid system in his state. He was born full term and has never been in the hospital or had surgery. Tanika is still attending high school and plans to graduate this year. She and Gavin are living with her boyfriend's (Gavin's father) parents until they can raise enough money to live on their own. Gavin's father does not come to the well-baby visits. Gavin attends child care while his mother is at school. He is up-to-date on immunizations so far and there is no significant family medical history, but there is smoking in the home. Gavin has been walking since he was 9 months old. He is able to point, wave, clap, and speak two words. He is able to drink from a cup and put objects into a cup. He has been growing and thriving at an appropriate pace. Tanika describes him as a good eater and tells you that he is currently on whole milk. He has soft stools daily and five to six wet diapers per day. He sleeps through the night and takes two naps per day. Tanika describes him as an extremely active child and has worked on childproofing everything in the house.

1. What is the role of the nurse in caring for Gavin and his parents in the clinic?
2. What data does the nurse collect to perform a family assessment?
3. What strengths and stressors are likely to be present in this family?
4. What information should the nurse provide to help Tanika prepare for evacuation with Gavin since springtime flooding is anticipated?

Chapter 11
Nursing Considerations for the Hospitalized Child

Mel Curtis/Getty Images

We live 50 miles from the hospital and have three other children. We were worried about how we were going to be able to stay with Sabrina. She's only 4, and it's her first time in the hospital. Fortunately, they have beds for parents, so one of us can always be by her side throughout her procedure and recuperation.

—Mother of Sabrina, 4 years old

Learning Outcomes

11.1 Compare and contrast the child's understanding of health and illness according to the child's developmental level.

11.2 Explain the effect of hospitalization on the child and family.

11.3 Describe the child's and family's adaption to hospitalization.

11.4 Apply family-centered care principles to the hospital setting.

11.5 Identify nursing strategies to minimize the stressors related to hospitalization.

11.6 Integrate the concept of family presence during procedures and nursing strategies used to prepare the family.

11.7 Summarize strategies for preparing children and families for discharge from the hospital setting.

Hospitalization, whether it is elective, planned in advance, or the result of an emergency or trauma, is stressful for children of all ages and their families. Because most pediatric conditions can be managed within the home and community, hospitalization is not always required to manage the child with an illness. Additionally, many pediatric surgical procedures are being performed on an outpatient basis. However, for children who are hospitalized, the illness acuity is frequently high. Because of advances in medical technology in recent years, children with complex medical conditions have improved survival rates, resulting in an increase in the rate of chronically ill children who require frequent and sometimes long-term hospitalization (LeGrow, Hodnett, Stremler, et al., 2014).

Hospitalized children experience a variety of emotions because they are in an unknown environment, surrounded by strangers, unfamiliar equipment, and frightening sights and sounds. These children are subjected to unfamiliar procedures, some of which are invasive or painful and may even require surgery. For both children and families, routines are disrupted and normal coping strategies are tested.

Nurses today are challenged to provide individualized care for the hospitalized child with complex medical conditions, acute illnesses, or injury. As a key aspect of that role, nurses must address the psychosocial and developmental concerns that accompany hospitalization. (Developmental theorists and stages are presented in Chapter 4.) To minimize the stress of hospitalization, nurses provide support and education to children and their families before, during, and after hospitalization.

During hospitalization, nurses use a family-centered approach and work collaboratively with parents to implement various strategies that promote coping and adaptation and to prepare children for necessary procedures. Nurses also

collaborate with members of a multidisciplinary team and partner with families to prepare them for discharge home or transfer to a long-term care or rehabilitation facility.

Effects of Hospitalization on Children and Their Families

Children's Understanding of Health and Illness

Can you remember as a child thinking that yelling at your mother caused your strep throat? Young children have limited knowledge about the body and its relation to health and illness. They do not understand what causes them to get sick. Their understanding is based primarily on their cognitive ability at various developmental stages and on previous experiences with healthcare professionals. As children become older, they develop a more accurate understanding of illness. For example, perhaps as an adolescent you believed that you would never become ill or have an accident; or maybe you feared being in a car crash similar to that of a friend. Knowledge of a child's understanding of health and illness is essential in assisting a child to adapt to the hospital experience.

Hospitalization and the accompanying medical procedures are very stressful for children, especially very young children such as toddlers and preschoolers. The child's attempts to deal with these stressors impact both the psychologic and physiologic well-being of the child. Infants, toddlers, and preschoolers lack the cognitive skills to understand hospitalization and are the age groups most likely to exhibit regressive behaviors. Young children have fears and anxieties related to things such as the dark, strangers, and monsters. A hospital's unfamiliar environment can exacerbate those anxieties. Significant stressors for hospitalized children include:

- Separation from parents, the primary caretaker, or peers
- Loss of self-control, autonomy, and privacy
- Painful and/or invasive procedures
- Fear of bodily injury and disfigurement

Nursing care of the hospitalized child focuses on minimizing the child's fears, anxieties, and disruption of the child's usual routine, and supporting the family through the stressful experience. Strategies include minimizing separation anxiety, loss of control, pain related to procedures, and fear. Table 11–1 highlights key stressors of hospitalization for children at each developmental stage.

INFANT

By about 6 months of age, infants have developed an awareness of themselves as separate from their mothers or fathers. They are able to identify primary caretakers and to feel anxious when in contact with strangers. Hospitalization can be a traumatic time for an infant, particularly if the parents are not staying with the child. Infants can sense the anxiety their parents are experiencing during a hospitalization.

Common stressors to the infant include painful procedures, immobilization of extremities, and the sleep deprivation caused by the disruption of the infant's normal sleep patterns and routines. However, the most common stressor of hospitalization for the infant is separation from parents, which is manifested by **separation anxiety**. Characteristic behaviors of children in the three phases of separation anxiety are listed in Table 11–2. Infants and toddlers between 6 and 19 months of age who are hospitalized often display some of these behaviors, particularly if parents are unable to remain with the child. In addition to separation anxiety, children between 6 and 18 months of age may display **stranger anxiety** (wariness of strangers) when confronted with unfamiliar healthcare professionals. See *Evidence-Based Practice: Anxiety and Fears in Children Related to Hospitalization and Surgery*.

Encourage family members to be active participants in the care of the hospitalized infant through touch, sight, and sound. Infants get satisfaction from meeting their oral needs, so parents and nurses should provide sources for oral stimulation, such as pacifiers and age-appropriate teething toys. The infant should be rocked and touched with light stroking to provide tactile stimulation for developmental growth. However, minimize excessive noise and prolonged stimuli to allow the infant periods of rest.

Encourage parents to stay with the hospitalized infant. If family members are unable to remain at the hospital, encourage them to visit their infant as often as possible. Explain and emphasize the importance of parent–newborn attachment and bonding to the parents.

Clinical Tip

Children encounter many members of the healthcare team, in addition to other hospital personnel, when hospitalized. Children ages 6 to 18 months perceive these people as strangers and may cry when someone new enters the room. As the child sees a person over and over again, the stranger anxiety for that person subsides. Providing consistent nursing staff as much as possible will limit the number of "strangers" that the child encounters while hospitalized.

TODDLER

Toddlers are the group most at risk for a stressful experience as a result of illness and hospitalization. This age group is old enough to understand that their routine has been disrupted, but they do not understand why. Separation from parents is the major stressor, and toddlers protest vigorously when their parents depart. When one or both parents cannot be present, they can leave mementos to comfort the child. These might include an object belonging to a parent, a picture, or an audiotape or videotape with messages from the parents.

Disruption of routine also causes stress for the toddler. The nurse encourages parents to remain present as much as possible for important rituals such as toileting, carrying out bedtime routines, and singing favorite nursery rhymes. Autonomy is the developmental task of the toddler (see Chapter 4). Having their activities limited and being confined especially threaten children in this age group. When possible, maintain the toddler's normal home routines for bathing and other activities. Offer the toddler choices when possible, such as choosing the color of Jell-O or which gown/pajamas to wear.

Clinical Tip

Toddlers may challenge a nurse by refusing to cooperate with treatments and procedures, including physical assessments. To diffuse such confrontations, encourage cooperation by offering the toddler some sense of control. For example, a nurse might let the child handle the stethoscope first before listening to the child's heart.

TABLE 11–1 Stressors of Hospitalization for Children at Various Developmental Stages

DEVELOPMENTAL STAGES AND STRESSORS	RESPONSES	NURSING MANAGEMENT
INFANT		
Separation anxiety Stranger anxiety Painful, invasive procedures Immobilization Sleep deprivation, sensory overload	Sleep–wake cycle disrupted Feeding routines disrupted Displays excessive irritability	Encourage parental presence. Adhere to infant's home routine as much as possible. Utilize topical anesthetics or preprocedural sedation as prescribed (see Chapter 15). Promote a quiet environment and reduce excess stimuli.
TODDLER		
Separation anxiety Loss of self-control Immobilization Painful, invasive procedures Bodily injury or mutilation Fear of the dark	Cries if parents leave the bedside Is frightened if forced to lie supine Wonders why parents do not come to the rescue Associates pain with punishment	Encourage parental presence. Allow parents to hold child in their lap for examinations and procedures when possible. Allow choices when possible. Utilize topical anesthetics or preprocedural sedation as prescribed. Explain all procedures using simple developmentally appropriate language. Provide a night-light.
PRESCHOOLER		
Separation anxiety and fear of abandonment Loss of self-control Bodily injury or mutilation Painful, invasive procedures Fear of the dark and monsters	Displays difficulty separating reality from fantasy Fears ghosts and monsters Fears body parts will leak out when skin is not intact Fears that tubes are permanent Demonstrates withdrawal, projection, aggression, regression	Encourage parental presence. Allow choices when possible. Utilize topical anesthetics or preprocedural sedation as prescribed. Explain all procedures. Provide a night-light or flashlight.
SCHOOL-AGE CHILD		
Loss of control Loss of privacy and control over bodily functions Bodily injury Separation from family and friends Painful, invasive procedures Fear of death	Displays increased sensitivity to the environment Demonstrates detailed recall of events to self and other patients	Encourage parental participation. Allow the child choices when possible. Explain all procedures and offer reassurance. Utilize topical anesthetics or preprocedural sedation as prescribed. Encourage peer interaction via Internet, phone calls, and other methods of communication.
ADOLESCENT		
Loss of control Fear of altered body image, disfigurement, disability, and death Separation from peer group Loss of privacy and identity	Displays denial, regression, withdrawal, intellectualization, projection, displacement	Include the adolescent in the plan of care. Encourage discussion of fears and anxieties. Explain all procedures. Ask the adolescent about the desire for parental involvement. Encourage peer interaction.

TABLE 11–2 Stages of Separation Anxiety

PROTEST	DESPAIR	DENIAL (DETACHMENT)
Screaming, crying Clinging to parents May resist attempts by other adults to comfort them	Sadness Quiet, appear to have "settled in" Withdrawal or compliant behavior Crying when parents return	Lack of protest when parents leave Appearance of being happy and content with everyone Show interest in surroundings Close relationships not established

EVIDENCE-BASED PRACTICE | Anxiety and Fears in Children Related to Hospitalization and Surgery

Clinical Question

What fears do children experience related to hospitalization and surgery, and how do they best express them?

The Evidence

In the past several years, many research studies have focused on the child's response to procedures and hospitalization and how best to prepare children of different ages. Recent studies have focused specifically on the child's fears related to this experience, how they express those fears, and how nurses can provide support.

A study by Salmela, Aronen, and Salanterä (2011) examined how children experience fears related to the hospital in 90 children ages 4 to 6. The children were interviewed in either a kindergarten classroom or hospital setting. Interviews were semistructured and accompanied by pictures of a fairy-tale figure in a hospital setting. The main fears identified were those related to nursing interventions and pain, separation from parents and being alone, lack of information, and equipment and instruments. The children described their fears in a variety of ways, including verbally expressing the fear, shouting, crying, fooling around, downplaying the fear, or expressing the fear in a picture or in their surroundings. The meanings of the hospital-related fears were grouped into four categories: insecurity, being injured, helplessness, and rejection.

Researchers explored the views of 93 children ages 5 to 9 related to hospitalization (Wilson, Megel, Enenbach, et al., 2010). Both hospitalized and never-hospitalized children were included in the study. The Barton Hospital Picture Test, a tool consisting of eight drawings related to situations that occur in the hospital, was shown to the children. The children were asked to tell a story about the pictures. The main theme that emerged from the stories was fear of being alone. Other feelings included being scared, mad, sad, bored, and lonely. The stories also indicated that the children wanted to be protected from uncertainty and scary things, and they wanted companions because they were not at home.

Karlsson, Rydström, Enskär, and Carlson (2014) discussed fears of children related to needle-related medical procedures and described the experience of nurses providing support during these procedures. The study utilized video-recorded observations of 20 needle-related medical procedures with follow-up interviews with a nurse. Fourteen different nurses took part in the study, which was conducted in both inpatient and outpatient settings. The interviewers asked the nurses about their experiences supporting children during needle-related medical procedures. Findings of the study indicated that children experience needle-related medical procedures in a variety of ways, and that it is essential to assess each child's ability to cope, taking into account age, developmental level, and previous experiences.

Six components of supportive actions were identified in the study, including developing relationships through conversation with both the parent and the child and being sensitive to the body language expressed by the child and the parents. Another component was identified as balancing between tact and use of restraint. This sometimes involved the use of preparation and play to distract the child, but at times, the child needed to be restrained in order to complete the procedure. Being an advocate for the child was an additional supportive action identified. Although parents are generally the primary advocate for children during procedures, the nurse may take on this primary role if the parent is unable to do so. Adjusting time is a component that refers to the need for nurses to give the child the right amount of time for the procedure, including time for the child to become familiar with the environment. The final component of support identified in the study was maintaining belief, which referred to giving hope and courage prior to the procedure and praising the child afterwards. This might entail the use of the words *brave* and *good* and the opportunity for the child to look in a gift box prior to the procedure.

Best Practice

Research demonstrates that children have fears related to health care and hospitalization. These fears vary among children of different ages and those in well settings versus the hospital setting. Children fear medical staff, equipment, instruments, pain, procedures, and needles, and they fear being left alone. Policies that provide open visitation for parents and include them in the care of the child will decrease fears related to being alone. Therapeutic nursing interventions that provide developmentally psychosocial care and education to hospitalized children is essential to decrease fear and anxiety related to staff and procedures.

Clinical Reasoning

How can children in school settings be prepared for future encounters with health care? Describe policies that promote parental presence for hospitalized children. How can fears related to medical staff, equipment, instruments, pain, procedures, and needles be reduced in hospitalized children?

PRESCHOOLER

The greatest stressors for preschoolers are their fears: fear of being alone, fear of being in the dark, fear of abandonment, fear of loss of self-control related to the body and emotions, and fear of bodily injury or mutilation. Preschoolers may also feel guilty about being sick, or they may view illness and hospitalization as punishment.

Similar to the toddler, preschoolers desire a normal routine, and the nurse can partner with the family to maintain routines as much as possible. Developmentally, preschoolers exhibit a sense of initiative (see Chapter 4) as they explore the world around them. To promote that initiative, the nurse can encourage the preschool child's independence by offering choices such as, "Do you want to take the red medicine or the purple medicine first?"

Parents should be encouraged to stay with the child if possible. For those who cannot stay, preschoolers need to know when to expect their parents to return to the hospital. Because most preschoolers lack a conception of time measurements like "2 hours," "half-past 4," or "3 o'clock," respond with simpler statements of time, such as "after supper" or "before breakfast." Encourage parents to make telephone calls to the preschooler if possible. Some parents are able to make calls from work. Preschoolers get

a sense of security from hearing their parent's voice confirming that the parent will return to the hospital.

Parents often believe it is better to leave the hospital room after their child has fallen asleep, as their departure will not stress the child. In fact, the opposite is true. If a child awakens to find the parent gone unexpectedly, the child may become anxious and may develop a lack of trust. Instead, encourage parents to tell their child when they need to leave and why (e.g., has to go to work or go home). By providing honest information to the child, parents or caregivers demonstrate that they can be trusted.

SCHOOL-AGE CHILD

The school-age child relies on parents and others for support and understanding during stressful events and procedures. Although school-age children attempt to maintain their composure during painful or invasive procedures, generally they still require a great deal of support. Major sources of stress for hospitalized school-age children include:

- Loss of control related to bodily functions
- Privacy issues
- Fear of bodily injury, pain, and concerns related to death
- Separation anxiety from family and friends

School-age children understand concepts, so parents who cannot remain at the bedside are encouraged to tell the child what time they will return and to let the child know if the time changes. Parents are encouraged to be available for telephone calls to provide support and comfort to their child. Stressful procedures can lead to regression or other behavioral changes, although this is less likely than with younger patients. Inform the parents that this behavior is normal during stressful situations.

Developmentally, school-age children exhibit a sense of industry (see Chapter 4), taking pride in their achievements at home, at school, and in sports. To foster that sense of industry, allow children to participate in their care as much as possible. Encourage them to continue with schoolwork and engage in creative outlets such as art or crafts.

Growth and Development

School-age children between the ages of 5 and 8 years believe that the internal body consists mainly of a heart and bones. They view the digestive system as having two parts, the mouth and the stomach. Showing them how parts of the body are related can be helpful to enhance their understanding. However, young adolescents, ages 11 to 13 years, can describe the location and function of major body parts such as the brain, nose, eyes, heart, and stomach. However, they usually have gaps in understanding and may have misconceptions, so evaluating their knowledge is a part of the nursing plan in order to plan teaching to meet their knowledge needs.

ADOLESCENT

Preoccupation with appearance and body image are paramount in this age group. By offering education and explanations that focus on these issues, nurses can provide significant reassurance to the adolescent. Nevertheless, adolescents often try to maintain independence and rigid self-control when undergoing painful and invasive procedures. Because hospitalization may increase dependence on their parents, adolescents may respond with frustration and anger. The nurse who respects the adolescent's desire for privacy and independence is often successful in establishing a trusting relationship and assisting the adolescent to cope with the hospitalization and illness. Encourage the adolescent to discuss thoughts and feelings about experiences. Careful listening by the nurse is essential for establishing a positive rapport.

Major stressors for hospitalized adolescents include:

- Loss of independence, control, and privacy
- Fear of bodily injury or changes in body image
- Fear of disability, pain, and even death
- Separation from peers, home, and school

Adolescents are in the process of establishing their identity and becoming independent of their parents' influence, so control over aspects of their care is important. Partner with the family and multidisciplinary team to ensure that the adolescent is an active participant in decisions and the plan of care. Privacy and modesty are major concerns, as adolescents' physical characteristics are rapidly changing. To demonstrate respect for their feelings, knock on the door before entering and ask permission before conducting assessments or other procedures. By allowing choices in clothing, hair, and music, the nurse can acknowledge the importance of the adolescent's self-image.

The peer group is a major influence in adolescents' lives. Allowing flexible visiting hours for friends helps teens maintain their social network and provides needed support. When friends are not able to visit, providing teens with Internet access provides a means of accessing their friends for support. Encouraging participation in recreation and teen lounge facilities available during hospitalization provides the adolescent with additional peer group support opportunities.

Family Responses to Hospitalization

The hospitalization of a child disrupts a family's usual routines. Parental roles change when the child is hospitalized and care is being provided by nursing staff. Roles may be altered as one parent stays at the hospital with the child while the other parent or siblings take on additional tasks at home. Family members may experience anxiety and fear, especially when the outcome is unknown or a potentially serious health condition prompted the hospitalization.

Family members' ability to cope can be challenged by a serious emergency, lengthy illness, chronic condition, poor prognosis, lack of family support, and lack of financial or community services. The stress on parents can be compounded by the burden of missed work, additional expenses, and concerns about feeding and caring for children at home. (See Chapter 13 for a description of nursing support for the child with life-threatening illness or injury.) Stress interferes with the parents' ability to provide support to the hospitalized child (Agazio & Buckley, 2012).

It is essential that nurses assess parental needs and attend to those needs in order to establish a trusting relationship. Parents who have support from nursing staff have less anxiety and more self-confidence, and are better equipped to make decisions and participate in their child's care.

Nurses also need to be alert to family members' cultural views about health, illness, and the causation of illness, which can influence their response to hospitalization and the family's management of the experience. Cultural influences may also determine which family member is the decision maker regarding healthcare practices, and provide guidelines for acceptable treatments.

The siblings of a hospitalized child may receive little attention from the parents who are overwhelmed and anxious about their hospitalized child's health. How siblings respond depends on their developmental level and ability to understand what is going on. Younger siblings who do not understand the causes of illness and hospitalization may feel guilty about fighting with or

being mean to their brother or sister in the past. Some siblings may fear becoming ill themselves. Some may believe that they played a role in the child's illness or injury and need reassurance that they did not cause it. If the sibling did in some way contribute to the illness or injury, help that child cope with the guilt by providing an opportunity to discuss these feelings. Siblings often have nightmares about the illness or injury their brother or sister has sustained and about the ill child dying (see Chapter 13).

As hospitalization causes family roles and routines to change, siblings may feel insecure and anxious. Education and support for siblings of hospitalized children promotes coping and adaptation to a sibling's illness.

As appropriate, encourage siblings to visit. Such a visit is especially encouraged if the child could potentially die, as it allows the sibling the opportunity to say good-bye. (See Chapter 13 for further discussion of the dying child.) These visits often help improve the mood of the hospitalized child and assist the sibling in overcoming misconceptions or negative emotions. Because children's fantasies are often worse than reality, unfounded fears may be relieved by a visit.

Before the visit, prepare the siblings by explaining what they will likely encounter. Describe the hospital environment, including equipment, sounds, and smells. Describe how the ill brother or sister will appear. If the hospitalized child acts, moves, talks, or appears differently than before the hospitalization, provide an explanation beforehand. A child-life specialist may be involved with this preparation (see specific information related to this role later in the chapter). Consider using a doll, drawing pictures, or showing an actual photograph of the hospitalized child to help prepare the siblings. (See *Families Want to Know: Strategies for Working With the Sibling of a Hospitalized Child*.)

During the visit, demonstrate how to talk to and touch the ill child and encourage the siblings to do the same. After the visit, discuss with siblings what they saw and felt, and answer any questions they may have. When a sibling cannot visit, contact with the hospitalized child can be maintained by sending pictures, drawings, cards, and messages recorded on iPods or other electronic devices, and through e-mail, instant messaging, or webcam. Partner with the family to determine the most appropriate and effective method of communicating if the sibling is unable to visit. If parents are staying at the hospital with the hospitalized child, partner with them to help establish communication routines for the well siblings. For example, encourage the parents to call the siblings at home at a regular time each night. Allowing the siblings at home the opportunity to share their day, and to receive an update on the hospitalized child, provides a feeling of connectedness and may minimize feelings of worry and resentment. The phone call offers siblings a consistent link to the parent and the reassurance that they are important and loved.

Family Assessment

To support the hospitalized child and provide family-centered care, nurses develop an understanding of the family dynamics and individualize the nursing care according to the needs of the child and family. To develop a plan of care that involves all family members, the nurse assesses the impact of the child's illness or hospitalization on the family. Table 11–3 provides a list of questions to guide the nurse in determining the roles of family, knowledge of family, support systems, and effects on siblings. (See Chapter 2 for further discussion of family assessment.)

Collaborate with the family to determine their resources, such as:

- Coping strategies of family members
- Financial resources
- Access to health care
- Availability of community services

One family with limited financial support may manage quite well because they have effective coping strategies, whereas another family with greater financial resources may have difficulty if their coping strategies are ineffective. Staying with a hospitalized child can be a financial drain for parents if one or both must take a leave of absence from work, miss scheduled workdays, or travel to the hospital. Additional expenses may include hotel rooms, meals, parking fees, and child care for other children. Assess the family's ability to manage these additional expenses. To evaluate the burden of hospitalization, use a multidisciplinary approach, which may lead to increased access to community resources and support for families.

Assess the family dynamics by evaluating:

- The quality of communication
- Methods of coping with stress
- Risk factors
- Sources of strength

Families Want to Know

Strategies for Working With the Sibling of a Hospitalized Child

The nurse working with siblings of a hospitalized child can implement the following strategies to assist the siblings in understanding what is happening to their brother or sister:

- *Be truthful.* Explain why the child is hospitalized, what the treatment involves, and how long the hospitalization is expected to last.
- *Assure siblings that they did not cause the illness and that the hospitalized child did nothing wrong.* If a sibling had some involvement in or responsibility for the health crisis, referral for mental health counseling may be needed.
- *Allow siblings to ask questions and discuss fears and other feelings.*
- *Encourage siblings to visit if possible.* Cover tubes and wires with a sheet. Wash off blood or cover bloody bandages if possible. Prepare the siblings for any equipment, dressing, and procedures they might see and any sounds they might hear.
- *Warn siblings if the hospitalized child is not speaking.* Say something like, "John can't talk now. He seems to be sleeping deeply. He may be able to hear, though, so you can touch him and talk to him."
- *Encourage siblings to express their feelings related to the disruptive effect of the child's hospitalization on family life.*

TABLE 11–3 Family Assessment

FAMILY ROLES
• What changes will the child's illness create in the family?
• Will household tasks need to be reallocated?
• What specific burdens will be placed on family members?
• Will one parent stay with the child or spend a great deal of time in the hospital?
• Will one parent or guardian be primarily responsible for communicating with other family members?
KNOWLEDGE
• What knowledge does the family have about the child's condition and treatment? Does the family need further information?
• How quickly can discharge planning and teaching begin?
SUPPORT SYSTEMS
• Does the child or family have health insurance? What percentage of costs will it cover? Will other financial support be needed? Will costs continue for ongoing care after hospitalization? If so, will existing health insurance cover those costs?
• Are close friends or family available to provide care for other children, assist with family tasks, or help in other ways?
• Are there community services such as support groups, camps for children with disabilities, education sessions, or equipment and financial resources to which the nurses can refer the family?
SIBLINGS
• Have siblings been informed of the ill child's condition and the expected outcome?
• Have they been reassured that they did not cause the illness?
• Do they understand the change in roles and family routines?
• Are they able to visit the ill child?
• Have their teachers been informed of the family stress?
• If the hospitalized child's life is threatened, are the siblings involved in a plan to promote coping?

Common sources of strength and support include friends and relatives, religious leaders, hospital chaplains, and social workers.

Examine how the family has dealt with the health needs of the child if the child has been hospitalized or required home care in the past. (See *Developing Cultural Competence: Supporting Alternative Health Practices*.) Determine the family members' level of understanding related to the child's hospitalization and anticipated therapy. Collaborate with family members to determine their desired role in the child's care. Assess the family's needs for referral to family service agencies or other community organizations that may be required. Evaluate the need for support groups or agencies that provide medical equipment or other assistance.

Developing Cultural Competence Supporting Alternative Health Practices

Many cultural groups, such as Asians, African Americans, Europeans, Hispanics, and American Indians, may continue to use their traditional healthcare practices (Spector, 2013). They may not share this information with nurses or healthcare providers, both out of respect and in fear that they will be told not to use these methods. Recognizing and supporting use of traditional practices along with Western medicine can promote health and provide comfort for children and families. Ask the families about the use of traditional, complementary, or alternative therapies. Examples include herbal remedies, healers, acupuncture, prayer, and hot and cold foods.

Teaching the child and family, providing support, and referring them to community resources are key elements in providing family-centered care. Additional resources available for the child and family include social workers, child and family mental health professionals, and advanced practice nurses. Additionally, hospital programs and parent support groups are available to assist families in coping with a child's illness.

Nurse's Role in the Child's Adaptation to Hospitalization

Hospitalization of the child may be planned or unexpected. A child may be hospitalized for any of the following reasons:

- The child develops an acute illness or exacerbation of chronic illness.
- The child requires diagnostic or treatment procedures or requires elective surgery.
- The child who was previously healthy suffers an injury, necessitating unexpected hospitalization.

Planned Hospitalization

When hospitalization is planned, children and their parents have time to prepare for the experience. Assess the family's knowledge and expectations and then provide information about likely experiences. A variety of approaches can be used to provide information and allay fears:

- Tours of the hospital unit or surgical area are helpful. This activity assists the child and family to become familiar with the environment they will encounter. During tours, preschoolers and school-age children can see and handle items

Figure 11–1 **The child's anxiety and fear often will be reduced if the nurse explains what is going to happen and demonstrates how the procedure will be done by using a doll. Based on your experience, can you list five things you can do to prepare a school-age child for hospitalization?**

SOURCE: Poznyakov/Shutterstock

with which they will come in contact. If a tour is not possible, photographs or a DVD can be used to demonstrate the medical setting and procedures.

- The surgical team's attire is less frightening if the child has a chance to try it on and engage in play while wearing the attire.
- Medical equipment is not as frightening when the child learns what it does and observes how it is used—for example, through demonstration on a doll (Figure 11–1).
- Puppets and skits can be used to help explain procedures to children.
- Offer health fairs, as many hospitals do, to explain healthcare procedures to children. During a tour, while hospitalized, or at home, the child can be exposed to books or media that explain in age-appropriate terms what to expect during various procedures.
- Reinforce teaching through coloring books or other educational materials.

Different approaches may be more effective in helping adolescents prepare for hospitalization. In addition to written materials, models, and DVDs, adolescents also learn from talking with peers who have had similar experiences. To demonstrate respect for their sense of independence and privacy, offer adolescents an opportunity to ask questions without their parents present.

Include the family in preparing the child of any age for hospitalization. Parents can be instrumental in preparing a child for hospitalization by reviewing material presented, being available to answer questions, and being truthful and supportive (Tables 11–4 and 11–5).

Unexpected Hospitalization

An unanticipated admission places the child at emotional risk for several reasons, including:

- Lack of preparation for the experience
- Uncertainty and unpredictability of events that follow
- Unfamiliarity of the environment
- Heightened anxiety of the child's parents

An admission for exacerbation of a disease, such as cystic fibrosis or leukemia, can provoke feelings of depression or hopelessness. See Chapter 12 for information related to coping with chronic illness.

Assist the child and family who are not prepared for hospital admission to adapt to the experience by orienting them to the environment, providing an opportunity for questions, offering truthful responses, and explaining all procedures and expectations. Discuss the anticipated plan of care for the child and involve the family in the child's care. Give the family an opportunity to express their fears and concerns. Refer to social services and/or parent support groups if additional support is needed.

TABLE 11–4 Parental Preparation of Children for Hospitalization

The nurse can assist the parents in preparing the child for hospitalization by suggesting the following interventions:

- Read stories to the child about the experience. Numerous books and pamphlets are available (see Table 11–5).
- Talk about going to the hospital and what it will be like. Talk about coming home.
- Encourage the child to ask questions about the hospital and surgery.
- Encourage the child to draw pictures of what the hospital will be like.
- Visit the hospital unit before hospitalization if possible.
- Let the child touch or see equipment if possible.
- Provide a doctor or nurse kit for the child to play with.
- Provide clothing so the child can dress up like a nurse or healthcare provider if desired.
- Plan for support via parents' presence, telephone calls, and special items belonging to the parents that child can keep during the stay.
- Be honest.

Nursing Care of the Hospitalized Child

Family-centered nursing care of the hospitalized child focuses on promoting the child's and family's coping strategies to deal with the stressors of hospitalization, promoting optimal development and safety and minimizing disruption of the child's usual routine as much as possible.

Special Units and Types of Care

Children admitted to a hospital may be cared for in one or more of the following units: general pediatric unit, short-stay unit, outpatient unit, ambulatory surgical unit, emergency department, or pediatric intensive care unit. Hospitalized children may require surgical treatment involving preoperative and postoperative care. Children with infectious diseases require isolation precautions. Other children may need rehabilitative care to achieve or restore maximum potential.

GENERAL PEDIATRIC CARE UNIT

Smaller facilities typically incorporate all pediatric care specialties in one unit or area, whereas larger medical centers and children's hospitals have separate medical units for different specialties. Specialized units may include medical and/or surgical units, orthopedic units, oncology units, mental health units, and units specific to developmental levels (e.g., adolescent unit). Admission to a specialized unit may be the result of an acute condition, such as pneumonia or trauma, or the result of an exacerbation of a chronic condition, such as asthma. Other causes for admission include surgical procedures requiring longer than a 24-hour stay and the need for inpatient treatments and services. Nursing care for regular hospital admission includes orienting the child and family to the unit and procedures, adhering to the child's normal routine as much as possible, including both the child and the family in the decision-making process, providing direct care to the child, promoting a safe environment for the child, and promoting the child's growth and developmental needs.

SHORT-STAY, OUTPATIENT, AND AMBULATORY SURGICAL UNITS

Hospital stays for children have generally become short, with many procedures being performed in outpatient units such as minor surgery (in ambulatory surgical centers), diagnostic tests (such as cardiac catheterizations), radiology studies requiring sedation, and treatments (such as chemotherapy). The child may be admitted in the morning and discharged that afternoon. In addition, children who have potentially serious illnesses may be placed on a short-stay or observation unit for monitoring or limited treatment, after which medical staff decide either to hospitalize the child for additional treatment or, if improvement occurs, to discharge the child. These short stays are considered beneficial primarily because they cause minimal disruption of family patterns and are cost effective for the institution, health insurance company, and family. Nurses assist parents to prepare the child properly for planned admissions, monitor the child during the procedures, encourage family participation in care, and keep families well informed (Table 11–6).

Nursing care of the child in short-stay, outpatient, and ambulatory surgical units is the same as for regular hospital admission. However, time for teaching is compressed, requiring the nurse to implement teaching methods in a minimal amount of time to ensure the family understands discharge instructions.

TABLE 11–6 Nursing Considerations When Preparing Parents and Child for Planned Short-Stay Admission

- Are there special requirements prior to arrival, such as not being permitted food or drink or needing extra fluid intake?
- At what time and where must the child arrive?
- Are any special forms, insurance numbers, or previous records needed?
- How long will the child stay in the hospital?
- Can the child bring something familiar from home such as a blanket or stuffed animal?
- Are parents expected or encouraged to be with the child or stay in the health facility?
- Is there a chance the child may need to remain longer than expected?
- What will the child's condition be for discharge home?
- Will special equipment or care be needed?
- What symptoms can indicate problems?
- Where can the family go or whom can they call in case of problems or questions?

Effective teaching methods on this accelerated schedule include demonstration, videos, pamphlets with verbal review, and informal teaching sessions.

EMERGENCY CARE

When a child is brought to an emergency department, the parents are usually frightened and insecure and may even be in a state of shock. The fast pace and critical nature of the unit creates an atmosphere in which parents are hesitant to ask questions and are anxious about the outcome. Many factors can contribute to the parents' anxiety and stress (see Chapter 13), including the unexpected nature of the situation; uncertainties in the emergency

Clinical Reasoning Preparing Children for Hospitalization or Short-Stay Surgery

Six-year-old Kate has had several nosebleeds and fainting spells recently. After examination by her healthcare provider and a number of diagnostic studies, such as chest x-ray examination, echocardiography, and electrocardiography, coarctation of the aorta is diagnosed. Kate will come in this week for a cardiac catheterization. She is scheduled to have open heart surgery in 2 weeks.

Kate has had few health problems, and her experiences with healthcare professionals are limited. Her parents, who are anxious about the heart surgery, are concerned about how their daughter will adapt to hospitalization.

How should you prepare Kate for the cardiac catheterization and later for the surgery? Include knowledge of her developmental stages and cognitive understanding in your planned intervention approaches. How far in advance should teaching take place? What teaching aids are helpful? How can Kate's parents be involved in and reinforce the teaching? What kind of support do her parents, siblings, and friends need during hospitalization?

Professionalism in Practice Parental Presence During Procedures and Resuscitation

The Emergency Nurses Association (ENA) (2012) recommends that family members be allowed to be at the bedside during invasive procedures and resuscitation following the written policy of the institution. The clinical practice guideline developed by the ENA recommends that a healthcare professional be designated for explanations and support for the family. During development of the guideline, research by the ENA concluded that family presence during invasive procedures and resuscitation is not detrimental to the patient, family, or healthcare professionals. The ENA also concluded that development of a written policy can provide some structure and support for the healthcare team.

Parents who wish to remain with a child even during invasive procedures or resuscitation efforts should be allowed to do so. The nurse collaborates with the family members to determine their desired presence in critical situations and keeps them informed about the health care provided.

Figure 11–2 Rehabilitation units provide an opportunity for the child to relearn tasks such as walking and climbing stairs. They provide an important transition from hospital to home community.

SOURCE: CandyBox Images/Shutterstock

environment; the necessity for quick decision making; the need for numerous procedures, tests, and treatments; and fear of pain. The nurse keeps both the child and the family informed about what is being done and when more news may be available. The parents and child are encouraged to remain together as much as possible (see Chapter 13).

INTENSIVE CARE UNIT

Intensive care units provide nursing care to infants and children, including children with life-threatening illnesses and injuries, acute exacerbations of chronic illness (such as severe or life-threatening asthma exacerbation), or any other condition requiring advanced support and continuous monitoring (see Chapter 13). Parents of a critically ill or injured child admitted to the pediatric intensive care unit (PICU) experience high levels of stress (Ames, Rennick, & Baillargeon, 2011). They are likely to be anxious, particularly since the child's condition may be severe and the prognosis may be guarded. The unfamiliar equipment may create an atmosphere of fear or anxiety. Numerous healthcare professionals work in the intensive care environment, and without effective and open communication, parents may not know whom to question or even what questions to ask. Partner with the family and encourage them to write down their questions and direct them to the appropriate source if you are unable to answer the question.

ISOLATION

Children who require isolation to prevent spread of infection may experience lack of stimulation due to limited contact with other children and visitors. Frequent family visits are important and should be encouraged. Family members may be reluctant to wear protective garments either out of fear of using them incorrectly or because they believe they are unnecessary. The nurse ensures that the family understands the reason for isolation and any special procedures. Having contact with and holding the child are encouraged when possible.

REHABILITATION

Rehabilitation is the process of assisting a child with physical or mental challenges to reach full potential through therapy and education. Rehabilitation units provide children with ongoing care and support to continue recovery beyond the initial period of illness or injury (Figure 11–2). These may be separate units within a hospital or independent centers. The objective of rehabilitation is to assist children with physical, psychosocial, or educational challenges to reach their fullest potential and to promote achievement of developmentally appropriate skills. Collaboration with a multidisciplinary team including parental involvement is essential.

Parental Involvement and Parental Presence

Family members are essential to the child's care during illness. Integrity of the family unit is fostered through parental involvement during the child's hospital stay. Involvement provides parents with control and a feeling that they are active participants in their child's progress, and it also prepares the family for care that will be required when the child goes home. The child benefits greatly from parental presence and participation and experiences less emotional distress and anxiety if the parents are present (see *Developing Cultural Competence: Support Systems*). If the parent–child attachment remains uninterrupted, the child experiences fewer behavioral maladjustments.

A positive relationship between the parents and the healthcare team is an essential component of family-centered care. Parental satisfaction is enhanced when parents' questions about their child's care and condition are answered; when the healthcare team is kind, caring, and takes experiences of parents seriously; and when prompt and consistent care is provided (Fisher & Broome, 2011). Parents need to feel valued. Romaniuk, O'Mara, and Akhtar-Danesh (2014) found a significant difference in parents' desires to participate in their child's care and their actual level of participation. Parents indicated that they wanted to be more involved in the care of their child, especially in activities related to being an advocate for their child. The nurse should partner with the family to determine the extent to which parents desire to be involved in the child's care.

PREPARATION FOR PROCEDURES

Hospitalized children may experience numerous procedures during hospitalization, from collection of urine or blood specimens to lumbar punctures and surgery. Fear of the unknown increases the child's anxiety. Maintain a positive attitude when preparing the child and reassure the child that it is normal to be frightened of unknown experiences. Special techniques can help the child understand and cope with feelings about these procedures. Techniques used to prepare the child depend on developmental age, coping abilities, and previous experience.

Developing Cultural Competence **Support Systems**

Culture can have a significant influence on health beliefs and practices. For example, Mexican Americans view family as a strong support. Extended family may want to be with a hospitalized child. The father of the child is often the spokesperson, and mothers commonly are influential in decisions regarding child health care. The nurse should incorporate all the people the family wishes to have present in the hospital and include them in explanations about health care.

PSYCHOLOGIC PREPARATION

Preparation may begin a few moments to several days before the procedure, depending on the child's age and developmental level. In providing sensitive care to the child, nurses assume that a procedure can potentially be traumatic for the child. Even providing urine in a specimen cup or undergoing radiologic examination can be frightening if the child does not understand the reason for the procedure or know what to expect. Administration of medication can also make the child frustrated or anxious. When preparing the child for medication administration using techniques appropriate to the developmental level of the child, the nurse ensures that the medication is safely given (see Table 11–7).

Use developmentally appropriate techniques to assess the child's knowledge and feelings about an upcoming procedure. For example, with a school-age child, the nurse might explain the procedure using drawings, stories, body outline dolls, anatomically correct dolls, and conversation. When assessing the child's perception about procedures, the nurse should consider the following:

- Does the child know the purpose of the procedure?
- Has the child experienced this procedure before? If so, was the experience painful, frightening, or reassuring?
- What does the child think will happen? Are the child's beliefs accurate?
- Is the procedure painful?
- What techniques does the child use to gain control in challenging situations?
- Will the parents or other caregiver be present to provide support?

When explaining a procedure and its purpose, use words that the child understands. Older children require explanations geared to their cognitive level and previous experiences. They will want to know what is happening, why, and what they can do to cope during the procedure (see Table 11–8).

Figure 11–3 **Health facility policies that permit parents to be present during a procedure performed on their child are an example of a family-centered care policy. The parent plays an important role in providing security and comfort to this child who is having blood drawn.**

For adolescents, provide written information, DVDs, and other available media. Schedule time for questions and discussions. Allow adolescents to make choices about their own health care when possible. For example, ask them to make those choices with questions such as, "Do you want your hand numbed for the IV start?" Maintain a positive attitude when preparing adolescents and reassure them that it is normal to be frightened of unknown experiences.

Parental presence can provide comfort and support to the child during procedures. Parents should be allowed to choose whether they want to stay for the procedure (Figure 11–3). Some parents may feel that they will be too upset to support the child; many choose to stay. Some adolescents want their parents to be involved in their care; others prefer to minimize their parents' roles. Partner with the adolescents to ensure that their wishes are known regarding parental presence.

PHYSICAL PREPARATION

Physical preparation depends on the age of the child and the procedure. Preprocedural sedation may be required. If sedation is required, the child will not be able to have anything by mouth (NPO) for a period of time. Young infants might be provided sucrose for procedures (see Chapter 15 for pain management). Procedural checklists are often utilized.

Performing the Procedure

Procedures on young children are generally performed in a **treatment room** (a room designated for performing treatments such as intravenous starts, blood draws, and lumbar punctures) to promote the children's sense of security that their own room is a "safe" and relatively pain-free site unless this is contraindicated, such as in the presence of skeletal traction or isolation. Older children can be given the option of having a procedure performed in the treatment room or in their own hospital room. Older school-age children and adolescents may prefer to remain in their room for the procedure.

Perform the procedure as quickly and efficiently as possible. If the parents wish to participate, ask them to hold the child's

TABLE 11–7 Variations in Medication Administration to Children

ROUTE	DEVELOPMENTAL CONSIDERATIONS	TECHNIQUES
Oral	Children under 5 years cannot generally swallow pills and capsules. Children may not want to take medicine.	• Medications are usually given in liquid form (e.g., elixir, syrup, or suspension). • Sometimes tablets are crushed or capsules are opened and mixed with a small amount of food. Check with pharmacy to be sure this does not inactivate the drug. Never crush enteric-coated or timed-release medicine. • When choosing a vehicle for crushed tablets, use only 1 spoonful of applesauce, pudding, jelly, or similar food or 1–2 mL of liquid so that it is easier to ensure that the entire dose will be taken. • Use an oral syringe to increase accuracy when administering a liquid medication. • Position young children upright to avoid choking and aspiration. • Give liquid medicines slowly by oral syringe (for infants) aimed at the inside of the cheek or by medicine cup (for toddlers and preschoolers) for drinking. • Communicate with the child that you expect that the medicine will be taken. Let children choose the type of fluid to drink after, but do not ask if they will take their medicine now.
Rectal	Colon is small in size.	• Lubricate the tip of the suppository before placement. • Place the suppository at the rectal opening and advance past the sphincter. • For children younger than 3 years, the nurse's gloved fifth finger is used for insertion. After this age, the index finger can usually be used.
Ophthalmic and otic	Young children may be fearful of medicines placed in the eyes or ears.	• Adequate immobilization is needed to avoid injury. • The nurse's hand can be stabilized by resting the wrist on the child's head. • Explanations and therapeutic play can be used with children old enough to explain the process of administration. • Have medication at room temperature.
Topical	Skin of infants is thin and fragile.	• Only prescribed doses and medicines appropriate for young children should be used on the skin. • Covering the area or keeping the child's hands occupied may be necessary to ensure adequate contact of medication with the skin.
Intramuscular	Anatomy and physiology of children differ from those of adults.	• The gluteus maximus muscle (dorsal gluteal site) is not recommended in children because of danger of injury to the sciatic nerve (Engorn & Flerlage, 2015). • The vastus lateralis site is preferred for children. • The deltoid muscle is rarely used in young children except for the small amounts injected in some vaccines. • Amounts to be administered should be limited to no more than 1–2 mL for ventrogluteal and vastus lateralis sites and 0.5 mL for deltoid depending on muscle size. Refer to the *Clinical Skills Manual* SKILLS for illustrations. • Z-track technique (retracting tissue to the side and releasing it after injection to prevent seepage into tissue) is often used.
Intravenous	Veins are small and fragile. Fluid balance is critical.	• Careful maintenance of sites is needed. • Common infusion sites include hands and feet, although scalp veins are sometimes used in infants. • Infusion pumps require frequent monitoring. • Syringe pumps are often used to administer medications when minimal fluid is to be given. • Central lines are commonly used for long-term intravenous medication therapy.

Note: See *Clinical Skills Manual for Maternity and Pediatric Nursing, Fifth Edition*, for further medication administration techniques. See Appendix F for information related to how drug dosages are determined for children.

Source: Bindler, R. C., Ball, J. W., London, M. L., & Davidson, M. R. (2017). *Clinical skills manual for maternity and pediatric nursing* (5th ed., p. 106). Hoboken, NJ: Pearson.

hand or stand close by for comfort. Utilize nursing staff instead of parents to immobilize the child as needed. The parents, or another nurse, can be designated to support the child by means of a gentle touch, talking, singing, giving reassurance, or illustrating stress-reduction techniques.

After the procedure, no matter how the child responded, the child should be praised. A choice of reward often soothes the young child. If the procedure is performed in a treatment room, the child is returned to the room for comfort and reassurance.

TABLE 11–8 Assisting Children Through Procedures

DEVELOPMENTAL STAGE	BEFORE PROCEDURE	DURING PROCEDURE
Infant	None for infant. Explain to parents the procedure, the reason for it, and their role. Allow parents the option of being present for procedures. Parents may be able to touch a foot, rub a cheek, and talk soothingly to the infant.	• Nursing staff should immobilize the infant securely and gently. Parents should not be asked to hold the child down. • Perform procedure quickly. Use touch, voice, pacifier, and bottle as distractions. • Ask parent to hold, rock, and sing to infant after procedure.
Toddler	Give explanation just before procedure, since toddler's concept of time is limited. Explain that child did nothing wrong; the procedure is simply necessary.	• Perform in treatment room. • Nursing staff should immobilize the child securely. • Give short explanations and directions in a positive manner. • Avoid giving choices when none is available. For example, "We are going to do this now" is better than "Is it okay to do this now?" • Allow child to cry or scream. • Comfort child after procedure. Give child a choice of favorite drink, if allowed, or special sticker.
Preschool child	Give simple explanations of procedure. Basic drawings may be useful. While providing supervision, allow the child to touch and play with equipment to be used, if possible. Since any entry into the body is viewed as a threat, state that the child's body will remain the same, and use adhesive bandages to reassure the child that the body is intact and parts will not "fall out."	• Perform in treatment room. Nursing staff should immobilize the child securely. • Give short explanations and directions in a positive manner. Encourage control by having the child count to 10 or spell name. • Allow child to cry. Give positive feedback for cooperation and getting through procedure. • Encourage the child to draw afterward to explore the experience.
School-age child	Clear, thorough explanations are helpful. Use drawings, pictures, books, and contact with equipment. Teach stress-reduction techniques such as deep breathing and visualization. Offer a choice of reward after procedure is completed.	• Be ready to immobilize the child if needed. Allow child to remain in position by self if child is able to be still. • Explain throughout procedure what is happening. • Facilitate use of stress-control techniques. • Praise cooperative efforts.
Adolescent	Give clear explanations orally and in writing. Teach stress-reduction techniques. Explore fear of certain procedures, such as staple removal or venipuncture.	• Assist adolescent in self-control. Assist with use of stress-control techniques. • Explain expected outcome and tell when results of test will be completed.

Refer to Chapter 15 for discussion of pain management and sedation for procedures.

Preparation for Surgery

A child's surgical experience may be elective, planned in advance, or the result of an emergency or trauma. How a child responds to the experience is related to the psychologic and physical preparation the child receives. Preoperative preparation, including familiarization with the environment and equipment and explaining surgical procedure, can decrease anxiety in both the child and the parent (Healy, 2013). The accompanying nursing care plan provides information related to care of the child undergoing surgery. Additional nursing diagnoses include (NANDA-I © 2014):

- ***Infection, Risk for,*** related to exposure to hospital-acquired infection
- ***Injury, Risk for,*** related to exposure to hospital-acquired infection and use of preoperative medication
- ***Skin Integrity, Impaired,*** related to disruption of skin surface and limited mobility after surgery
- ***Constipation, Risk for,*** related to surgical procedure and anesthetics
- ***Fluid Volume: Imbalanced, Risk for,*** related to intravenous infusion and NPO status
- ***Gas Exchange, Impaired,*** related to anesthetics and pain

Nursing Care Plan: The Child Undergoing Surgery

1. Nursing Diagnosis: *Knowledge, Deficient,* related to preoperative and postoperative events (NANDA-I © 2014)

GOAL: The child and family will acquire knowledge related to the operation.

INTERVENTION	RATIONALE
• Ask questions of the parent and child about surgery.	• Prior knowledge and understanding can be reinforced and used to guide your presentation.
• Teach about preoperative and postoperative events using appropriate developmental methods such as dolls, drawings, stories, and tours.	• Developmental level determines the cognitive approach that works best for teaching.
• Reinforce information the family has received about the purpose of surgery.	• The healthcare provider may have explained operation.
• Have the children demonstrate postoperative events that pertain to their care such as deep breathing, putting bandage on doll, taping intravenous line on doll, and pressing patient-controlled analgesia button.	• Concrete experience promotes learning.
• Allow the parents and child to ask questions.	• Learners must have opportunity to ask questions.

EXPECTED OUTCOME: Child and family will be able to verbalize details about expected preoperative and postoperative events. They will ask questions that demonstrate understanding. Child will demonstrate skills needed in the postoperative period.

2. Nursing Diagnosis: *Anxiety* related to planned surgery (NANDA-I © 2014)

GOAL: The child and family will show decreased behavior indicating anxiety.

INTERVENTION	RATIONALE
• Question the child about expectations of hospitalization and previous experiences.	• Previous experiences can influence present anxiety level.
• Orient the child to the hospital setting, routines, staff, and other patients.	• Familiarity with the setting and people can decrease anxiety by removing unknown factors.
• Institute age-appropriate play and interactions with the child.	• Play can increase trust level and decrease anxiety.
• Explain procedures and prepare for those that might cause trauma. Encourage parents to support the child.	• The child is more likely to trust healthcare providers if they are truthful and if parents are present.
• Allow the parents and child to ask questions.	• Questioning provides an opportunity to explain the unknown, which decreases anxiety.

EXPECTED OUTCOME: Child and family will demonstrate less anxiety. They will verbalize understanding and comfort in hospital routines. Parents will support the child during traumatic procedures.

3. Nursing Diagnosis: *Pain, Acute,* related to surgical procedure (NANDA-I © 2014)

GOAL: The child will maintain an adequate comfort level.

INTERVENTION	RATIONALE
• Assess behavioral cues (e.g., crying, movement, guarding ability to participate in activities of daily living).	• Behavior of preverbal children provides clues to pain experience.
• Use an appropriate pain assessment tool for verbal and nonverbal children.	• An age-appropriate pain assessment tool allows verbal children to quantify the amount of pain. Pain assessment tools designed for nonverbal children allow the nurse to quantify the amount of pain when the child cannot provide a self-report. (See Chapter 15 for descriptions of a variety of pain assessment tools.)
• Administer prescribed pain medications around the clock.	• Narcotics and nonnarcotic analgesics alter pain perception.
• Use age-appropriate nonpharmacologic methods of pain control (e.g., distraction, repositioning, massage).	• Nonpharmacologic interventions interfere with pain perception and may decrease the child's anxiety.

(*continued*)

Nursing Care Plan: The Child Undergoing Surgery (*continued*)

EXPECTED OUTCOME: Child's pain will be controlled as demonstrated by a low number on the pain assessment tool (behavioral or verbal).

4. Nursing Diagnosis: *Knowledge, Deficient,* related to care at home (NANDA-I © 2014)

GOAL: The child and family will verbalize self-care required at home.

INTERVENTION	RATIONALE
• Provide oral and written home care instructions regarding surgical wound care, medications, activities, and diet.	• Teaching regarding home care is necessary early in hospitalization.
• Provide a number to call for questions or concerns. Instruct on follow-up visits.	• Parents need to know emergency information and that follow-up care is required.

EXPECTED OUTCOME: Child and family will demonstrate skills needed for home care following discharge. They will verbalize plans for future care.

PREOPERATIVE CARE

Preoperative care of the child includes both psychosocial and physical preparation for surgery. The goal of preoperative teaching is to reduce the fear associated with the unknown and decrease stress and anxiety associated with surgery.

Psychosocial Preparation. Preoperative teaching is geared to the child's developmental level. If child-life specialists are available, they can play an important role in preparing the child for surgery. When the child will be transferred to an intensive care unit or recovery room after surgery, a visit to the area before surgery can reduce the fear and anxiety associated with waking up in a strange environment filled with frightening sights, sounds, and smells. The use of DVDs, body outline dolls, anatomically correct puppets and dolls, drawings, and models is encouraged to teach the child about the surgical procedure (Figure 11–4). Playing with stethoscopes, gowns, masks, and syringes without needles also helps the child feel more in control (see discussion about dramatic play later in this chapter). Children are reassured that their parents can accompany them to the operating room floor and will be waiting when they awaken from surgery. Parents should be allowed to carry infants and young toddlers to the pediatric holding area or have them ride in one parent's lap in a wheelchair. Older toddlers and preschoolers should be allowed to ride in a special wagon if possible. Special teddy bears and blankets are generally allowed in the preoperative holding area and provide comfort to the child. The nurse should make sure that the item is labeled with the child's name. Prepare family members for what to anticipate and what is expected of them. Explain the purpose of special equipment such as intravenous setups and monitoring devices. In some hospitals, only one or two immediate family members are allowed to visit the child at one time. Visitors may be required to wear special gowns, shoes, or hats, and they may be restricted to certain areas.

Figure 11–4 **Showing young school-age children equipment that will be used in surgery will help to decrease anxiety related to the unknown. What are other methods the nurse can use to teach young school-age children about surgery?**

Parental Presence During Anesthesia Induction. Many hospitals now allow parents to be present with their child during anesthesia induction and again in the postanesthesia recovery area. Parents often want to support their child before and immediately after a surgical procedure, and their presence offers reassurance and comfort to the child. The decision to allow parents to be present during anesthesia induction must be made on an individual basis. The nurse explains expectations, such as surgical gown, cap, shoe covers, and the parent's role during induction. The nurse offers the parents an opportunity to ask questions and voice concerns.

Physical Preparation. Preparation for surgery may occur in designated preoperative areas. Procedures generally conducted in preoperative areas include premedication, intravenous start (if not performed following general anesthesia), and preparation of the surgical site. If urinary catheterization is necessary, it is usually not performed until the child has been anesthetized.

Preoperative procedures and guidelines vary among hospitals and outpatient surgical centers. Preoperative checklists, such as the sample shown in Table 11–9, are used in ambulatory and acute care settings to ensure proper physical preparation of patients for surgery. Weigh the preoperative child accurately, measure vital signs, and ask about last fluid intake amount and type. Monitor urinary output. NPO status in an infant and young child is distressing to both the child and the parents. Reinforce teaching regarding necessary NPO status and provide support to the family as needed.

Nursing management during the preoperative period includes establishing accurate baseline data, administering prescribed fluids, and performing assessments of fluid status. When an intravenous infusion is prescribed, start the infusion (see the *Clinical Skills Manual* SKILLS), ensuring that the type of fluid and flow rate match those that are ordered and that would be expected for the weight of the child.

TABLE 11–9 Preoperative Checklist

_____	Check that consent forms are witnessed and signed and in the patient's chart.
_____	Be sure the child's name band is in place.
_____	Be sure any allergies are prominently noted in the child's chart and on a special name band.
_____	Remove any prosthetic devices, including orthodontic appliances and body piercings.
_____	Check the child's mouth for loose teeth and tongue piercings.
_____	Remove eyeglasses, jewelry, and nail polish.
_____	Bathe and cleanse the operative site if ordered.
_____	Put the child in a hospital gown, allowing the child to wear underwear.
_____	Check that all special tests have been completed and the results are in the child's chart.
_____	Have the child void before surgery.
_____	Keep the child NPO before surgery.
_____	Give the child prescribed medications.
_____	Check vital signs and record on chart.
_____	Transport the child safely to the operating room.

Of necessity, the young child who undergoes surgery usually is restricted from consuming oral foods and fluids just before, during, and for a period after surgery, thus creating a risk of fluid imbalance. The length of time the child is kept without oral intake before surgery varies. Recommendations from the American Society of Anesthesiologists indicate that clear liquids may be given up until 2 hours before surgery, breast milk until 4 hours before surgery, and infant formula 6 hours before. Milk and a light meal may be consumed up until 6 hours before surgery (American Society of Anesthesiologists, Committee on Standards and Practice Parameters, 2011).

Infants will generally have very specific orders related to what time they should be made NPO for breast milk, formula, and clear liquids. This time will depend on what time the infant is scheduled for surgery. Because children beyond infancy do not usually eat or drink during the night, orders are usually written for NPO after midnight. However, if surgery is not scheduled for the morning, more specific orders should be written, especially for the toddler and preschool-age child, who will not be as tolerant of an extended NPO status. The ultimate decision on how long the child is NPO lies with the anesthesiologist. Sometimes, because of emergencies, planned surgeries for infants and young children may be postponed for several hours. These children are NPO and generally do not have IV access. What action should the nurse take in this case?

POSTOPERATIVE CARE

Postoperative care of the child includes both physical and psychologic care. In the immediate postoperative period, the nurse should perform baseline monitoring of vital signs according to hospital protocol, maintain effective airway clearance and monitor for evidence of respiratory depression or distress (see Chapter 20), evaluate the child's level of consciousness, evaluate the surgical site for evidence of drainage or bleeding, and record urine output and output from drainage tubes. The nurse should also examine the postoperative orders and ensure that the child receives the correct type and amount of intravenous fluid prescribed. In addition, the nurse should provide comfort and pain relief (see Chapter 15).

Resumption of oral intake depends on the surgical procedure, the child's condition, and surgeon protocol. Once oral fluids are resumed, the nurse should monitor for emesis. When the child is consuming adequate fluids, the rate of intravenous fluids should be decreased or discontinued according to healthcare provider orders.

Parents are encouraged to visit with the child as soon after surgery as possible (Figure 11–5). In some facilities, children are brought to postoperative anesthesia care units (PACUs) after surgery, where they recover from anesthesia. Depending on the child's condition, the child may be discharged home directly from an outpatient surgical procedure or admitted to a short-stay, general pediatric, or intensive care unit.

POSTOPERATIVE HOME CARE INSTRUCTIONS

Routine postoperative instructions for the family of the child undergoing outpatient or 1-day-stay surgical procedures include monitoring for signs of infection such as drainage, redness, or swelling of the surgical incision, fever, and change in behavior. Instructions for follow-up visit, medications, other treatments, wound care, and signs and symptoms that require medical attention are also provided. Additional instructions are tailored according to the surgical procedure and the child's condition. The nurse ensures the family understands home care instructions through their return demonstration statement of understanding.

Figure 11–5 This child has just undergone surgery and is in the postanesthesia care unit. Although the child's physical care is immediate and important, remember that both the child and the family have strong psychosocial needs that must be addressed concurrently. It is important to reunite the family as soon as possible after surgery.

Strategies to Promote Coping and Normal Development of the Hospitalized Child

During hospitalization, care of the child focuses not only on meeting physiologic needs, but also on meeting psychosocial and developmental needs. Nurses can employ several strategies to help children adapt to the hospital environment, promote effective coping, and provide developmentally appropriate activities, such as rooming in, child-life programs, therapeutic play, and therapeutic recreation.

Rooming In

The practice of **rooming in** involves a parent staying in the child's hospital room during the course of the child's hospitalization. Some hospitals provide cots, others have special built-in beds on pediatric units, and, in some institutions, a parent is provided a separate room on the unit. Parents who stay at the bedside usually want to help care for their child to some degree. Most parents are comfortable providing basic care to their child, such as feeding and diapering, while parents of chronically ill children might be comfortable participating in more technical aspects of care (Romaniuk et al., 2014). Communication between the nurse and family is important so that the parents' desire for involvement is understood and supported.

Rooming in provides the child with the comfort and security of parental presence. Some parents may feel more comfortable staying with their child and participating in care, others may experience more stress if they are missing work and are away from home and other children. Partner with the parent to assist them in establishing a rooming-in plan that is beneficial to both the child and family. For example, in longer hospital stays, parents may alternate turns staying with the child. Grandparents, aunts and uncles, and grown siblings may be included in the plan.

Some facilities offer free or reduced-cost meals to the parent rooming in. The parent who does not receive these meals may often skip many meals because of the financial impact on an already overburdened budget related to illness and hospitalization. The nurse should be alert to the parent who never leaves the bedside and should make sure parents are eating. Emphasize the importance of the child's need for a healthy parent. Social services or other departments may be able to assist the family in obtaining meals while rooming in with the hospitalized child.

Parents rooming in with their child for an extended hospitalization can be encouraged to take advantage of facilities such as the Ronald McDonald House or other housing available for parents, at some point during the stay, as a respite for a few hours. This break will provide them with an opportunity for needed rest and privacy.

Child-Life Programs

Many hospitals have child-life programs that focus on the psychosocial needs of hospitalized children. Professional child-life specialists, paraprofessionals, and volunteers staff these departments (Figure 11–6). A **child-life specialist** plans activities to provide age-appropriate playtime for children either in the child's room or in a specialized playroom. Some of the planned activities are designed to assist children in working through feelings about illness. Examples include playing with medical equipment, acting out procedures or treatments on dolls, using games to act out feelings, or drawing pictures about hospital treatments.

Therapeutic Play

Play is a significant component of childhood, and the stress of illness and hospitalization increases the value of play. Yet, because of the need to contain costs, hospitals may minimize their play programs. Therefore, nurses should document the need for and

A

B

Figure 11–6 *A,* Volunteers such as this grandmother can provide stimulation and nurturing to help young children adapt to lengthy hospitalizations. *B,* Child-life specialists plan activities for young children in the hospital to facilitate play and stress reduction.

benefits of play. Beyond facilitating normal development, play sessions can provide a means for the child to:

- Learn about health care
- Express anxieties
- Work through feelings
- Achieve a sense of mastery or control over frightening or little-understood situations

Play that presents an opportunity to deal with the fears, concerns, and stressors of health experiences is called **therapeutic play**. Therapeutic play has many benefits for both the child and the health professional. It allows the child an opportunity to relive, understand, and integrate fearful healthcare experiences. The child can achieve a sense of mastery by being in control of the occurrences during play. This helps lower the child's stress and anxiety about the events. In addition, the healthcare professional can observe the child's play to learn more about the type of events that cause anxiety to the child. The child's coping methods can be observed and additional techniques offered to the child. *Play therapy* is a mental health technique used to treat children with mental health problems rather than normal life events that have caused anxiety. This technique is discussed in Chapter 28.

Through therapeutic play, children's knowledge of their illnesses or injuries can be assessed. A common technique involves using an outline drawing of the body (Figure 11–7) or having the child draw a picture about the hospitalization. Drawings can be used to determine what the child knows and understands about the hospitalization. In addition to assessment, drawing can be used as a nursing intervention. Demonstrate to the child on a drawing what will occur during surgery or a treatment. Children's drawings of healthcare experiences allow them to express fears and gain mastery over the situation.

Dramatic play, in which medical situations encountered are reenacted by the child, often helps the child cope with painful treatments and intrusive procedures. Play using safe medical equipment, such as bandages and syringes without needles, and providing scrubs and uniforms for dress-up are effective materials for encouraging dramatic play. Dramatic play offers an outlet for anxiety in children who are trying to deal with stressful and confusing situations. At the same time, these activities allow the nurse to observe and assess the child's perception of the illness and procedures. The nurse is then able to clarify any of the child's misconceptions.

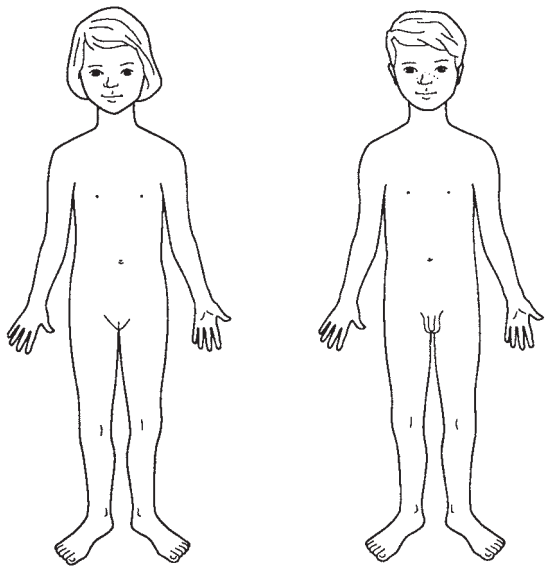

Figure 11–7 **The nurse can use a simple gender-specific outline drawing of a child's body to encourage children to draw what they think about their medical problem. Such drawings reveal a child's interpretation, which the nurse can work with to provide appropriate care.**

A variety of techniques may be used to promote therapeutic and dramatic play (Table 11–10), depending on the child's developmental stage. The nurse can ensure that a selection of age-appropriate toys, distraction materials (stress balls, bubbles, music), and "prizes" are available.

Many hospitals, particularly children's hospitals, provide playrooms on each of the units to allow children a place to play and socialize with same-age peers. These rooms are generally brightly decorated in children's themes, and provide numerous opportunities for play, such as board games, video games, supplies for painting or drawing, and age-appropriate toys for each developmental level. For younger children, families may be encouraged to bring the child's favorite age-appropriate toys from home. For older children, there may be options for computer communication with children in other hospitals. Portable electronic gaming equipment may be available to children in isolation or those unable to come to the playroom or teen lounge. Specific interventions according to developmental level are discussed next.

INFANT

Infants require external stimuli for growth. The use of mobiles, music, mirrors, and other methods promotes stimulation and offers comfort to the newborn or infant. Parents and family are encouraged to cuddle or rock the infant and sing lullabies. Talking to the infant encourages interaction and play.

TODDLER

Approach toddlers slowly and make the initial approach in their parents' presence, if possible, to decrease feelings of stranger anxiety. Playing a variation of peek-a-boo or hide-and-seek using the curtain surrounding the toddler's crib or bed helps promote the realization that objects out of sight, such as parents, do return. Transitional objects, such as a familiar blanket or stuffed animal, can temporarily substitute for the security of parents. The toddler can be read familiar stories. Repetition of stories promotes a sense of stability in the unfamiliar hospital environment.

A doll is a familiar toy that can be used to re-create a stressful environment, thereby providing an opportunity for the child to express and work through feelings. Children's hospitals may have condition-specific and anatomically correct dolls for this purpose. Other developmentally appropriate toys for toddlers include familiar objects from home such as measuring cups or spoons, wooden puzzles, building blocks, and push-and-pull toys. Playing with safe hospital equipment helps toddlers overcome the anxiety associated with these items. Supervise these play sessions and remove hospital equipment when you leave.

PRESCHOOLER

The nurse can intervene to reduce the stress produced by preschoolers' fears through the use of some kinds of play. A simple outline of the body or a doll can be used to address the child's

TABLE 11–10 Therapeutic Play Techniques

TECHNIQUE	ASSESSMENT	INTERVENTIONS
Stories	Have the child make up a story about a picture. Analyze content and emotional clues in the story. Have the child tell a story about an important experience in a group of other children.	Read or make up stories to explain illness, hospitalization, or other specific aspects of health care. Emotions such as fear can be included.
Drawings	Ask the child to draw a picture about being in the hospital. Consider subject matter, size, and placement of items in drawings, colors used, presence or absence of physical barriers, and general emotional feeling.	Use the child's drawings or outlines of the body to explain care, procedures, or conditions. Provide an opportunity for children to draw pictures of their choice or directed topics such as a picture of the child's family or healthcare encounter. Ask the child: "Tell me about your picture." Be alert to the child's emotions: "This child must be frightened by the big x-ray machine."
Music	Observe types of music chosen and effects of played music on behavior.	Encourage parents and children to bring favorite music to the hospital for stress relief. Have music playing during tests and procedures. Parents can tape their voices to play for infants and young children during separations. During longer hospitalizations children can tape messages for siblings or classmates, who are then encouraged to retape their responses. Playtime can include the opportunity to play instruments and sing.
Puppets	The puppets can ask questions of young children, who are often more likely to answer the puppet than a person.	Perform short skits to teach children necessary healthcare information. Include emotional content when appropriate.
Dramatic play	Provide dolls and medical equipment, and analyze the roles assigned to dolls by the child, the behavior demonstrated by the dolls in the child's play, and the apparent emotions. Dolls with health problems like those of the child are especially helpful.	Provide dolls and equipment for play sessions. To ensure safety, supervise closely when actual equipment is used. Respond to emotions and behavior shown. Use dolls and equipment such as casts, nebulizer, intravenous apparatus, and stethoscope to explain care. Use dolls with problems or handicaps similar to those of the child when available. Provide toys that foster expression of emotion, such as a pounding board and indoor darts.
Pets	Provide animal-assisted therapy. Watch the interaction between child and animal.	Respond to emotions the child shows. Facilitate touch and stroking of animals.

Note: Additional techniques, such as sand or water play, may be appropriate in specific situations.

Figure 11–8 **Age-appropriate play will help the child adjust to hospitalization and care.**

fantasies and fears of bodily harm. Playing with safe hospital equipment may help preschoolers to work through feelings such as aggression (Figure 11–8).

Preschoolers prefer crayons and coloring books, puppets, felt and magnetic boards, play dough, books, and recorded stories. Preschoolers and older children often enjoy animal-assisted therapy. Some hospitals and units may have scheduled visits from pets, most commonly dogs. **Animal-assisted therapy (AAT)** is goal directed and individualized for each child while animal-assisted activity (AAA) may include visits to several children without specific goals. Both of these have positive benefits for hospitalized children (Goddard & Gilmer, 2015) (Figure 11–9).

SCHOOL-AGE CHILD

Although play begins to lose its importance in the school-age years, the nurse can still use some techniques of therapeutic play to help the hospitalized child deal with stress. School-age children often regress developmentally during hospitalization, demonstrating behaviors characteristic of an earlier state, such as separation anxiety and fear of body injury. Outlines of the body and anatomically correct dolls or condition-specific dolls can be used to illustrate the cause and treatment of the child's

Figure 11–9 **Hospitals may have animal-assisted therapy from specially trained animals to provide comfort and distraction during health care. Both the child and the dog seem to be smiling.**

Figure 11–11 **Having interaction with other hospitalized adolescents and maintaining contact with friends outside the hospital are very important so that the teenager does not feel isolated and alone.**

SOURCE: Cusp/Superstock.

illness (Figure 11–10). Use terms for body parts that are suitable for older children. Drawings provide an outlet for expression of fears and anger.

School-age children enjoy collecting and organizing objects and often ask to keep disposable equipment that has been used in their care. They may use these items later to relive the experience with their friends. Games, books, puzzles, schoolwork, crafts, tape recordings, and computers provide an outlet for aggression and increase self-esteem in the school-age child. The type of play used should promote a sense of mastery and achievement.

Therapeutic Recreation

Many of the special play techniques used with younger children are not suitable for adolescents, but adolescents do need a planned recreation program to help them meet developmental needs during hospitalization. Peers are important, and the isolation of hospitalization can be difficult. Telephone contact with other teenagers and visits from friends should be encouraged. Interactions with other teenagers at a pizza party, video game, or movie night or during other activities can help adolescents feel normal (Figure 11–11). Physical activities that provide an outlet for stress are recommended. Even adolescents on bed rest or in wheelchairs can play a modified form of basketball. Some hospitals provide a teen room or teen lounge with age-appropriate activities such as a pool table, video games, and computers.

The independence of adolescence is interrupted by illness. Nurses can provide choices for teenagers to assist them in regaining control. Providing adolescents options and encouraging them to choose an evening recreational activity can promote their feelings of independence.

Figure 11–10 **Having the child play with specialty dolls will help the child adjust. Such play helps the child realize what activities are possible.**

Strategies to Meet Educational Needs

Some hospitalizations are so brief that the absence of the child or adolescent from school and peers is of minimal concern. However, if hospitalization is expected to last longer than a few days or if the child's condition changes so that the child needs special school arrangements, the nurse should assess the effects of hospitalization on the child's education.

When an elective procedure occurs, encourage families to assist in the arrangement of the extended school absence with teachers. The child can then be provided with schoolwork to complete in the hospital or at home when capable. This minimizes educational deficits and future problems for the child. Pencils, paper, comfortable work areas, computers, and quiet work times are provided to meet the child's educational needs. Telephone calls, Internet connections, and live video conferencing with teachers can be arranged as needed.

Hospitals or rehabilitation units may have classrooms, teachers, and facilities to promote learning. The hospital teachers collaborate with the child's school teachers to ensure the child is meeting the educational objectives to avoid deficits upon return to school. Many school districts provide tutors or computer connections for students who are hospitalized or receiving home care for extended periods. Teachers can visit children at the hospital or at home. Parents are often pivotal in making arrangements to meet the child's educational needs, since they interact with the child, the school, and the healthcare team.

Nurses should also consider the social aspects of school and peers. Peers can be encouraged to visit a hospitalized classmate, send cards and letters, call on the phone, or communicate via the Internet. Classmates may even videotape a class session, allowing everyone the opportunity to send messages to the hospitalized child. When the child returns to school, information may be shared about the child's special needs. Maintain the child's and family's privacy by discussing with them the information needed by others, and obtaining written permission before disclosing any information. The hospital and school nurse often collaborate with each other, as well as the child and family, to plan for the child's needs. The child with chronic health problems or who requires long-term hospitalization has additional needs with regard to school. See Chapter 12 for information related to the child with a chronic condition in a school setting.

Growth and Development

For children who are given the opportunity to hear, touch, see a model or equipment, read, look at pictures, or even smell things like alcohol swabs, learning is more complete. This is particularly important for the school-age child in the stage of concrete operational thought, who must be able to manipulate material in order to learn.

CHILD AND FAMILY TEACHING

Teaching is an essential part of the nurse's role in care of hospitalized children and their families and begins with the initial contact between the family and healthcare providers. Teaching may be informal, as when the nurse integrates an explanation during routine care, or structured, as when the nurse plans and implements a formal teaching program.

Nurses emphasize to the family that most teaching will occur in informal sessions rather than in formalized programs. The family should be aware of the teaching process to encourage active listening and participation. Actively involve the family in the learning process to ensure their understanding. The nurse and family partner together to identify the family's learning needs and appropriate teaching method to best convey the information. Recall that family members may be at various cognitive and anxiety levels and therefore have needs for different types of teaching. Develop a plan with both the family and other healthcare professionals to facilitate learning among the child and family members.

Prior to implementing teaching for the child, it is essential to assess the child's developmental level. Teaching directed at parents must also be geared to their level of understanding. If English is not spoken or is the parents' second language, an interpreter may be necessary. If interpreters are needed to facilitate understanding, be sure they are contacted and are available for teaching sessions.

Depending on the information to be presented, teaching may use the cognitive, psychomotor, or affective domains of learning. Teaching that includes all three domains is more effective. Explanations or reading materials, including pamphlets, booklets, DVDs, and models, are tailored to a level the parent can understand. The choice of tools used varies depending on the child's diagnosis and available materials.

Timing is a critical factor in teaching. Parents and children are less receptive to teaching when they are preoccupied with stress or activities. Collaborating with the parents in scheduling specific times for teaching sessions may be helpful.

TEACHING PLANS

A teaching plan is a written plan that includes goals and expected outcomes, interventions needed to achieve the specified goals, and a method and time for evaluation of the expected outcomes. The teaching plan may also specify teaching methods and types of materials to be used. By developing a teaching plan, a nurse helps to ensure that all the necessary information is included and taught efficiently. Additionally, this written documentation of teaching allows for continuity of care between nurses and other disciplines. Multidisciplinary teaching plans provide clear communication for all healthcare team members in the teaching process.

The child's primary caretaker should be an active participant in the development and implementation of the teaching plan. The primary caretaker is most often a parent but may be a close family member (uncle, aunt, or grandparent). Before establishing a teaching plan, the nurse should assess the child's or parent's knowledge, skills, and feelings by considering the following questions:

- What does the parent/caretaker or child know about the health issue?
- What are the expectations of the child and family?
- What is the cognitive level or ability to learn?
- Is there a desire to learn?
- What previous experiences affect the learning experience, either positively or negatively?
- What previous interventions have been the most useful for the child and family?
- What resources are available to the parents, child, and nurse that enhance understanding of the health condition?
- Are there feelings or beliefs that might interfere with the learning process?
- What complementary care does the family use, and how does this relate to the teaching plan?

The second step involves deciding what knowledge, skill, or change in attitude is desired. Outcome criteria or objectives are established with the parent and child. Possible teaching methods and a range of approaches are explored. A variety of resources, including written materials (books, pamphlets, handouts, and stories), computer software, audiovisual presentations, dolls, and body models are available to encourage interest from the child and family. Refer to Chapter 1 for information on reading level of patient education materials. In some settings, audiovisual and computer resources may be limited. Small group teaching sessions (e.g., for children with recently diagnosed diabetes) may be another option and provide the child with an opportunity to interact and learn from peers experiencing the same condition. Gathering two or three parents together on a unit to learn and share experiences may also be helpful. For some conditions, standardized teaching plans are available in books and from healthcare agencies. These plans can serve as a guide in developing an individualized teaching plan.

TEACHING FOR CHILDREN WITH SPECIAL HEALTHCARE NEEDS

Children who have disabilities may have special learning needs. If the child has a visual impairment or perceptual difficulty,

material is presented in auditory and tactile ways. Children who have hearing deficits require visual and tactile presentations. Children who have learning disabilities may require more frequent reinforcement and shorter teaching sessions. These children are evaluated often for comprehension in order to adjust teaching as necessary.

Children who have chronic conditions or special healthcare needs may have been hospitalized numerous times and have received other health care at home and in the community. They usually have adapted coping mechanisms that help them deal with their illness. Nurses can talk with the child to determine what has helped in the past, provide information about what to expect during the current hospitalization, assign staff members who are familiar when possible, and follow each child's lead in assisting the child in coping. Do not assume that the child with a history of numerous hospitalizations understands all activities, for each hospitalization is different. Even the most routine activities should be explained. Regularly review the updated plan of care with the parents and child. Provide the child with opportunities to ask questions and express concerns and fears. Assess the child's individual learning needs. Older children can be asked how they best like to learn. Determine the necessity for special equipment or teaching methods.

Preparation for Home Care

Nurses play an important role in preparing the child and family for discharge home; this preparation starts early during the hospitalization. The nurse works with the social service department, home care agencies, and the family to plan for equipment, procedures, and other home care needs. Home care nurses collaborate with the hospital nurse and assist families to meet the child's healthcare needs.

Assessing the Child and Family in Preparation for Discharge

Preparations for the discharge process are best started upon admission to the hospital. The healthcare team, including the primary healthcare provider, nurse, social worker, and discharge planner partner with the family to ensure a smooth transition. Assess the family's ability to manage the child's care and if any special adaptation to the home environment is necessary.

When a child who has been hospitalized for an extended time is to be discharged home, the school district is contacted by the hospital school teacher (if available) or social worker, and plans for education or reentry into school are made. This involves an assessment of the child by the school district and formulation of an individualized education plan (IEP). The IEP may include home tutors, specialized services from persons such as physical or speech therapists, or arrangements for transport of the child with a disability to the school and provisions for special medical care as needed. An individualized health plan (IHP) may also be required. See Chapter 12 for definitions and a detailed discussion on IEPs and IHPs. Some common problems that interfere with successful discharge planning include financial concerns, the family's unavailability for teaching and planning, lack of equipment, and lack of teamwork among involved healthcare disciplines. Nurses who assess for these potential problems from the initial contact with the child and family can intervene and assist the family to resolve them as soon as possible.

Preparing the Family for Home Care

The family may need to learn physical and rehabilitative procedures for the child's care. Short-term care may be necessary until the child regains full function. In other situations, care may be required throughout the child's life. This may involve measuring vital signs or assessing blood glucose levels.

For the child requiring complex long-term care, parents may need to learn about intravenous lines, medications, oxygen administration, or ventilators (Figure 11–12). See Chapter 12 for discussion of the child with a chronic condition.

Parents need to be taught how to use the equipment needed for the child's care and must show that they can use it correctly. They must be able to identify symptoms of distress and report them immediately to the healthcare provider. The education provided and the parents' ability to perform care are discussed with a visiting nurse or individual who manages the home care program. Parents should be encouraged to learn cardiopulmonary resuscitation (see the *Clinical Skills Manual* SKILLS). Help parents explore options for respite care. If they cannot provide daily care or need a break, they should be able to rely on others for a short period. Some agencies are available to provide respite care. Ongoing assistance may be needed to help families deal with finances, time, and other challenges. If parents must take a leave of absence from work to provide care for the child, inform them about the coverage provided by the Family Medical Leave Act (U.S. Department of Labor, 2012).

Preparing Parents to Act as Case Managers

The family is an integral part of the plan of care for an ill or hospitalized child. The child with a chronic illness or an injury requiring long-term care will probably require the services of numerous healthcare personnel or healthcare agencies. One person needs to be identified as a **case manager** to coordinate health care and to prevent gaps and overlaps. In some hospitals, nurses act as case managers. They may organize a patient care conference while the child with a chronic condition is hospitalized. Management goals are set and decisions are made about which healthcare provider or agency is responsible for helping the child meet each goal.

Figure 11–12 **This child with chronic medical problems is being cared for at home. Are there any legal implications for the hospital and the nurse associated with the preparation of the child and family for home care?**

SOURCE: Karen Kasmauski/Corbis.

Parents can also be case managers. The parent as case manager coordinates medical care, hospital stays, and visits to specialists; meets with school district representatives to plan the individualized education program for the child; finds equipment, personnel, and other services for home care; and manages the child's overall care.

Nurses should strongly encourage parents who want to take over case management to do so. Help them learn the management skills required. Many community agencies such as social service or home health agencies hold workshops for parents managing the complex care of their children.

Chapter Highlights

- Hospitalization is a stressful event for all children and their families and affects families in a variety of ways, including disruption of usual routines, anxiety and fear related to the unknown, sibling concerns, financial difficulties, and parental anxiety over changing roles.
- The understanding of children about their illnesses and hospitalizations is based on cognitive and psychosocial stage/level and on previous healthcare experiences.
- Nurses assess the impact of the child's illness or hospitalization on the family unit and provide individualized family-centered care. Supporting rooming in by parents or other family members, promoting development and safety, minimizing disruption of routines, and orientation to special units and expectations are specific strategies that can be implemented.
- Families are always disrupted by a child's hospitalization, and various approaches can help them understand the process and cope more successfully. Specific examples include promoting parental involvement in care; orienting the child and family to the hospital setting, routines, and staff; age-appropriate explanations of procedures; and encouraging parents to support the child.
- When hospitalization is planned, both the child and family can prepare for the experience. Nurses assist this process by teaching them what to expect. Preparation may include tours, therapeutic play, books, and developmentally appropriate explanations.
- When hospitalization is unplanned, nurses can prepare the child and family by orienting them to the environment and use of developmentally appropriate explanations of procedures and equipment.
- A teaching plan includes goals and expected outcomes, interventions needed to achieve the specified goals, and a method and time for evaluation of the expected outcomes. How the teaching plan is implemented depends on the unique characteristics of the child/family to be taught.
- The child is prepared for procedures using a variety of techniques, taking into consideration the child's developmental age, coping abilities, and previous experience.
- Strategies such as child-life programs, rooming in, therapeutic play, and therapeutic recreation help meet the psychosocial needs of the hospitalized child.
- The nurse assists the family in planning for the child's long-term healthcare needs and home care issues. Culturally competent care is integrated throughout all provisions of care.

Clinical Reasoning in Action

Five-year-old Tiona has a history of frequent tonsillitis and was scheduled for a tonsillectomy and adenoidectomy (T&A). Following the operation, Tiona refused to drink liquids because she was afraid it would hurt when she swallowed. After receiving intravenous pain medication, Tiona realized that she could swallow without too much pain and began to eat popsicles and drink liquids. She was then switched to oral pain medication. Later in the day, Tiona was drinking liquids well enough to be discharged home.

1. What information should the nurse include in the discharge teaching plan for Tiona's mother?
2. As Tiona and her mother are preparing to leave the hospital, Tiona states, "I am going to be good so I do not have to come to the hospital anymore!" How should the nurse respond?
3. Tiona's mother states that she is worried that her daughter will not drink enough at home. What can the nurse suggest to Tiona's mother to encourage her to drink fluids? What are the symptoms of dehydration that Tiona's mother should watch for over the next few days?
4. Children Tiona's age have many fears and stressors related to hospital and surgery. How can Tiona's mother assist her daughter to express her feelings about the hospital experience once she is home?

Chapter 12
The Child With a Chronic Condition

Ethno Images, Inc./Alamy

I'm nervous about going to school for the first time since my diabetes was diagnosed. I'm worried that my friends will make fun of me because I have to check my blood and give myself a shot at lunchtime. I wish this would just go away, but I know it's something I will have for the rest of my life. My mom and dad were really upset, but they are getting used to the idea now and will do anything to make sure I am doing okay.

—Mark, 10 years old

Learning Outcomes

12.1 Explain the causes of chronic conditions in children.

12.2 Identify the categories of chronic conditions in children.

12.3 Describe the nurse's role in caring for a child with a chronic condition.

12.4 Assess the family of a child with a chronic condition.

12.5 Prepare the family of a child with a chronic condition to effectively care for the child in the home.

12.6 Summarize nursing management for the child with a chronic condition to support transition to school and adult living.

12.7 Discuss the family's role in care coordination.

Overview of Chronic Conditions

A **chronic condition** is generally thought of as one that is expected to last at least 3 months (Kennedy, 2011). An estimated, 14.6 million children under the age of 18 in the United States have special healthcare needs related to some type of chronic condition (Data Resource Center for Child & Adolescent Health, 2012). Chronic conditions vary in etiology, manifestations, severity, and their effect on the child's physical, psychosocial, and cognitive development. Chronic conditions develop from multiple causes:

- Genetic or inheritable conditions may manifest as a chronic condition. Examples include muscular dystrophy, hemophilia, sickle cell disease, and cystic fibrosis.
- Conditions may result from a congenital defect or insult to the infant during fetal development, such as neural tube defect, maternal substance abuse, cleft palate, and cerebral palsy.
- Insult or injury may be associated with birth and care following birth (sepsis, prematurity, intraventricular hemorrhage) that lead to conditions such as bronchopulmonary dysplasia, attention deficit disorder, and vision or hearing impairment.
- Conditions can be acquired through injury or acute medical condition such as brain injury, cancer, HIV infection, drowning, and mental health problems. These and additional chronic illnesses are discussed in the systems chapters later in this text.

In most cases, these chronic conditions become lifelong disorders, but the impact on the affected child varies according to the severity of the condition, the stage of growth and development when the condition occurs, and the child's and family's responses to the condition. Whereas some conditions require intense monitoring and technologic support for survival, other conditions cause few limitations and have a minimal effect on quality of life (Figure 12–1).

A

B

Figure 12–1 **Children with chronic conditions may have a visible or nonvisible health condition, or nonvisible until an acute episode of their condition makes the condition visible. *A,* The child in a wheelchair has a visible disability. *B,* The child with a seizure disorder may have no visible signs of the condition unless a seizure is witnessed.**

TABLE 12–1 Examples of Conditions by Special Healthcare Need Category

SPECIAL HEALTHCARE NEED CATEGORY	CHRONIC HEALTH CONDITION EXAMPLES
Dependent on medications or special diet	Diabetes mellitus, asthma, seizures, phenylketonuria, organ transplantation, cystic fibrosis, celiac disease
Dependent on medical technology	Renal failure, bronchopulmonary dysplasia
Increased use of healthcare services	Cancer, sickle cell disease, cystic fibrosis
Functional limitations	Down syndrome, brain injury, autism, myelodysplasia, cerebral palsy

Categories of chronic conditions may include functional limitations, developmental disorders, behavioral issues, anatomical problems, and limb dysfunction (Goodman, Posner, Huang, et al., 2013). The condition may also be further defined based on the amount of care that is needed, such as special medications, special diet, or medical technology. Children with chronic conditions require more care than healthy children require.

See Table 12–1 for examples of chronic conditions that may fall into a specific category. Many children with chronic conditions have special healthcare needs that fall into several of these areas. In the majority of cases, the more severe the chronic condition, the greater the number of categories of special healthcare needs. Many children with a chronic condition and children dependent on technology require specialized health care. The term **children with special healthcare needs (CSHCN)** is applied to "those who have one or more chronic physical, developmental, behavioral, or emotional conditions for which they require an above routine type or amount of health and related services" (U.S. Department of Health and Human Services, Health Resources and Services Administration [USDHHS/HRSA], 2011).

Many of these children have a **disability**, a limitation that interferes with a child's ability to fully participate in society, which can be related to medical impairment (chronic health condition), functional limitation (mobility, self-care, communication, or learning behavior impairment), or a mental condition that interferes with social interactions.

Data show that 19.8% of children in the United States have a special healthcare need (Data Resource Center for Child & Adolescent Health, 2012). Although these children represent a small percentage of the nation's children, they require significantly more healthcare resources than those without special healthcare needs, including more visits to clinics and emergency departments, dental visits, inpatient hospital days, and prescription medications. Efforts to reduce health costs have resulted in fewer hospitalizations and more care in the community for children with special healthcare needs.

The child with a life-threatening illness or a chronic condition as the result of a complex illness, prematurity, or a congenital defect may be considered **medically fragile** (Miles, Holditch-Davis, Burchinal, et al., 2011). Some of these children are **technology assisted**, dependent on a medical device that is required to sustain life or to maintain health status (mechanical ventilators, intravenous nutrition or drugs, tracheostomy,

Healthy People 2020

(DH-5) Increase the proportion of youth with special healthcare needs whose healthcare provider has discussed transition planning from pediatric to adult health care

(MICH-30) Increase the proportion of children, including those with special healthcare needs, who have access to a medical home

(MICH-31) Increase the proportion of children with special healthcare needs who receive their care in family-centered, comprehensive, coordinated systems

suctioning, oxygen, or nutritional support with tube feedings) (Figure 12–2). Other children depend on medical devices that compensate for vital body functions and require nursing care management such as renal dialysis, urinary catheters, and colostomies.

Children assisted by technology can be cared for at home because compact portable equipment is available. Home-based equipment used for the child with a chronic condition may include ventilators, enteral feeding tubes, intravenous catheters, infusion pumps, dialysis equipment, and oxygen. With the support of home health services, parents can learn to manage the child's care. The benefit of home health services to the child is support of physical, emotional, and cognitive growth and development within the normal environment of the home.

All families with children experiencing a chronic condition need to make lifestyle adjustments, ensuring a baseline of care that helps maintain the child's health status and promotes growth and development. In many cases, the child has a baseline level of home management with episodic exacerbations that require the family to make sudden adjustments in family routines, such as may occur with the child who has seizures or an infection. These exacerbations often cause stress and disrupt family routines. In other cases, the chronic condition requires the family to learn and provide care that is complex and time intensive, such as cystic fibrosis, diabetes mellitus, bronchopulmonary dysplasia, and significant cognitive impairment. These more severe chronic conditions often impact the child's physical and psychologic development. Table 12–2 outlines healthcare needs of these children and families and the nursing implications related to planning health services delivery to children and their families.

Figure 12–2 **This child needs a gastrostomy tube to ensure adequate nutrition is obtained to support growth and promote resistance to infection.**

Role of the Nurse

The nurse's role in caring for the child with a chronic condition includes the following:

- Providing health supervision from infancy to transition into adulthood
- Collaborating with the multidisciplinary healthcare team
- Partnering with parents or caregivers to manage the child's care at home
- Referring the family to appropriate community services
- Assisting with planning for education services
- Promoting positive parenting behaviors and psychosocial adaptation and well-being of the child and family
- Promoting growth and development of siblings

Assess each family member's level of understanding of the condition, treatment, and anticipated outcome of the condition. Determine the family's stage of acceptance of the child's chronic illness, and how well the child's care is integrated into family routines. Evaluate the child's home care environment to determine the potential for abuse, lack of adequate care, or neglect, or for opportunities to enhance care provided. Assess the family's strengths, stressors, risk factors, and coping strategies. Provide information related to community resources. See *Nursing Care Plan: The Child With a Chronic Condition*. See Chapter 13 for stages that a family might progress through when faced with a diagnosis of a life-threatening illness or injury in a child.

The Child With a Newly Diagnosed Chronic Condition

Informing the child of a newly acquired chronic condition is individualized and is based on the child's developmental level and age. See *Growth and Development: Developmental Considerations for the Child With a Chronic Condition*. Questions the child may ask vary, but often focus on the cause of the condition, how to make it better, and how it will affect daily life. Provide information tailored to the child's level of understanding and answer questions honestly. The nurse should also address the fears and concerns of the family. Provide condition-specific education to help prepare the family for care at home and begin discharge planning. See *Families Want to Know: Discussing a Child's Condition* and *Families Want to Know: Informing Parents of Their Child's Chronic Illness or Disability*. The parents' heightened anxiety level may reduce the comprehension of information heard. See *Developing Cultural Competence: Cultural Sensitivity in Healthcare Providers for Children With Special Healthcare Needs*.

Most children with chronic conditions live at home, which causes other family members, including siblings, to be affected as well (Nielsen et al., 2012). Siblings of children with a chronic condition are affected in a variety of ways. These children experience some degree of disruption in their lives and demonstrate a variety of emotional responses (Fleary & Heffer, 2013). They may feel powerless and may receive less attention from their parents than the ill child. Siblings may have feelings of jealousy, anger, depression, guilt, resentment, worry, and anxiety (Fleary & Heffer, 2013; Vermaes, van Susante, & van Bakel, 2012). Siblings may fear that they themselves will have the same disease or condition as the affected child.

TABLE 12–2 Healthcare Needs of Children With Chronic Conditions

HEALTHCARE NEED	DEFINITION	NURSING ACTIONS
Access to care	Care includes the availability and accessibility of providers with knowledge as well as ancillary services needed by children and their families.	Assist the family in obtaining transportation assistance if required. Assist the family in identifying healthcare providers who provide health promotion and other services to address the child's specific healthcare needs.
Appropriateness of care	Services and care are delivered by individuals with expertise and experience and are developmentally and culturally appropriate for the child and family.	Support the family by outlining educational and health services needed when developing an individualized education plan (IEP) and individualized health plan (IHP).
Comprehensiveness of care	Care includes coverage of the preventive, primary, and tertiary care needs of children, and linkages with other service systems, such as education, social services, and family support systems.	Provide the family with resource contacts such as social services, family support groups, and other systems to help the family manage the child's condition. Assist the family in identifying a care coordinator or developing the skills to take on the care coordination role themselves.
Coordination of care	Families are linked to medical care, financial health resources, and educational and community-based services; information is centralized.	Assist the family to identify a care coordinator or to develop the skills to become the care coordinator. See additional information in this chapter related to care coordination. Provide guidance and resources if the family decides to assume the role of care coordinator. Encourage the family to partner with the healthcare team to ensure continuity of care.
Continuity of care	Care is provided through a medical home or pediatric healthcare home; linkages between primary, specialty, therapeutic, and home care exist throughout childhood.	Facilitate communication between all the child's healthcare providers. Include the family and older child in all decision making.
Degree to which family-centered services are provided	The importance of the family is reflected in the way services are planned and delivered, building on individual and family strengths, and respecting the diversity of each family.	Determine the needs of the child and the family to ensure they are being addressed. Assist the family in identifying local and specialized healthcare providers. Recognize and respect the culture and cultural practices of the child and family.

Developing Cultural Competence Cultural Sensitivity in Healthcare Providers for Children With Special Healthcare Needs

The 2009/2010 National Survey of Children with Special Health Care Needs found that the majority of physicians and other healthcare providers were sensitive to family values and customs. Specific results indicated that 69.6% of physicians or other healthcare providers were always sensitive to family values and customs, 19.3% were usually sensitive, and 11.1% were sometimes or never sensitive (Child and Adolescent Health Measurement Initiative, 2012). It is essential for all healthcare providers to be sensitive to family values and customs of children with special healthcare needs.

Siblings may also have positive responses related to growing up with a chronically ill sibling, including an increased awareness of illness, maturity, family bonding and support, and an increased appreciation for life (Fleary & Heffer, 2013). See Chapter 11 for siblings' responses to the child experiencing an illness.

Discharge Planning and Home Care Teaching

As the child with a newly diagnosed chronic condition transitions to the home, parents often feel overwhelmed with preparations for home care, the anxiety of caring for a child with special healthcare needs, and supporting the child's growth and development needs. Work with the parents to ensure a smooth transition from hospital to the home environment. Assist the family in the initial discussions with the multidisciplinary team that participates in developing the child's care plan. Ensure that the family understands the role of each care provider. Provide contact numbers for parents to call should any issues arise at home.

Education to provide care of the child at home may be initiated by the hospital nursing staff, and then transitioned to special nurse educators or the home health nurses. Care is taken to ensure that all aspects of management are discussed with the family and that they demonstrate an understanding of and ability to perform the care required.

During discharge planning it may be helpful to identify a parent peer or peer support group to provide support to the family. Parent peers who have had similar experiences may be very helpful in identifying strategies for the initial care transition in

Nursing Care Plan: The Child With a Chronic Condition

1. Nursing Diagnosis: *Knowledge, Deficient (Child),* related to learning self-care skills (NANDA-I © 2014)

GOAL: The child will acquire self-care skills for lifetime management.

INTERVENTION	RATIONALE
• Assess the child's developmental level and select an educational approach and self-care activities to match.	• Learning goals for the child must match knowledge and skill expectations appropriate for developmental stage.
• Review with the child all steps involved in the self-care skill and how to perform the skill.	• The child may have watched the routine used by parents many times, and asking the child to list each step helps the nurse identify extra training needed.
• Use demonstration/return demonstration until the child is comfortable with procedures.	• Evaluation permits positive reinforcement and guidance for modification of techniques.
• Help parents develop a planned sequence of self-care skills to teach the child.	• Parents need guidance to identify appropriate self-care skills that the child is developmentally ready to learn.
• Discuss a plan for increased responsibility for self-care with the child and parents.	• Parents often need encouragement to transition responsibility to the child, becoming a supervisor rather than the person controlling care.

EXPECTED OUTCOME: Child will demonstrate the proper technique in the self-care skill and be able to assume responsibility for that skill with supervision by the parent. Responsibility for self-care increases as new skills are learned.

2. Nursing Diagnosis: *Family Processes, Interrupted,* related to management of chronic disease (NANDA-I © 2014)

GOAL: The child and family will manage the required treatments, monitoring, and medication regimen for the child's condition while maintaining family routines and functioning.

INTERVENTION	RATIONALE
• Assess the child's and family's lifestyle and attempt to fit the child's care needs into those schedules.	• Fitting the child's care to the child's and family's lifestyle promotes adherence to regimen and healthier family processes.
• Discuss the family's routines for special occasions and vacations and any activities important to the child. Identify ways to modify the child's management for these occasions and activities.	• It is important for the child to participate in special events with the family and peers as a normal child to promote psychologic development.

EXPECTED OUTCOME: Child and family will maintain important family routines and successfully manage the child's condition.

3. Nursing Diagnosis: *Coping: Readiness for Enhanced* related to self-care management of chronic condition (NANDA-I © 2014)

GOAL: The child will develop a support system network.

INTERVENTION	RATIONALE
• Talk with the child about how to tell friends, teachers, and other important people about the chronic condition.	• These important people can assist the child in an emergency if they have enough information to assess the problem.
• Discuss ways to explain the condition to important people and how to answer questions.	• Having an opportunity to plan and role-play the conversation will reduce the child's anxiety about condition disclosure.
• Role-play ways to talk about the condition with friends and teachers.	• Sharing information about the condition helps others understand changes in lifestyle needed by the child.
• Encourage the child to attend peer support groups or camps specific to the child's condition.	• Learning and support networks developed at camp can promote development of problem-solving skills that increase coping abilities.

EXPECTED OUTCOME: Child will identify the friends, teachers, and other important persons informed about the chronic condition who can provide support when needed.

Growth and Development Developmental Considerations for the Child With a Chronic Condition

Newborns and Infants

- Newborns and infants who are medically fragile are at risk for chronic conditions related to brain injury, oxygen deprivation, and respiratory problems.
- Newborns cared for in the NICU are exposed to an environment of bright lights and high-pitched noises that can negatively affect their development (Aita, Johnston, Goulet, et al., 2013).
- Promote development and parent–infant bonding by encouraging the parents to spend time with the infant and engage in face-to-face interaction. When the newborn is stable, provide opportunities for parents to touch, soothe, and care for the infant.
- Provide sensory stimuli such as mobiles, soft music, and different textures for the infant to touch.

Toddlers

- Chronic illness can interfere with the achievement of autonomy and development of self-control. Some parents are overprotective and may do simple tasks they feel the child is incapable of accomplishing, rather than encouraging the child to try to do things independently. The child can lose independence and lack opportunities to meet developmental tasks.
- Nurses can promote the development of toddlers with chronic conditions by offering the child choices when possible, such as which color gown to wear or which food to eat first.
- Help parents recognize the toddler's capabilities, and allow the child to take the time to practice and learn a skill. Identify the next most appropriate developmental tasks for the child to learn and give the parents some strategies they can use to offer learning opportunities.

Preschoolers

- Preschool children recognize the association between body parts and problems associated with the chronic condition. The preschooler engages in magical thinking during this stage, and the child may believe that his or her thoughts or behaviors caused the condition. The child may also think the condition is a form of punishment.
- Hospitalization or implementation of a treatment plan, such as a new medication, may interfere with the preschool-age child's developing independence (University of Michigan Health System, 2014).
- Nurses can promote development by explaining the purpose of treatments and procedures in terms the preschooler can understand, and by emphasizing that treatments and procedures are not punishment for any wrongdoing.
- Look for ways to use play so the child can learn an aspect of self-care, perform an activity, and feel a sense of accomplishment. Encourage social interactions with other children when possible. Give positive feedback to the child for appropriate efforts and successes.

School-Age Children

- Early school-age children have an increased understanding of their condition and are capable of participating in certain aspects of monitoring and care. Older school-age children begin to understand about managing their condition and the long-term needs associated with their condition. They can assume more responsibility for their care such as serum glucose monitoring, intermittent self-catheterization, or monitoring the condition of skin under braces.
- Some children with chronic conditions have learning difficulties and other limitations that interfere with education and social competence. The child needs to gain social skills, interact with peers, master new information, learn to cope with stress, and acquire skills that lead to self-sufficiency in order to develop a sense of industry.
- The school-age child senses that he or she is different from peers and may feel left out, especially if functional limitations affect his or her ability to participate in extracurricular activities. It is important that children with chronic health conditions be allowed to participate in activities as much as their condition allows and their physician approves (University of Michigan Health System, 2014).
- Nurses can promote development of school-age children by encouraging their interaction with children in the same age group. When possible, this should occur with children who have the same type of chronic condition. Link the child to a peer support group to promote social interaction and to help the child recognize that others also have the same condition. When the child has an extended absence from school because of the chronic condition, encourage contact from school peers and friends through cards and computer messages, as well as the completion of school assignments.
- Begin to identify aspects of the child's care that the child can learn to assume under the parents' supervision. Inform families of the benefit of special camps for children with the chronic condition (when available) to promote recreation, social interaction, and learning skills of self-care.

Adolescents

- The adolescent with a chronic condition has numerous challenges with the rapid changes in growth and sexual maturation; ongoing development of identity, body image, and self-concept; and the need to plan for vocational and healthcare transitions. Cognitive development and abstract thinking skills are achieved during this stage, allowing the adolescent to develop an understanding of the short-term and long-term consequences related to the condition.
- The adolescent becomes more aware of differences between self and peers. Some adolescents are unable to cope with the recognizable differences between themselves and healthy peers, and they withdraw from social activities and relationships. Others may engage in risky behavior (e.g., alcohol, sexual activity, eating foods that interfere with therapy) that may be harmful to themselves or to management of their condition, just to be accepted by peers.
- Nursing actions to promote development of the adolescent include client education to help the adolescent learn about the chronic condition, care needed to manage or control the condition, and problem solving and specific skills for integrating self-care management into daily life. Parents need to be coached to transition care over to the adolescent and to support the adolescent to make healthy decisions regarding care.
- Encourage the adolescent to build a safety net of friends who know enough about the chronic condition to assist if a problem occurs, such as a seizure, asthma episode, or insulin reaction.
- Discuss sexual maturation and the importance of protected sexual activity, and discourage risky behaviors by the adolescent.
- Provide adolescents with an opportunity to express concerns regarding self-management, vocational planning, and future independent living. Refer them to their local vocational rehabilitation services.

Families Want to Know

Informing Parents of Their Child's Chronic Illness or Disability

The following guidelines may be considered when informing parents of the diagnosis of a chronic illness or disability in their child:

1. Inform parents of their child's diagnosis in person, in a private setting, and free from interruptions. Tell both parents together. Offer parents the opportunity to have a relative or friend as a support person during the discussion.
2. Present information in small amounts at a time and at the level of the parents' understanding.
3. Plan and organize the information to be provided. Use simple, direct language without medical jargon. Individualize the pace of the interview and approaches taken to present the explanation, taking into consideration a family's culture and the family's response to the information.
4. Share accurate, up-to-date information about the diagnosis, treatment options, specialty referrals, and community resources.
5. Talk about the strengths and positive attributes of the child, as well as the child's limitations and characteristics due to the illness or disability.
6. Evaluate the discussion to assess whether the family's needs were met and to determine the type of support and/or additional information that should be provided.
7. Plan a follow-up discussion to repeat and clarify the information provided, and to give the parents a chance to get additional questions answered.

Families Want to Know

Discussing a Child's Condition

When discussing a child's chronic condition with the family, use the child's name. Avoid labeling the child with a condition, such as "diabetic child"; instead, refer to the situation as "the child with diabetes." This places the emphasis on the child rather than the condition.

the home and additional issues that arise over time. If the family has a computer that family members frequently use, Internet resources for information and family support should be provided.

Collaborate with the family and healthcare team to ensure that the child has a medical or healthcare home in the local community to provide health promotion and maintenance and to assist with the coordination of local community resources. Promote communication and joint planning of care between the specialty care provider and local healthcare provider. Nurses working in hospital specialty clinics and other community settings can help ensure that children with chronic conditions receive multidisciplinary referrals and have appointments scheduled. Social services may be called to assist the family with identifying financial resources and other community resources for home management. Ongoing assistance may be required to help families deal with financial issues, time management, and other challenges.

Coordination of Care

Care coordination is the process of planning and integrating healthcare services among providers in an effort to achieve and promote good health in the child. Care coordination in a medical home facilitates transition from a pediatric healthcare provider to an adult healthcare provider (American Academy of Pediatrics, 2012). Care coordination also improves the quality and safety of client care (Taylor et al., 2012). See *Evidence-Based Practice: Care Coordination for Children With Special Healthcare Needs*. A **case manager**, often a nurse or social worker, may be given responsibility to help the family with care coordination. Case managers are often paid by a healthcare insurer to reduce healthcare costs by coordinating the healthcare team, determining family needs, identifying financial and local support resources, and arranging for needed healthcare services.

Care coordination may help families who have children with special healthcare needs (Lawson, Bloom, Sadof, et al., 2011; Taylor et al., 2012). It may include helping the family modify the home to support required technology, such as mechanical ventilation or wheelchair use. Assistance may be required in purchasing or leasing ventilators, infusion pumps, or other specialized equipment. The coordination plan also includes determining the potential need for home health nursing, physical therapy, or other home health services. See *Developing Cultural Competence: Disparities in Care Coordination*.

Developing Cultural Competence Disparities in Care Coordination

Research by Toomey, Chien, Elliott, et al. (2013) found that children with special healthcare needs (CSHCN) were more likely to have inadequate care coordination than children without special healthcare needs. The study also found that Black and Latino children were more likely to have unmet care coordination needs than White children. Effective care coordination is essential for all CSHCN.

Families become very well educated about their child's condition and the services that would make managing the condition easier. After management goals are established by the multidisciplinary team, the case manager partners with the family to help in the decision-making process regarding how goals will be met. An important role is helping the family determine cost-effective

EVIDENCE-BASED PRACTICE | Care Coordination for Children With Special Healthcare Needs

Clinical Question

How can care coordination enhance the care that children with special healthcare needs (CSHCN) and their families receive?

The Evidence

Taylor et al. (2012) evaluated the effectiveness of a care coordination program for CSHCN. The goal of the program was to assist families in achieving competency in care coordination and to support healthcare providers in the care coordination process. This study evaluated the effectiveness of a care coordination counselor implemented at a children's hospital with 430 beds and 50 outpatient care sites. The care coordination counselor was a BSN-prepared nurse who was made available to clients and families with complex needs. Additional tools provided to the families included a care binder, Care Coordination Network Committee, and the Community Resources for Families database. A survey was used to compare responses from families who received services from the care coordination counselor and those who received only a care binder. Twenty-five families who received services from the care coordination counselor and 50 families who received only the care binder completed the survey. Eighty-three percent of those receiving services responded positively overall to the survey, compared with 55% of those receiving only the binder. Additionally, 67% of those receiving services stated that care coordination for their child had improved over the past 6 months, compared to 47% of those who received only the care binder.

Looman et al. (2013) examined the importance of the role of the advanced practice nurse in relationship-based care coordination of children with complex special healthcare needs. Outcomes were measured using the Tele-Families study, a 4-year randomized controlled study whose goal is to evaluate the effectiveness of an enhanced interactive telehealth program and care coordination by the advanced practice nurse for children with complex special healthcare needs. Preliminary findings based on qualitative data from 94 families receiving telenursing interventions from an advanced practice nurse indicate increased parent satisfaction with having one person to coordinate care. Parents also expressed satisfaction with decreased time needed to have forms and prescriptions updated.

Petitgout, Pelzer, McConkey, et al. (2013) described the development of a hospital-based care coordination program for CSHCN. The program includes inpatients and outpatients and utilizes a family-centered approach to provide care coordination and a medical home. Over the past 10 years, improved client outcomes have been noted and include a decrease in length of stay, high family satisfaction, and decreased cost. In this program, the pediatric nurse practitioners collaborate with other healthcare providers and services to provide care coordination.

Best Practice

Care coordination is essential when working with CSHCN and their families. Care coordination in which nurses work with families to facilitate coordination of services is effective and leads to greater satisfaction with care and improved client outcomes. The nurse assists families to identify needed programs and services and is in an excellent position to serve as a liaison between these programs and the family to decrease the risk for fragmentation of care.

Clinical Reasoning

Why is care coordination a vital aspect of care for CSHCN? Provide an example of coordination of services for CSHCN. How do nurses play a role in care coordination for CSHCN?

strategies to meet healthcare goals and to delay the time when the child reaches the cap on health insurance benefits.

Some families assume the role of care coordinator for their child. It is essential for the family to understand that care coordination is time consuming and requires ongoing assessment and evaluation of the child's status and anticipated outcomes. Support family members in their decision to lead the care coordination process by helping the parents to become knowledgeable about the child's condition and treatment regimen. Encourage the parents to take an active role in the treatment planning and decision-making process so that they gain confidence in their abilities. Many hospitals have workshops for parents who are managing the complex care of their children. Parent-to-parent support groups can provide advice, support, and suggestions for referrals. Review the care coordination to ensure that the child has access to the most appropriate care and resources. Provide positive feedback to the parents as their advocacy skills increase.

Suggest that the family maintain a log of the healthcare team members, their roles, when the child was seen and any interventions, the results of interventions, and future planned interventions or treatments. The family can use this information when communicating with the healthcare providers, particularly in an emergency, and it may also help eliminate unnecessary duplication of procedures.

Community Sites of Care

Most children with chronic conditions are cared for in the home with or without home nursing or other health services. The healthcare provider for children with chronic conditions varies by the type of condition, type of health insurance coverage, preferences of the family, and availability of pediatric specialty resources.

Office or Health Center

Every child should have a "healthcare home" or "medical home," a consistent, continuous, comprehensive, family-centered, and compassionate source of primary health care. A healthcare home or medical home for these children is especially important because children with chronic conditions need regular preventive health care just as healthy children do. Health promotion, disease prevention, and anticipatory guidance have greater significance for the child with special healthcare needs. These children already have a condition that places them at higher risk for additional problems, such as infectious diseases, injury, or developmental delay. Information about community resources that may help the child and family is usually more extensive when the child's healthcare home is in the local community. The goal is for the child to have as normal a childhood as possible.

Ideally, this healthcare provider is located in the community where the family resides, making it more convenient for the family to obtain routine health care as well as care for episodic illnesses. Having a regular healthcare provider has many advantages for the family:

- Because the child and family are seen more frequently, a trusting, family-centered relationship can develop. The healthcare provider learns about the family's strengths and coping abilities.
- The healthcare provider sees the child and family when things are going well and during exacerbations. This may enable the healthcare provider to identify strategies that help the family to better coordinate the child's care.
- When the provider is based in the same community as the child, it is likely that information about community resources is known; this will reduce the efforts that families must make to identify appropriate services needed by the child.

Specialty Referral Centers

An optimal healthcare arrangement for the child with a chronic condition exists when the medical or healthcare home provider collaborates with a pediatric team or specialist that specializes in the care of children with a specific chronic condition. Pediatric specialists, advanced practice nurses, and other healthcare providers (e.g., physical therapists, social workers, and nutritionists) often function as a team, providing coordinated care to the family and child with a chronic condition, such as spina bifida, cystic fibrosis, or diabetes. These specialty teams are often found in major medical centers, requiring travel to the facility. When communication flows from the team to the child's healthcare provider and back to the team, new treatments can be monitored by the child's physician, and consultation can be sought if the child's health status changes (Figure 12–3).

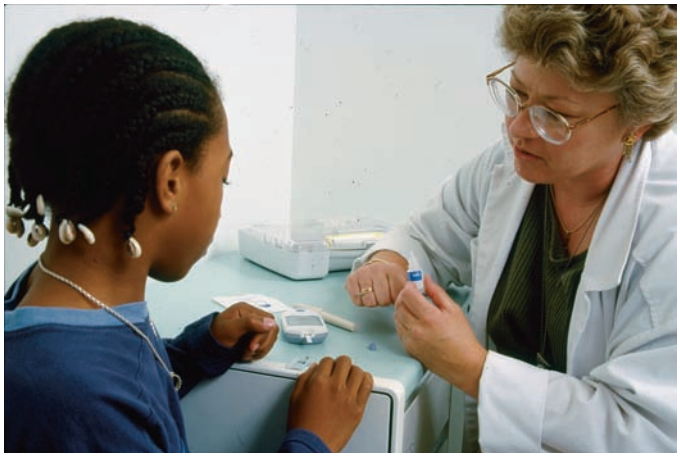

Figure 12–3 Nurses often assume a larger role in working with children and families with a chronic health condition in the ambulatory setting. Developing a care plan and educating the child and family to manage type 1 diabetes is an important role of this pediatric nurse, who is also a certified diabetes educator.

Nurses working in hospital specialty clinics and other community settings can help ensure that these children receive the appropriate health promotion services. The nurse in a tertiary care facility needs to identify appropriate resources and to help the family connect with local community resources. This is a greater challenge if the child and family have traveled a distance to obtain the specialty services, supporting the need for a primary care provider in the home community to provide regular care and to help coordinate local community resources.

Schools

All children, including those with chronic conditions and special healthcare needs, are entitled by federal law to a free education that is matched to their developmental and functional capabilities (Individuals with Disabilities Education Act [IDEA] and Section 504 of the Rehabilitation Act of 1973). **Early intervention** provides special services for infants and toddlers up to age 3 years who have a developmental delay or are at risk for a developmental delay. Early intervention programs are federal programs administered by the states. Children are evaluated at age 3 to determine continued eligibility in preschool (Caley, 2012; Pacer Center, 2012). IDEA has led to support of communities that are developing early childhood education programs and to schools with students who are blind, deaf, or have autism or traumatic brain injury. Provisions for adolescent transitional planning for adult living, including vocational training and independent living, are also included in the Individuals with Disabilities Education Act (U.S. Department of Education [USDOE], 2011).

Attending school is an important transition for children with chronic conditions and their families. Sending the child to school has several benefits for the child and family, including opportunities for socialization with children and adults outside of the family. School attendance promotes a feeling of normalcy in the family and provides a break for the primary care provider. Integration into the school system requires collaboration of family, school personnel, the nurse, and other members of the healthcare team.

EDUCATIONAL SYSTEM PLANNING

Careful planning is needed when a child with special needs attends school or receives other education services. Many children have chronic medical conditions that require management during the day in the school environment, such as asthma, diabetes, and attention deficit disorder. Some children simply need medications administered regularly or episodically. Other children require more extensive interventions integrated into the school day, such as blood glucose monitoring or intermittent self-catheterization. The education system is obligated to provide reasonable accommodations to ensure that the child's medical needs are met during the school day. The education system's obligation is negotiated with the family in formalized plans. The school nurse is an active participant on the team that collaborates with the family to develop these formalized plans.

- An **individualized family service plan (IFSP)** is developed for the early intervention process for infants with special healthcare needs and their families. The IFSP contains information about the services required to support a child's development and enhance the family's capacity to facilitate the child's development. The family and education service providers work as a team to plan, implement, and evaluate services specific to the family's unique concerns, priorities, and resources.

Clinical Tip

Federal laws for providing education services for children with special healthcare needs include:

- The Rehabilitation Act, PL 93-112, of 1973 prohibited discrimination against people with a disability. Section 504 specifies that each student who has a disability is entitled to **accommodations**—services or special assistance provided in the school setting to ensure that a student with a physical or mental impairment has access to an appropriate education and is able to participate as fully as possible in school activities. Examples of accommodations might include allowing additional time to take a test, using strategies that decrease exposure to peanuts in a child who has an allergy to peanuts, or allowing a child to test his or her blood glucose level. Students with disabilities must be provided with educational services to meet their needs just as services are provided to those without disabilities. See Chapter 10 for further discussion on the nurse's role in the school setting.
- The Education for All Handicapped Children Act, PL 94-142, of 1975 mandated that all children, even those with disabilities, be provided with free public education and related services. Safeguards were put into place to ensure that the rights of children with disabilities and their parents are protected. Additional purposes of this legislation were to assist states to provide education to children with disabilities and to evaluate the effectiveness of efforts to educate children with disabilities.
- The Education for All Handicapped Children Amendments, PL 99-457, of 1986 expanded the scope of PL 94-142 to include appropriate services for infants and toddlers with disabilities and their families.
- The Individuals with Disabilities Education Act (IDEA), PL 105-17, of 1997 and the Individuals with Disabilities Education Act of 2004, PL 108-446, with final regulations published in 2006 (reauthorization of the 1997 legislation), ensure that all children with disabilities have available to them a free and appropriate public education that emphasizes special education and related services designed to meet their unique needs and prepare them for employment and independent living. Every child with a disability must have a written individualized education plan (IEP), and parents have the right to question placement decisions and to due process when settling differences. In addition, the 2004 legislation focused more on state and local accountability to educate children with disabilities. This legislation also added a requirement that the child be invited to the IEP meeting.

(2013). *Special education public policy*. Retrieved from http://www.projectidealonline.org/v/special-education-public-policy/; Yell, M. L., Conroy, T., Katsiyannis, A., & Conroy, T. (2013). Individualized education programs and special education programming for students with disabilities in urban schools. *Fordham Urban Law Journal, 41*(2), 669–714.

Figure 12–4 **Because some children need medications or other therapies during school hours, the parents and child, school nurse, teacher, and school administrators develop a plan to manage the child's condition during school hours. The resulting document is the child's individualized health plan.**

- An **individualized education plan (IEP)** is developed for a child with cognitive, motor, social, and communication impairments who needs special education services. The IEP is jointly planned with the school administrator, teacher, parents, and other special support professionals as appropriate for the child's condition. The child is also included in the process when possible. The plan is developed after an assessment of the child's abilities and specific functional limitations.
- An **individualized health plan (IHP)** is developed for the child with medical conditions that need to be managed within the school setting. An IHP may be developed simultaneously with the IEP for the child with a health problem and a coexisting functional impairment. Some children need an IHP only for management of their chronic medical condition at school, such as daily medication administration or for glucose monitoring and insulin injection. An order from a licensed healthcare provider is required for medication administration and special treatments. Learning may be challenged when the child has frequent acute illness episodes that result in missed days of school, and the IHP often integrates methods to prevent the child from being penalized for those absences (Figure 12–4).
- An Individualized Section 504 Accommodation Plan may be used rather than an IHP for children with physical or mental impairments. The same process is used for development of the plan.
- An **individualized transition plan (ITP)** is included in the development of an IEP for each child with a chronic disability who is 14 years or older. The ITP focuses on helping individuals receive vocational training and in moving successfully from the home into other community living settings as they grow older.

Parents have an important role in advocating for their child to ensure that the child receives the most appropriate educational services. School systems must provide a full range of educational services for the children with special healthcare needs, including services that support cognitive development, self-care skills, mobility, improved communication, and social skills. Because each child's severity and combination of impairments is unique, identifying and matching the specific services for each child requires discussion and negotiation. Parents should make an effort to learn about the different types of educational services that address a child's specific disability in preparation for the IEP meeting. Parents often need a mentor or experienced parent to help with the development of the IEP the first few times. In this way, the parents are better prepared to participate in the educational planning and development of the child's IEP. School nurses are employees of the school system and may be limited in their

Clinical Tip

The elements of an IEP are as follows:

- Student's name
- Date of meeting to develop or review the IEP
- Statement of transition service needs of student beginning at age 14 years
- Present level of assessments and education performance, including how the child's disability affects the child's involvement and progress in a general curriculum or participation in appropriate activities
- Measurable annual goals that include short-term objectives in meeting the child's needs that enable the child to be involved in or progress in the general curriculum or participate in appropriate activities
- Special education and related services, supplementary aids and services, and program modifications or supports for school personnel needed to enable the child to make advancements toward attaining annual goals
- Explanation of the extent to which the child will or will not participate with nondisabled children
- Any specific modification in the administration of state or districtwide assessments of achievement that are needed for the child to participate in the assessment, or reasons for excluding the child from assessment
- How the child's progress toward annual goals will be measured
- How the child's parents will be regularly informed of the child's progress toward annual goals and the extent to which the child's progress is sufficient to meet goals by the end of the year

Source: Data from U.S. Department of Education (USDOE). (2000). *A guide to the individualized education program*. Individualized education programs and special education programming for students with disabilities in urban schools. *Fordham Urban Law Journal, 41*(2), 669–714.

advocacy role on behalf of individual students. However, school nurses are in a good position to educate the IEP team about specific interventions needed by children with medical conditions and ways to integrate those interventions into the school day.

Teachers will need to learn to identify specific health problems, such as increased respiratory effort in a child with asthma or sweating, and pallor and loss of concentration in a child with diabetes. The child's teachers become part of the child's safety net for rapid access to needed healthcare intervention. With support from the school administration and school nurse, teachers can learn about the child's condition and special care that may be needed during the school day, such as a snack for the child with diabetes, management of the child who has a seizure, and ways to reduce the spread of infection within the classroom.

THE CHILD'S RESPONSE TO ENTERING SCHOOL

Children with chronic conditions—whether the conditions cause minimal interference in the child's daily life or significant interference, such as dependence on technology—face certain challenges in the school setting. They may for the first time recognize differences between themselves and other children, such as appearance, abilities, social skills, or special treatment needs. Limitations in abilities may cause the child to be shy or embarrassed. Affected children may also be teased or bullied by other children because of their disability (Vessey & O'Neill, 2011). Some children, particularly adolescents, may attempt to hide their condition or fail to adhere to necessary recommendations, such as dietary restrictions, to appear like their peers.

EDUCATION FOR CHILDREN WHO ARE MEDICALLY FRAGILE

Children who are medically fragile or technology assisted are also entitled to education and education services in the school setting. The parents and the school system must carefully consider the child's need for skilled supportive nursing care. Parents are often anxious about how well the child will be cared for by others during the school day. Risks for the child in the school setting include safety issues related to ventilators, tracheostomy, and medication therapy, as well as exposure to infectious diseases. The school administration must provide the personnel resources and equipment needed to ensure that care and a care provider are consistently available. Modifications to the school setting for the child, such as wheelchair ramps or an elevator, may be needed. Sometimes the child is placed in a classroom with healthy children, and the teacher is expected to monitor the child with a chronic condition and provide care as needed. Health aides may be assigned to provide care for one or more children with school nurse supervision. Some children are placed in classes composed of children with special healthcare needs where health aides are more available to provide needed care.

Nurses play a key role in assisting the family to understand that a teacher's primary responsibility is to teach, not to provide health care. The teacher is responsible for the health and safety of all children in the classroom. Parents need to have realistic expectations about the level of skilled support services that can be provided to a child who is medically fragile in a classroom. The need to balance the obligations for a child's special education services with the needs of all other children in a classroom can be a challenge for teachers and education leaders.

HOME SCHOOLING

The family of a child who is medically fragile or technology dependent may choose the option of home schooling the child, with resources provided through the school system. Home schooling may be used for all of the child's education or for periods when the child is experiencing exacerbations or more complications from the condition. The benefits of home schooling include continuity of education when the child would otherwise be unable to attend school and reductions in the child's stress and fatigue levels. Potential negative effects of home schooling include lack of peer and social interaction and decreased opportunity to develop social skills. The family that chooses home schooling needs to establish a routine for the education process.

TRANSITION TO ADULTHOOD

The number of adolescents with special healthcare needs transitioning to adulthood has increased as medical advances have increased life expectancy for many people with disabilities and chronic healthcare conditions (Oswald et al., 2013). Effective transition from pediatric-focused to adult-focused healthcare systems is essential in adolescents with these chronic health conditions (Huang et al., 2014). When their chronic condition could affect their future ability to work and live independently, customized transition planning is needed in preparation for adulthood and self-determination. A transition plan is developed in collaboration with the family based on the needs that have been identified in relation to the adolescent's goals for health care, employment, and community living. The plan should be individualized with psychosocial support provided to the adolescent during the transition planning and process (Oswald et al., 2013). Healthy & Ready

to Work services may be particularly helpful to adolescents and families in planning for transition to adulthood (HRTW National Resource Center, 2014).

Clinical Reasoning **Transitioning to Adulthood**

Martin is a 17-year-old with sickle cell anemia. As he reaches adulthood, the need to transition from a pediatrician to an adult healthcare provider will arise. What factors should be taken into consideration in deciding when this healthcare transition should occur?

Professionalism in Practice **Health Insurance Coverage**

Health insurance helps to ensure that young adults have access to comprehensive healthcare services. The Patient Protection and Affordable Care Act of 2010 (PPACA) includes legislation that prevents denial of healthcare benefits based on preexisting conditions (Sorrell, 2012). This legislation also allows young adults to stay on their parents' insurance policies up to age 26 (Slive & Cramer, 2012). Nurses who work with adolescents with special healthcare needs should collaborate with the care coordinator, advanced practice nurse, physician, social worker, and other members of the healthcare team to facilitate a successful transition to adulthood without interruption in quality health care and health insurance coverage.

Home Care

Many families become the primary caregiver for the child with a chronic condition, assuming responsibility for assessment and treatment despite the level of skill and complexity involved in that care. The numerous benefits of home care include the promotion of health, well-being, and development for the child, decreased financial costs to health insurance companies and the healthcare system, and a sense of satisfaction to families when they are able to care for their child at home. The family faces numerous challenges for home care, including modification of the home. Management of the condition involves technologic support, medications, and treatment regimens, all potential necessities to maintain the child in the home. Family members must decide who has responsibility for different aspects of the child's care. Many families must also decide whether both spouses will continue to work or if one parent will stay home to care for the child. Home health nursing care may be needed if both parents continue to work or to cover the night shift so parents can sleep.

Moving the child who is chronically ill, or a technology-assisted child, to the home setting is a life-changing decision for the family and it must be done with collaboration between the family and the healthcare team. Preparation for the child's transition to the home requires that the family receive extensive training and instructions on the child's care. Management of the condition involves technologic support, medications and treatment regimens, and all potential necessities to maintain the child in the home.

This transition is often challenging and intimidating for the family who now must assume the role of independent caregiver for a child who may have been hospitalized for several months. Family members often feel unprepared to handle the complex situation of the chronic condition and/or technologic supports. They are at risk to develop **caregiver burden**, the unrelenting pressure and anxiety related to providing daily care to a child with disabilities while meeting other family obligations. The family needs to be highly motivated and possess strength and resiliency factors to overcome the obstacles that will arise. These characteristics will help them be successful in assuming management responsibility for the child's care (Figure 12–5).

Figure 12–5 **Daily caregiving demands of the child who is medically fragile continue 24 hours a day, 7 days a week. Parents need to identify ways to share the care of the child and other family care management. When the child lives with a single parent, additional healthcare resources are needed so the parent can sleep.**

Source: Jaren Jai Wicklund/Shutterstock

RESPITE CARE

Respite care is an important support service that involves caring for the child with a chronic condition while the parents take a short break away from the daily care. Whiting (2014) identified respite care as the greatest unmet need of parents of children with complex healthcare needs. Respite care may be provided by extended family, friends, or an agency, and may take place in the home or an area outside of the home. An example of respite might be skilled nursing care in a facility or the home so the family can have a weekend away. Assist the family in identifying respite care that meets the individual family's needs from the services available in the community. Many states have passed legislation for in-home family support services that include respite care. Because many respite services charge for their assistance, the family may require help in identifying respite waiver subsidies available to them. Reliable childcare and enrollment in school are other mechanisms for families to obtain respite care.

EMERGENCY PREPAREDNESS

Advance planning is needed to ensure that medically fragile children who require technology for survival or have the potential for life-threatening episodes have the necessary resources in the event of a disaster. The designated shelter for such children, with health professionals and electrical power for the needed equipment, should be identified and known to the family. In the meantime, battery packs for power backup should be available at all times. Additionally, parents need to arrange for durable power of attorney so that consent for emergency medical care can be available as needed. The child and parents may become separated during the disaster, or the parents may become injured and unable to care for the child. Refer to Chapter 10 for more information related to emergency preparedness.

Chapter Highlights

- A chronic condition is a long-term, ongoing condition that is expected to last 3 months or more and may involve functional limitations, developmental disorders, behavioral issues, anatomic problems, and limb dysfunction or require special medications, a special diet, or more healthcare services than a healthy child would require.
- Approximately 14.6 million children in the United States have special healthcare needs related to a chronic condition.
- Chronic conditions can occur as a result of a genetic condition, congenital anomaly, injury during fetal development or at birth, complication of care after birth, serious infection, or significant injury.
- Children who are medically fragile are dependent on a medical device for survival or prevention of further disability.
- A developmental delay results when there is failure to achieve anticipated milestones during specific developmental stages.
- Families with children experiencing a chronic condition need to make lifestyle adjustments, ensuring a baseline of care that helps maintain the child's health status and promotes growth and development.
- Siblings of the child with a chronic illness may have feelings of jealousy, anger, depression, guilt, resentment, worry, and anxiety.
- The time of diagnosis is one of the most stressful times for families of children with chronic conditions as the parents wait anxiously for the outcome of diagnostic procedures. Other times associated with significant stressors for the family include developmental milestones, school entry, adolescence, and planning for the transition to adult health and vocational services.
- Moving the child with a chronic illness who is dependent on technology to the home setting is a life-changing decision for the family, and it must be done with collaboration between the family and the healthcare team.
- Caregiver burden is the unrelenting pressure and anxiety related to providing daily care to a child with disabilities while meeting other family obligations.
- The financial burden of caring for a child with special healthcare needs is significant even when the family has health insurance.
- Sending the child to school has several benefits for the child and family, including socialization for the child beyond the immediate family and respite for parents.
- An individualized education plan (IEP) is developed for a child with cognitive, motor, social, or communication impairments who needs special education services in the school setting. An individualized health plan (IHP) is developed for the child with medical conditions that need to be managed within the school setting.
- All children, including those with chronic conditions and special healthcare needs, are entitled by federal law to a free education that is matched to their developmental and functional capabilities.
- An individualized transition plan (ITP) is developed for adolescents with a chronic condition in collaboration with the family to assist in identifying appropriate support programs, living arrangements, and employment for adult life.
- Children with chronic health conditions require regular health promotion, health screening, and health maintenance care, as well as specialized health services to assist the child and family in management of the condition.
- The role of the nurse in caring for the child with a chronic condition includes providing health supervision from infancy to transition into adulthood, collaborating with the multidisciplinary healthcare team, partnering with the family to manage the child's care at home, referring the family to appropriate community services, assisting with planning for education services, promoting positive parenting behaviors and psychosocial adaptation and well-being of the child and family, and promoting growth and development of siblings.
- Nurses who specialize in caring for children with complex chronic conditions may experience compassion fatigue as they continue their efforts to meet the ongoing needs of these families.

Clinical Reasoning in Action

Haley is an 8-year-old child with cerebral palsy who will be attending school for the first time. Her mother had initially preferred home schooling for Haley and now wants to support her social development with other children. A case manager is asked to assist with facilitating Haley's entry into school. The case manager coordinates a multidisciplinary meeting of the clinic nurse, physical therapist, physician, and Haley's family to review her health status and to discuss the transition to school. They also discuss potential accommodations needed for Haley's mobility limitations. The multidisciplinary team assists the parents in developing a plan for Haley's transition to school.

1. What role will the clinic nurse and case manager have in helping develop Haley's IEP and IHP?
2. What role will the school nurse have with the child, caregivers, teacher, and classmates during the facilitation of school entry?
3. What actions will the mother need to take in preparing the school personnel for Haley's health needs?
4. Haley's 10-year-old sister attends the same school. What effects of Haley's entry into school might the sibling experience?

Chapter 13
The Child With a Life-Threatening Condition and End-of-Life Care

Michael Matisse/Getty Images

It all happened so fast. No one saw the car coming. Next thing I knew, we were in the emergency room talking about abdominal and head injuries. Now Alexa is in the intensive care unit, and I'm worried because she is still unconscious and on a ventilator. It was helpful for the nurse to tell me that even though Alexa couldn't respond, it was good to talk to her, because she will probably hear me and be comforted.

—Mother of Alexa, 6 years old

Learning Outcomes

13.1 Summarize the effects of a life-threatening illness or injury on children.

13.2 Examine the family's experience and reactions to having a child with a life-threatening illness or injury.

13.3 Identify the coping mechanisms used by the child and family in response to stress.

13.4 Develop a nursing care plan for the child with a life-threatening illness or injury.

13.5 Apply assessment skills to identify the physiologic changes that occur in the dying child.

13.6 Develop a nursing care plan to provide family-centered care for the dying child and family.

13.7 Plan bereavement support for the parents and siblings after the death of a child.

13.8 Evaluate strategies to support nurses who care for children who die.

The intense emotional and physical demands placed on the critically ill or injured child present a challenge to nurses' attempts to provide developmentally appropriate care. The child's parents and siblings are confronted with a stressful situation. A family-centered model of nursing practice offers a framework for performing interventions that help minimize stress and enhance coping by the ill or injured child, parents, and siblings.

Life-Threatening Illness or Injury

A **life-threatening condition** is one in which there is a likelihood that the child will die prematurely (Randall, Cervenka, Arday, et al., 2011). A threat to a child's life may be expected, as in a chronic illness or progressive disabling disease. More often, the death is unexpected as a result of an unintentional injury, the leading cause of death in children, or an acute illness. How children, parents, and siblings cope with the threat will depend on the anticipated or unanticipated nature of the event and the conditions surrounding the child's admission to the hospital.

When death results from a chronic disease or terminal illness, the child and family have time to adjust to episodes of life-threatening crises and impending death. Although the child could die unexpectedly during treatment, parents have some knowledge of the condition, the hospital setting, and the health-care team and have had an opportunity to become involved in the child's therapy as integral members of this team. Emergency

admission for an acute illness or unintentional injury, in contrast, brings with it sudden stressors as the child and family are thrust into an unfamiliar environment, confronted with frightening or invasive procedures, and faced with an uncertain outcome.

Nursing care of children and families coping with specific chronic diseases or terminal illnesses such as cancer, cystic fibrosis, or muscular dystrophy is discussed elsewhere in this text. The following discussion focuses on care of children with life-threatening illnesses or injuries and care of the dying child.

Child's Experience

Admission to the hospital, emergency department, or pediatric intensive care unit (PICU) is one of the most frightening experiences a child can have. Critically ill children may appear extremely anxious and fearful, or withdrawn, solemn, and preoccupied with their own physical condition. The illness or injury often brings pain, decreased energy, and changes to the affected child's level of consciousness.

Young children admitted to the PICU may be unable to understand what is happening to them. The PICU environment appears overwhelming, fast paced, and frightening, secondary to the numerous machines, noises, people, and procedures the child encounters. The child's normal sleep patterns can be disrupted because of the lack of day–night patterns in many intensive care units (Figure 13–1). Being cared for by strangers contributes to the child's anxiety. The child's limited ability to move intensifies feelings of powerlessness and vulnerability.

Children's responses to stress are influenced by their developmental levels, past experiences, types of illness, coping mechanisms, and available emotional support. Nurses must consider how their developmental level and coping skills will influence their ability to deal with the emergency department or PICU experience. Successful coping can provide these children with the skills to handle difficult situations in the future.

An unanticipated admission places the child at emotional risk because of the lack of preparation for the experience, the uncertainty and unpredictability of events that follow, the unfamiliarity of the environment, and the heightened anxiety of parents. An admission for an acute exacerbation of a disease such as cystic fibrosis or leukemia can provoke feelings of depression or hopelessness. Chapter 11 describes the stressors and responses to hospitalization of children by age group.

The child cared for in the PICU will experience the same stressors as any child who is hospitalized. However, the PICU environment is more intense and is very stressful for children. Treatment, disease, and/or environmental-related stressors place these children at risk for posttraumatic stress disorder. They are exposed to strangers, unfamiliar equipment, other sick children, and noises from alarms, phones, and pagers (Dow, Kenardy, Long, et al., 2012).

Figure 13–1 **Jooti feels pain, hears noises, has her sleep disrupted, and has limited mobility because of all the equipment attached to her.**

Coping Mechanisms

Coping refers to the cognitive and behavioral responses that help a person manage specific internal and external demands that exceed personal resources, enabling the person to solve problems and to respond appropriately. The child may mirror the parents' behaviors and responses, which may help or hinder the child's response to stress. The child's temperament, previous coping experiences, and availability of **support systems** (extended network of family, friends, and religious and community contacts that provide nurturance, emotional support, and direct assistance to parents) all combine to influence the child's ability to cope with the current experience.

The nature and severity of the illness and an emergency admission to the hospital stress a child's coping capabilities. Defense mechanisms displayed by children in these situations include **regression**, or return to an earlier behavior (a common reaction to stress), denial, **repression** (involuntary forgetting), postponement, and bargaining.

Nursing Management

For the Child With a Life-Threatening Illness or Injury

Nursing care of the child with a life-threatening illness or injury and the child's family includes assessing the child's physical and psychosocial needs, assessing the family's psychosocial needs, providing physical and psychosocial care for the child, and providing support for parental physical and emotional needs.

Nursing Assessment and Diagnosis

Nursing assessment involves physiologic parameters, plus skilled observation of the child's psychosocial and emotional needs. An understanding of normal psychosocial and cognitive development is necessary to plan developmentally appropriate interventions. Assessment should include the child's response to illness, the environment, coping strategies, and the need for information and support.

The accompanying *Nursing Care Plan* includes common nursing diagnoses for the child with a life-threatening illness or injury. The following nursing diagnoses may also be appropriate (NANDA-I © 2014):

- ***Communication: Verbal, Impaired,*** related to the effects of endotracheal intubation and mechanical ventilation
- ***Spiritual Distress*** related to the crisis of illness or suffering
- ***Sleep Pattern, Disturbed,*** related to circadian asynchrony, excessive stimulation, pain, and anxiety caused by the critical care unit environment
- ***Activity, Deficient Diversional,*** related to forced inactivity

Planning and Implementation

Nursing care focuses on promoting a sense of trust, providing education about the illness or injury, preparing the child for

Clinical Reasoning PICU Stressors

The PICU receives a call from a community hospital requesting transport for an unstable 12-year-old boy, Gavin, who is in status epilepticus. Gavin has a seizure disorder controlled with medications, but several days ago he decided to stop taking his medications. After receiving several medications in the community hospital emergency department to stop the seizures, Gavin experienced some respiratory depression. He has been intubated to maintain his airway until the medications wear off.

The transport team is in the air within minutes and arrives at the rural community hospital 25 minutes later. The team stabilizes Gavin, receives reports from the medical and nursing teams, meets briefly with his parents, answers a few questions, and is back in the air.

Gavin is admitted directly to the PICU and connected to cardiorespiratory and noninvasive blood pressure monitors. His existing intravenous lines and endotracheal tube are evaluated for patency as team members quickly complete a head-to-toe assessment. When Gavin's parents arrive, his nurse meets them and prepares them for what they will see.

What stressors do children like Gavin face after sudden admission to the PICU? What stressors will parents face during the initial period when you work with them?

procedures, facilitating the use of play, and promoting a sense of control. Physiologic care for the child in the PICU may include the following: frequent physiologic assessment, pain and sedation management, nutritional support, medication administration, management of multiple IV lines and pumps, maintenance of ventilatory and hemodynamic monitoring equipment, and wound care.

PROVIDE PSYCHOSOCIAL CARE FOR THE CHILD

Children admitted to a PICU need support for the stressful experience. They often feel and hear, even when unconscious, so touch and talking to the child are important. Nurses play a key role in providing developmentally appropriate support to the child. Nursing interventions are directed at building a trusting relationship, minimizing the stressors experienced by the child, and promoting coping. Ongoing reassessment of progress in meeting the child's needs is critical.

PROMOTE A SENSE OF SECURITY

For children of all ages, feeling secure depends on a sense of physical and psychologic safety. A sense of physical security is difficult to attain within the PICU because frequent procedures are part of the child's treatment plan. Parental presence at the bedside is one of the best ways to decrease anxiety and promote a sense of security. Including parents as partners in the child's care provides comfort and reassurance to the child. Children whose parents have high anxiety levels pick up their parents' emotional cues and become more anxious. Consistency of staff is

Nursing Care Plan: The Child Coping With a Life-Threatening Illness or Injury

1. Nursing Diagnosis: *Anxiety (Child)* related to separation from parents, unfamiliar environment, strangers as caretakers, invasive procedures (NANDA-I © 2014)

GOAL: The child will exhibit or express an increased sense of security.

INTERVENTION	RATIONALE
• Encourage parents to remain at the bedside (open visitation) and to participate in the child's care by touching, talking to, reading to, and singing to the child.	• Presence of the parents is comforting to the child.
• Talk with the child. Avoid discussions at bedside that the child should not overhear.	• The child may overhear and remember, even if unconscious.
• Offer to arrange a visit from the chaplain or other spiritual support.	• Spiritual support often provides comfort and sustenance in a time of crisis.
• Provide the child with developmentally appropriate explanations when possible. Encourage the child to ask questions and express concerns.	• Information reduces anxiety and builds trust.
• Make the child's bedside more personal and familiar by encouraging parents to bring in security objects, family photos, and favorite toys from home.	• Security objects decrease foreignness of hospital environment. The child derives comfort from presence of personal items.
• Involve the child in play appropriate to developmental age (see Chapter 4).	• Play provides familiarity, decreases fantasy, and provides motor activity.
• Provide care using a primary nursing care model.	• Consistency in healthcare givers helps to build the child's trust. Healthcare giver learns child's cues.

EXPECTED OUTCOME: Child will appear more relaxed and acknowledge parents' presence. Behavioral manifestations of anxiety will be absent. Restful periods of sleep will be noted.

2. Nursing Diagnosis: *Powerlessness* related to inability to communicate and control relinquished to the healthcare team (NANDA-I © 2014)

GOAL: The child or adolescent will have an increased sense of control over the situation.

INTERVENTION	RATIONALE
• Provide opportunities for choices when possible. Encourage participation in self-care.	• Such opportunities provide sense of control and autonomy through decision making.
• Prepare the child or adolescent in advance (timing dependent on developmental level) for procedures. Describe the sensations that will be experienced. Allow some choice in timing or method of pain relief.	• Providing information to children or adolescents lets them know what to expect. Allowing choices gives them a sense of involvement and lets them know their input is important.
• Provide routines for the child both within a 24-hour period and for scheduled care. Tell the child before the procedure (timing dependent on developmental level), repeat explanation of why procedure is necessary, complete procedure in a consistent manner, and offer praise or a special story when completed. When possible, incorporate rituals from home.	• Routines and rituals provide a sense of continuity and comfort for the child.
• Provide other means of communication to the intubated child (e.g., a word board or finger board).	• Fostering communication by some means helps the child maintain some sense of control.
• For the child requiring restraints or immobilizers, use as seldom as possible, provide appropriate explanations, and release at regular intervals. Wrapping IV lines well can help maintain lines and avoid the need for restraints.	• Release from restraints or immobilizers helps diminish the sense of powerlessness that accompanies their use.

EXPECTED OUTCOME: Child or adolescent will express satisfaction over ability to control some elements of situation. Child or adolescent will participate in self-care and decision making.

3. Nursing Diagnosis: *Pain, Acute,* related to injuries, invasive procedures, surgery (NANDA-I © 2014)

GOAL: The child will experience reduced pain and improved comfort.

INTERVENTION	RATIONALE
• Assess the child's pain location, intensity, and what makes it better or worse.	• Assessment provides baseline information from which a plan of care can be developed.
• If appropriate, use a pain assessment scale (see Chapter 15).	• Use of a scale provides continuity and consistency in monitoring of the child's pain.
• Provide optimal pain relief with prescribed analgesics. Provide comfort measures such as position changes and back rubs. Provide diversional activities as appropriate or possible. Incorporate the family in pain-relief modality.	• Physiologic and psychologic methods of pain control can be used in combination to maximally improve outcomes.

EXPECTED OUTCOME: Child will experience a perceived or actual improvement in comfort level.

invaluable in developing familiarity and a trusting relationship with the child.

Personalizing the child's bedside can promote comfort and a sense of security. Pictures from home, a favorite blanket or toy, music tapes, or posters can make the environment friendlier and more familiar to the child (Figure 13–2). Religious or spiritual symbols may also provide psychologic support.

PROVIDE EDUCATION AND PREPARE THE CHILD FOR PROCEDURES

The ability of children to understand the cause of their illness and its therapy depends on their cognitive abilities. Help younger children to understand that illness and hospitalization are not a punishment.

Preparation for procedures is important at all ages, even for the unconscious or sedated child. Toddlers will benefit from being talked to, soothed, and touched during and after the procedure. Provide preschoolers, school-age children, and adolescents with an explanation of the sensations they can expect to experience (temperature, vibrations, sounds, smells, tastes, sight). (See Chapter 11.)

FACILITATE THE USE OF PLAY

Play can be used to alleviate stress and to help prepare children for procedures. The nurse can also use play to assess the child's developmental level. Even within the PICU, therapeutic play diminishes negative fantasies, provides motor activity, and helps the child cope with stressors (see Chapter 11). Children with limited

Figure 13–2 **By their very nature, PICUs are ominous and sterile. To lessen this effect, it can help to personalize the child's space. Being there with the child and parent, answering questions, or just talking can be a comfort to both.**

mobility due to tubes and immobilizers can still feel a sense of accomplishment, for example, by completing a puzzle, even if the nurse points and moves each piece as the child responds through nods and gestures to indicate where the puzzle piece should be placed. Play can help children work through a painful situation, making it more tolerable. The child-life specialist may also be able to facilitate coping by assisting in preparation for procedures and providing distraction during procedures. See a discussion of the role of the child-life specialist in Chapter 11.

PROMOTE A SENSE OF CONTROL

Children between toddlerhood and adolescence experience a loss of control during a life-threatening illness. This loss of control may be related to the body, emotions, normal routines, or privacy. Nursing interventions should promote a sense of control over these areas.

Children hospitalized in an intensive care unit experience a heightened sense of loss of control secondary to the many machines, noises, and limits on mobility. These children often self-remove or threaten to self-remove technologic equipment or devices employed in their care such as an endotracheal tube, peripheral IV line or central line, nasogastric tube, or arterial line. Physical immobilizers are sometimes used in children with altered levels of consciousness to prevent them from pulling out tubes and lines. Although immobilizers are sometimes necessary, they contribute to the child's sense of powerlessness. Nurses should position these devices in a way that maintains comfort as much as possible.

Enhance the child's coping skills by teaching the child and family a combination of relaxation, visual imagery, or distraction techniques, and comforting self-talk phrases, such as "This will be over soon," "If I stay calm, it will be all right," and "It will be over fast so I can do something fun." Help the parents become the child's coping coaches.

Evaluation

Expected outcomes of nursing care include the following:

- A trusting relationship is developed with the child and family.
- The child is given preparation and support for procedures.
- The child's coping is promoted by family presence and therapeutic play.

Clinical Tip

The Joint Commission requires that hospitals have policies and procedures for the use of restraints or immobilizers and a plan to release them for short periods. Documentation in the medical record according to hospital policy is also required. Restrain all children as little as possible, and explain the rationale for immobilizers, emphasizing that they are not a punishment (see the *Clinical Skills Manual* SKILLS).

Parents' Experience of a Child's Life-Threatening Illness or Injury

The uncertainty and unpredictability of a child's life-threatening illness or injury challenge a family's coping and stability. Admission of a child to the pediatric intensive care unit is one of the most stressful events that a parent can experience (Jee et al., 2012). The sudden loss of the parenting role with the child's emergency admission causes stress. Families display many different responses and coping mechanisms such as crying, emotional outbursts, fear, and demanding information. Parents are at risk for long-term psychologic effects, including the development of posttraumatic stress disorder (PTSD), when the child is hospitalized in an intensive care unit (Jee et al., 2012). Parents may find it difficult to support the child if their own needs are not met. They may also transmit their anxiety to the child, who then becomes even more anxious. Family-centered care must be provided to meet the needs of parents with a variety of personalities, coping mechanisms, and responses to the crisis. Clear, concise communication is imperative.

The Family in Crisis

The critical care environment and the implications of a child's life-threatening illness or injury are far removed from the everyday experiences of most families. The unfamiliarity of the environment and the uncertainty and seriousness of the illness or injury create a **family crisis**, which occurs when the family encounters a problem that seems insurmountable and usual coping skills are not effective.

Since families have little time to prepare for the experience, a sudden admission threatens family integrity, causing enormous stress and separation from loved ones. The interruption of the unique parent–child relationship can be more stressful to parents than the physical PICU environment. Siblings are also affected. See the section titled *The Siblings' Experience* later in this chapter. In addition, extended family members such as grandparents must be considered. Stresses are further intensified in the case of divorce, separation, and stepparenting. Financial problems, a long distance from home to hospital, or another ill or injured family member can compound the crisis.

Clinical Tip

In addition to dealing with the child's life-threatening condition, parents may need to quickly arrange for the care of other children. For example, the child's siblings may be at band practice or other activities and a ride home must be planned. Parents must decide if one of them will leave the hospital to pick up the siblings and inform them about their brother's or sister's illness/injury, or whether a family member or friend will do it for them. This decision may not be easy and will depend in part on the condition of the hospitalized child. The parents may need assistance to make these arrangements when they are in a state of crisis.

Parental Reactions to Life-Threatening Illness or Injury

When faced with a threat to their child's life, parents typically progress through stages that might include shock and disbelief, anger and guilt, deprivation and loss, anticipatory waiting, and readjustment or mourning. Some families progress through these stages in a linear fashion, whereas others go back and forth between stages, especially if the child's condition improves and then worsens.

SHOCK AND DISBELIEF

The universal reaction to a child's life-threatening condition is shock and disbelief. As the familiar is disrupted, parents experience a loss of control, an inability to regain their bearings, and feelings of immobility. The hospital environment, emergency department, or PICU may seem unreal. The emotions parents experience initially are intensified by the physical appearance of their child (particularly after a major injury); the presence of monitors, tubing, and equipment; and the actual injury or illness.

Shock and disbelief begin in the first few moments after hearing the "news" and can last for days. The shock helps postpone the full impact of the crisis. During this period, parents search for answers and explanations about the illness or injury. Information must be repeated many times to parents, since in this stage they are often unable to assimilate information easily.

ANGER AND GUILT

Anger and guilt surface as parents become more aware of their child's illness or injury. Their anger may be directed toward themselves or each other because they could not protect the child. Other individuals may be blamed, such as the driver of a motor vehicle who injured the child. Parents may also be angry with their child. This anger may be a result of injuries the child sustained when breaking known rules, such as drinking and driving, playing with matches, or riding a bike without a helmet. Last, the anger may not be directed at anyone specifically. Injuries caused by natural disasters such as an earthquake, flood, or hurricane provoke just as much anger as those that result from the actions of people, and they may pose a challenge to the parents' spiritual beliefs.

Parents typically react to their child's illness or injury with some degree of guilt. This reaction may be magnified in the PICU environment. The fact that the guilt usually has no basis in real events does not lessen the feeling. A question parents frequently ask at this stage is, "Why not me instead of my child?" Parents' feelings of guilt may be related to the following:

1. They may feel responsible for causing the illness or injury. A statement such as "If only I hadn't sent him to the store on his bike, this wouldn't have happened" reflects feelings of guilt for causing or failing to prevent the injury.
2. They may feel guilty about not noticing the onset of an illness or disregarding earlier illness symptoms. The mother of a 1-year-old with meningitis might repeatedly say, "I shouldn't have waited so long to take her to the doctor!"

DEPRIVATION AND LOSS

As the shock associated with the child's life-threatening condition slowly recedes, new stressors emerge. Within minutes or hours, parents are deprived of their familiar role as the parent of a healthy child and find themselves in an unexpected and unfamiliar role as the parent of a critically ill child.

The difficulty and ambivalence parents feel in releasing a part of their responsibility as the child's primary caretakers can threaten their self-esteem and self-control. If parents cannot participate in the child's care, they may feel helpless or worthless.

ANTICIPATORY WAITING

When the child's condition is stabilized and survival seems likely, parents often move into a period of anticipatory waiting. This stage is characterized as "life suspended in time." Parents spend a great deal of time waiting: for test results, for explanations, for their child to become conscious, or for surgery to be over. Parents may fear leaving the area because they may miss an important procedure, healthcare provider visit, or decisions or changes in treatment. Lack of mobility decreases the parents' use of typical coping mechanisms, so anxiety and the sense of powerlessness may increase. If the parents have a cell phone, write down the number and ensure them that they will be called for any change in the child's condition. This allows parents to feel like they can leave at least for a few minutes. If the parents do not have a cell phone, provide a pager if available.

Parents may have a preoccupation with medical details. During this period, they may ask questions about the long-term effects of the illness or injury on the child, about the potential for brain damage, or about the need for additional surgeries. Parents may place demands on staff and be frustrated when the child's progress is slow.

READJUSTMENT OR MOURNING

The last stage that parents experience is readjustment or mourning. Readjustment is experienced as the child recovers, improves steadily, and prepares for transfer and discharge. In contrast, parents of the child who dies reenter the cycle of emotions characteristic of grief. Parents also mourn when the child remains seriously ill or unresponsive, when the outcome remains uncertain for an extended period, or when long-term care is required.

Table 13–1 lists the most important needs of parents when a child is hospitalized with a life-threatening illness or injury.

Nursing Management

For the Parents of a Child With a Life-Threatening Illness or Injury

Nursing care of the family includes assessing the family's psychosocial needs and providing support for parental physical and emotional needs.

Nursing Assessment and Diagnosis

Nurses who work with families of critically ill children have a unique opportunity to help them adapt and to promote family functioning. Begin by assessing the family's reaction to the illness, coping skills, stressors, and needs. (See Chapter 12.) This initial assessment provides a baseline of information for developing a care plan and strategies to meet the psychosocial as well as physiologic needs of families.

Several nursing diagnoses may apply to parents who are dealing with their child's life-threatening condition. Examples include the following (NANDA-I © 2014):

- ***Family Processes, Interrupted,*** related to the impact of a critically ill child on the family system
- ***Spiritual Distress*** related to the child's life-threatening condition, suffering, or death
- ***Fatigue*** related to extreme stress, sleep deprivation, and crisis

TABLE 13–1 Nursing Interventions to Meet Parental Needs When a Child Is Hospitalized With a Life-Threatening Illness or Injury

PARENTAL NEEDS	NURSING INTERVENTIONS
Information	• Provide information and frequent updates about the child's condition using terminology that parents can understand. • Repeat the information and provide other materials frequently because parents forget or cannot concentrate on details with all the stress they are under. • Explain the child's condition, equipment being used, and procedures of care. • Facilitate a discussion with the healthcare provider at least daily. • Provide general information about unit policies, team members, and phone numbers.
Proximity to their child	• Provide permission for the parents to remain at the bedside. • Encourage parents to touch and speak with the child and demonstrate ways if parents are hesitant. • Work within the unit to provide open, flexible visiting hours.
Reestablishment of their parental role and control	• Implement family-centered care so parents feel recognized as important to their child's recovery and as the decision maker for the child's treatment options.
Participation in their child's care	• Encourage parents to participate in care (e.g., bathing and hair care, diaper changes, feeding, range-of-motion exercises, massages). • Encourage parents to help with diversional activities (e.g., reading, singing, telling stories). • Encourage parents to explain equipment and procedures to the child to reduce the child's fears.
Confidence in the treatment plan and caregivers	• Try to maintain continuity in staffing and healthcare contacts. • Demonstrate caring for the child. • Provide assurance that the child is receiving appropriate treatment and pain management.
Psychologic support	• Acknowledge that the situation is difficult. • Help parents focus on the positive or unchanged aspects of the child's appearance. • Encourage parents to get rest and nutrition to help them maintain physical resources necessary for coping. • Provide space and privacy as needed. • Give hope if realistic—an essential component of coping. • Offer the choice of other family members to be present. • Discuss the possible responses of siblings and the long-term emotional responses of the patient.

- ***Hopelessness*** in parents related to the child's deteriorating physical condition
- ***Grieving*** related to potential death of the child or loss of body functions
- ***Coping: Family, Compromised,*** related to the severity of the illness or injury in the child

Planning and Implementation

Nursing care focuses on providing family-centered care to help meet the needs of families, minimize stress, and enhance family coping (see Table 1–1). Nurses are challenged to blend and balance technology with caring.

PROVIDE INFORMATION AND BUILD TRUST

Orienting parents to the hospital, as well as to the unit routines, helps them adapt to their surroundings. Parents will gain a sense of control and independence if they know where to get supplies and how to find the lounge, cafeteria, and restrooms.

Provide frequent and accurate information. Deliver information on the child's illness, condition, and plan of care in a manner and language readily understandable to parents. Upon admission, provide the parents with an idea of what to expect in the days ahead and to be prepared for special procedures or major changes in therapy. Parents also need to be prepared before they see the child the first time. Explain the tubes and monitors that are present and how the child will look and react.

Honesty in discussions is extremely important. If parents feel misled or that information is being withheld, a trusting relationship will be impossible. However, informed parents will feel that they are active participants in decision making and care planning for their child. Trust is facilitated when parents believe that the staff truly cares about the child and sees the child as a special individual. Trust is especially important when difficult decisions must be made, such as withdrawal of life support, or to reduce the risk for conflict.

Parents also need a sense of hope regarding their child's condition to help them cope. Focus on the positives as the child progresses through the different phases of the life-threatening condition.

Clinical Tip

Explain to the child and parents, in easy-to-understand terms, the purpose of equipment that is being used. Answer alarms quickly regardless of the reason for the alarm. Follow with an explanation of why alarms sound, including the fact that many times monitor alarms will sound when the child moves, if the monitor becomes disconnected, or if the monitor patches are loose.

FACILITATE POSITIVE STAFF–PARENT RELATIONSHIPS AND COMMUNICATION

Given the intensity of the parents' experience when their child is critically ill, it is easy to see how problems can arise between staff and parents. Each healthcare team member must be aware of the child's current status so that parents receive consistent information from all staff. A consistent message can instill confidence. Provide explanations geared to the parents' level of understanding, using language the parents can understand.

Introduce the parents to the nurse and the intensive care physician who have overall responsibility for the child's care. This is especially important in teaching hospitals that have rotating interns and residents. The attending physician with the overall responsibility should meet with parents as often as necessary to talk about changes in the child's condition or treatment plan and to allow time for parents to ask questions (Figure 13–3). Encourage parents to keep a daily log or notebook to record information on the child's care, progress, and needs, as well as questions they want to ask. Family care conferences can be helpful when a large number of team members provide care. Arrange for daily visits by an interpreter if the family does not speak or understand English. Have information about the child's condition and care summarized for communication at that time.

PROMOTE PARENTAL INVOLVEMENT

An important role of nurses is to encourage and support parents in their parenting role. The parents' place when possible is at the bedside. Parents can provide comfort to their child and can assist in explanations that offer reassurance to their child. They may also be able to assist with basic care needs such as bathing and changing diapers (Ames, Rennick, & Baillargeon, 2011). Parents provide continuity and may notice subtle condition changes that an assigned nurse may miss. Throughout the child's hospitalization, parents will continue to need reassurance and encouragement.

Participation in care of the child is an integral aspect of family-centered care and enhances the family's ability to cope with the child's illness or injury. Open communication with the family about the child's treatments and plan of care is essential. Parents need to know how their child is doing, understand the care being provided to their child, and know what to expect next (Ames et al., 2011). Parents who do not remain at the child's bedside may feel that they are not an important team member. When parents are unable to remain at the bedside, they should be allowed to call the unit at any time to check on their child.

Figure 13–3 **In times of crisis, everyone likes to know that someone is in charge and who that person is. The parents should meet and talk with the healthcare provider in charge and the nurses as often as possible. Parents need to know that someone is responsible, even if different people are providing care.**

FAMILY PRESENCE DURING RESUSCITATION AND INVASIVE PROCEDURES

Many hospitals are implementing policies that permit families to be present during resuscitation and invasive procedures. Healthcare professionals have expressed concern that parents who are allowed to witness resuscitation efforts might lose control and interfere. Another concern is that medical staff, especially those in training, might feel uncomfortable, and that there is an increased risk for litigation. However, reports related to family presence during resuscitation have failed to demonstrate any increase in litigation (Jabre et al., 2013). Families have reported that they felt being present during resuscitation and invasive procedures helped their child and helped them (Meert, Clark, & Eggly, 2013). In addition, studies have failed to show that family presence interrupts care or interferes with the healthcare providers' ability to intervene in the care of the child (Emergency Nurses Association [ENA], 2012).

The Emergency Nurses Association supports the option of family presence during invasive procedures and resuscitation (ENA, 2012). Parents and other family members (e.g., grandparents) may wish to be present during invasive procedures (such as lumbar puncture) or resuscitation of the child. The nurse partners with the family to determine their needs at the time. To better facilitate the needs of the family, the following should be determined:

- Who desires to be present during resuscitation or invasive procedures?
- What role will they play during the procedure (e.g., snuggle child for comfort)?

Healthcare agencies should have an established policy for family presence during invasive procedures or resuscitation (ENA, 2012). Care must be family centered and individualized to each situation according to the child's and family's needs. A designated healthcare professional should be available to stay with family members during resuscitation and provide comfort and explanations as needed (ENA, 2012).

Clinical Tip

If parents choose not to witness the resuscitation, regular updates (5- to 10-minute intervals) should be provided to the parents as they wait in a private area. A hospital chaplain or other family support team member should support the parents while they wait.

PROVIDE FOR PARENTAL PHYSICAL AND EMOTIONAL NEEDS

The experience of having a child with a life-threatening condition drains the parents' physical and emotional reserves. Parents often need encouragement to take care of themselves and to periodically take a break. A statement such as "It is important for you to eat and rest because Alexa is really going to need you when she wakes up" helps parents realize that becoming exhausted benefits neither them nor the child.

Many communities have a residence for families of hospitalized children. This is often an inexpensive but warm and supportive environment for families. The Ronald McDonald Children's Charities supports many of these residences. A Ronald McDonald Family Room may be found in some hospitals and is provided as a comfortable setting where families of hospitalized children can get away from the high-tech hospital atmosphere while remaining close to the child. Computer resources in one of these locations or in a Family Resource Center may make it possible for parents to stay in contact with concerned family and friends. When financial burdens are a consideration, parents may need family support and social service referrals.

Parents are often at different levels of coping during a crisis. The severity of the child's illness or injury may foster cohesion between the parents and build a stronger relationship. Unfortunately, the reverse may also be true—differences in styles or levels of coping may foster a sense of isolation, placing a strain on the couple's relationship. Nurses should be alert to family dynamics and refer the family for counseling or therapy if indicated.

MAINTAIN OR STRENGTHEN FAMILY SUPPORT SYSTEMS

Support systems enable parents to cope with overwhelming problems and crises. Most parents indicate that having family or friends nearby is crucial as a support system. Some families seek support through prayer and from religious or faith-based leaders.

Extended family, especially grandparents and friends, frequently offer the family assistance, but parents may need to be reassured that it is all right to ask for help as well. Some parents are uncomfortable asking for help, instead attempting to handle multiple responsibilities themselves, often to the point of exhaustion. Some parents are so overwhelmed that they are unable to respond to offers of help because it requires too great a mental effort on their part. The nurse should assist the parents in responding to these offers for assistance.

Nurses may need to intervene on parents' behalf when they have inadequate support. Parents may be frustrated by people who come to visit unannounced, stay too long, or visit too often. They may find it difficult to tell well-meaning but insensitive friends that they cannot deal with visitors right now. In these situations, it may be helpful for the nurse to offer to serve as a gatekeeper. Suggest that parents inform family and friends about specific times for visits or phone calls to allow for rest periods. An extended family member may be given the responsibility of relaying information to others.

Families of children with a life-threatening illness or injury often have emotional needs beyond the support capabilities of the nurse caring for the child. Referrals to family and support services or pastoral care may be beneficial in these instances.

Evaluation

Expected outcomes of nursing care include the following:

- The nurse establishes a trusting relationship and effective communication with the family.
- Parents participate in their child's care as much as desired.
- Parents and extended family members receive emotional support and nurturance needed to sustain them through the child's illness.

The Siblings' Experience

As the parents' focus shifts to the critically ill child, they may need support in dealing with the healthy siblings. Siblings of a critically ill child may experience stress related to parental absence, being cared for by others, changes in routine, and lack of information about their ill sibling (Meert et al., 2013). Nurses should recognize that siblings may fear becoming ill themselves or believe that they played a role in the child's illness. Siblings often have nightmares about the illness or injury their brother or sister has sustained and about the ill child dying. Inform siblings about their brother's or sister's condition using language and concepts appropriate to their ages and developmental levels. Being allowed to visit the sick child may help siblings to cope (Meert et al., 2013).

Before the visit, talk with the siblings about what to expect and describe how their brother or sister will look. If the ill child acts, moves, talks, or looks different than usual, provide an explanation beforehand. Describe the hospital environment, including equipment, sounds, and smells. Use a doll, draw pictures, or show an actual picture of the child to prepare the siblings. See *Families Want to Know: Strategies for Working With the Sibling of a Hospitalized Child* in Chapter 11. The child-life specialist may also be able to assist in preparing siblings for a visit to the intensive care unit (see Chapter 11).

During the visit the nurse should demonstrate how to talk to and touch the ill child and encourage the siblings to do the same (Figure 13–4). The length of the visit should be relatively short

Figure 13–4 **During the sibling's visit to the ill child, it is important to talk with the sibling and answer any questions in an honest manner at a level the child can understand.**

Figure 13–5 **It is important that parents and siblings feel comfortable communicating with the seriously ill child. If siblings cannot visit, they should be encouraged to paint or record messages. They need to be able to express themselves and to feel that they are helping.**

and based on the child's developmental age. After the visit, the nurse should talk with siblings about what they saw and felt, and answer their questions. When a sibling cannot visit, contact with the ill child can be maintained by sending pictures, drawings, cards, and messages recorded on audiotapes or cell phones if allowed (Figure 13–5).

If parents are staying at the hospital with the ill child, encourage them to call the siblings at home daily. This allows the siblings at home to feel connected by the opportunity to share their day and to receive an update on the ill child. The phone call offers siblings a consistent link to the parents and the reassurance that they are important and loved. Internet contact or text messaging may be another way to communicate with older siblings. Arrange for parents to access a computer, if possible, for families who might find this contact supportive.

Evaluation

Expected outcomes of nursing care include:

- Siblings are prepared for visits to the child with a life-threatening illness or injury.
- Siblings receive emotional support and assistance to cope with the unfamiliar environment.

End-of-Life Care

When the family is faced with end-of-life decision making and care because of a child's chronic condition or multiple acute care episodes, the family needs honest information about various treatment options and potential outcomes. Depending on cognitive abilities, developmental stage, physical and mental status, and prior experiences with health care, the child may also participate in the decision-making process. The family may need to consider issues such as palliative care, hospice care, do-not-resuscitate requests, continuation of schooling, organ/tissue donation, and autopsy.

Palliative and Hospice Care

Pediatric **palliative care** is a multidisciplinary care approach for children with life-shortening disorders and their families. It is intended to relieve suffering of all types (physical, psychologic, spiritual, and social); to enhance quality of life for patients and their families; to facilitate informed decision making by the patient, family, and healthcare professionals; and to improve care coordination (American Academy of Pediatrics [AAP] Section on Hospice and Palliative Medicine and Committee on Hospital Care, 2013). Palliative care may be provided along with curative care, life-prolonging care, or as the main focus of care. Palliative care may be seen as the holistic care provided to a child until the family decides to view dying as a natural process and stops curative care (Trotzuk & Gray, 2012). Children may require these services for many years.

Hospice is a form of palliative care that is provided by licensed agencies. For children it is most often provided in the home but may also be provided in special centers or the hospital. Federal regulations outline the required bundle of services that include nursing, healthcare provider, psychosocial, and spiritual services; medications; durable medical equipment; and a range of diagnostic tests and therapeutic interventions (AAP, 2013). Hospice care is provided to the child near the end of life, and it is focused on supporting the family and ensuring that the remaining time for the child is lived as comfortably and as fully as possible.

About 75% of all children who die each year in a hospital, often in an intensive care unit from a life-threatening condition, do not have palliative or hospice care management (Keim-Malpass, Hart, & Miller, 2013). It is estimated that 5000 children in the United States on any day are within the last 6 months of dying and could benefit from palliative or hospice services (Crozier & Hancock, 2012). These services are also an option for neonates on the edge of viability.

When a child receives hospice care, the family and healthcare providers collaborate to determine which treatments are appropriate to continue with the child's end-of-life care, such as IV fluids, gastrostomy feedings, and certain medications. The child is maintained as alert and comfortable as possible. Hospice also provides grief counseling and support to parents for 1 year following the death of the child. See *Evidence-Based Practice: Responding to the Needs of the Family*.

Ethical Issues Surrounding a Child's Death

Because the death of a child is so emotionally charged, misunderstandings and conflicts can develop between families and healthcare providers. The more common ethical issues that need to be addressed include withdrawing or withholding treatment, parental treatment refusal, and do-not-resuscitate orders.

Brain Death Criteria

A commonly accepted definition of death in the United States is **brain death**, the irreversible cessation of all functions of the brain. Specific medical protocols are used to declare brain death before

EVIDENCE-BASED PRACTICE | Responding to the Needs of the Family

Clinical Question

The families of children with life-limiting conditions often have difficulty expressing their needs for support. What are some of the most important focus areas for nursing support in palliative care programs for children and their families?

The Evidence

A survey of 50 parents whose child died as a result of advanced heart disease in the intensive care unit setting was conducted to gain information about the care provided at the child's end of life. The majority of parents (66%) believed they had little or no preparation for the way their child died or about the child's medical problems in the last month of life. Many (40%) reported receiving conflicting information from the child's healthcare team about expectations of the child's end of life. Parents (66%) reported that the child's quality of life was poor to fair during the final month, and half of children experienced suffering. Most did not realize their child would not survive until death was imminent, indicating a gap in understanding the child's prognosis (Blume et al., 2014).

A pilot study explored a method to promote advance care planning for 30 adolescents (with a mean age of 16 years) with cancer and a parent. Dyads were randomly assigned to the intervention group or control group. The control group received a brochure about advance care planning and no additional information. Six different end-of-life scenarios with possible care options for additional medical interventions or limiting treatment were provided by the research team during education and data collection sessions. Intervention adolescents were encouraged to write five wishes for their own care if a bad outcome were to occur in the future. Adolescents in the intervention group were significantly better informed about advance care planning, and adolescent–parent dyads were more likely to agree about when to limit treatment than control dyads. The intervention adolescents (100%) wanted their parents to select the best option at the time compared to control adolescents (60%) (Lyon, Jacobs, Briggs, et al., 2013).

A focus group qualitative research process was used to help plan a legacy-making project. Eight children (7 to 12 years old) with cancer and their parents were asked to provide feedback to the legacy-making project and the questions that would guide children when they shared their story. Children wanted to participate, and said they wanted to leave a story in which others would know or remember their personal characteristics, things they like to do, and the important people in their lives. Based on feedback, questions were revised to help guide the script for a customized digital story that a child could develop (Akard et al., 2013).

Best Practice

Palliative care professionals continue to seek evidence-based care interventions to support children and families with life-limiting conditions. The previously mentioned studies reveal challenges in care and strategies to support patients and families. Each of these topics was consistent with major themes found in systematic analysis of 21 qualitative and survey-based studies about patient and family needs. These included accurate and clear information about the child's illness, treatments, and prognosis; spiritual needs and ways to remember the child after death; and decision making with regard to treatment decisions (Stevenson, Achille, & Lugasi, 2013).

Clinical Reasoning

When in a clinical setting where children with life-limiting conditions receive treatment, seek information about the resources and strategies used by the palliative care team to meet the needs of children and their families. What additional resources would be helpful for nursing support in this population?

withdrawal of life support or when organ transplantation is planned. To declare brain death, the child must be unresponsive in an irreversible coma from a known cause and have absence of brainstem reflexes, and apnea testing must reveal hypercarbia. Before an evaluation for brain death is performed, it is confirmed that the child does not have hypothermia, conditions, or medications that could contribute to brain death findings. The two required examinations by different healthcare providers for brain death to be declared are separated by 24 hours for newborns and 12 hours for infants and children (Nakagawa, Ashwal, Mathur, et al., 2011).

Withdrawal of or Withholding Treatment

The decision to withdraw or withhold life-sustaining treatments, such as mechanical ventilation or dialysis, from the dying child is very difficult and emotional for parents. Parents may feel that agreeing to withdraw treatment is a form of abandonment. When treatments are withdrawn, reassure parents the child will receive comfort measures, including pain medication. Reinforce the fact that the underlying disease process is causing the child to die rather than withdrawing life-sustaining treatments.

Medically provided nutrition and hydration (through nasogastric or gastrostomy tubes and IV catheters) support a child's existence at the end of life, but research has not demonstrated an association with survival or improved quality of care (Rapoport, Shaheed, Newman, et al., 2013). Food and fluids may be withheld when they would be of no benefit to the child, but this is a difficult decision for parents because food and fluid are associated with nurturing and love.

Conflicted opinions often develop if parents and the healthcare provider are unable to discontinue aggressive therapies that may also cause discomfort. The nurse may experience moral distress, believing that the child's suffering is being extended without much hope for improvement. Consultation with a member of the hospital ethics committee can help clarify the issues involved and reduce the emotions of healthcare professionals associated with the conflict. During the consultation an unbiased professional collects facts about the child's condition, clarifies the beliefs and values of parents and healthcare professionals, and improves communication while investigating options for compromise. Families are often invited to a meeting in which

the ethical dilemmas regarding their child's care are discussed so they are better informed to make decisions.

Developing Cultural Competence **End-of-Life Care**

Discussing the option with parents about withholding or withdrawing therapy is challenging as they are struggling to accept that no further curative care is possible for their child. The focus becomes what is best for the child within the context of the culture, faith, and values of the family. Latino families may believe that all care and every effort should be provided to their child. African American families with a strong Christian belief may want all efforts continued in the hope of divine intervention. Palliative care with a focus on reducing suffering, promoting comfort, and providing information about end-of-life care planning may not be viewed by these families as the best care (Wiener, McConnell, Latella, et al., 2013).

Do-Not-Resuscitate Orders

Parents faced with a child's end-stage, irreversible life-limiting condition may be asked to consider a do-not-resuscitate (DNR) order. Terms becoming more common are **"allow natural death" (AND)** and comfort care, which involve the continuation of ongoing care, managing pain, and choosing not to initiate cardiopulmonary resuscitation if the child stops breathing or the heart stops beating. Medical care is not discontinued; rather the DNR order is part of the child's management plan. Palliative care is provided, and, in some cases, curative care continues for these children.

A DNR order is part of advance care planning. A recent survey of healthcare providers and nurses revealed that advance care planning discussions often occur later in the child's care than they should, either during an acute illness or when death is imminent rather than during a period of stability (Sanderson, Zurakowski, & Wolfe, 2013). This planning process is becoming more important in pediatrics because of the increasing number of children with complex health conditions that have a variable but prolonged disease trajectory that leads to death. Honest and compassionate discussions between healthcare professionals and families, including adolescents, should occur. The family should be informed about significant condition changes and what to expect. Time should be provided for the family and adolescent to consider what is important to them at the end of life. Families can participate in planning the child's end-of-life care with healthcare providers.

The Americans with Disabilities Act of 1990 and the Education for All Handicapped Children Act mandate that all children with disabilities—including those with complex chronic conditions and terminal illnesses—are entitled to the same education as other students. It is estimated that in the United States nearly 4000 children and adolescents attend school and may be within 6 months of dying from their chronic condition (National Association of School Nurses, 2014). These children may be at higher risk of dying while at school, and many school districts have established policies and protocols for dealing with a student's DNR order. Advance planning with an individualized health plan and emergency care plan are needed for the school setting.

Professionalism in Practice **DNAR Order in the School Setting**

The National Association of School Nurses' position statement on Do Not Attempt Resuscitation (DNAR) provides guidelines for the development of a plan for students who have such an order. The school nurse should work with the family, school administrators, the child's healthcare team, local emergency medical services providers, and others such as a local funeral director to develop plans for the supportive response when a child has an arrest. This plan is spelled out in the child's individualized health plan. The nurse must also educate school personnel about the planned response and their role, permitting discussion about their feelings concerning a child's death in the school setting. Keep in mind that a plan for bereavement support of faculty, staff, and students should also be developed for implementation when a child dies (National Association of School Nurses, 2014).

Care of the Dying Child

Caring for a dying child is challenging and requires the utmost sensitivity and compassion. Children as young as 5 years of age can sense when they are seriously ill. Their awareness of death develops more rapidly when they are experiencing the progression of a disease and ongoing medical treatment. Children with life-limiting illnesses often learn about death and their own illness from exposure to other seriously ill and dying children during hospitalization or clinic visits.

Awareness of Dying by Developmental Age

Infants and toddlers are not actually aware of death, but they are aware of and react to changes in normal routines and the behavior of parents. Toddlers know they feel tired and sick, but they do not understand that their physical symptoms are associated with impending death (Figure 13–6).

Preschool children can see their bodies deteriorate and feel the effects of medications used during disease progression and treatment. Changes in self-concept occur as they perceive these body changes. They often describe their illness in terms of mutilation to their body. These physical changes may make them realize that they are dying.

School-age children also have subtle fears about body integrity and anxieties about the seriousness of their illness. This greater preoccupation with illness is considered by many professionals as the child's version of **death anxiety**, a feeling of apprehension or fear of death. Children may express death anxiety as a concern with treatments that invade the body or interfere with normal body functions.

Adolescents have a mature understanding of death, but the normal developmental milestones of adolescence add to their problems in facing a terminal illness. They are struggling to establish their own identity and plans for the future. At a time when body image is extremely important, they may be faced with the possibility of mutilation and disfigurement. Dying adolescents are often isolated from their peers during a period when peers are the most essential social group. Adolescents nearing the end of life may be angry because they recognize that their loss is occurring at a time when the whole world is opening up to them.

Figure 13–6 **The toddler with a life-limiting condition recognizes that he feels sick and that routines are different. His anxiety may increase because of the concern and feelings of sadness exhibited by his parents.**

Do not expect adolescents to handle feelings in the same way that adults do. They often avoid expressing anger against the family, seeking to control and direct these feelings elsewhere. Adolescents may become angry at changes in treatment procedures, lack of explanations, and threats to their independence. As death nears, the adolescent may permit comforting and support and may accept care from warm and loving family members, as long as it is not given in a condescending manner.

Nursing Management

For the Dying Child

Nursing care of the dying child and family focuses on providing family-centered support for their physical and psychosocial needs.

Nursing Assessment and Diagnosis

Assess the child's physiologic status and comfort level. Physiologic changes in the dying child may be directly related to the child's disease process or injury. Signs and symptoms of approaching death are provided in Table 13–2.

Assess the child's awareness of impending death. Examples of questions the child may ask include: "What will death be like? Will it hurt? What happens to me when I die? Will I be with [a deceased person whom the child was close to] again? Will my parents be all right? Will you remember me?" Assess the ability of the parents to talk with the child about dying.

TABLE 13–2 Clinical Manifestations of the Dying Child

SYSTEM	CLINICAL MANIFESTATIONS
Cardiovascular system (decreased cardiac output and peripheral circulation)	• The heart rate may initially increase as hypoxia develops; then the heart rate and blood pressure decrease. • A change in pulse pressure and a decrease in the volume of Korotkoff sounds indicate imminent death. • Diaphoresis, clammy cool skin, and changes in skin coloring (mottled to cyanotic). Mottling is a sign of imminent death.
Respiratory system (pulmonary congestion due to impaired cardiac function)	• Tachypnea, diminished breath sounds, and hypoxia. • Dyspnea; **air hunger**, the most severe form of dyspnea, may cause the child to look panicked, gasp for breath, and sit upright; it may not be relieved by oxygen. • Cheyne-Stokes breathing (periods of shallow breathing alternating with apnea) is a sign of imminent death. • As muscles relax, secretions accumulate in the oropharynx and bronchi causing noisy breathing as air passes through the secretions. • Moaning or grunting with breathing is common.
Neurologic system (neurologic dysfunction due to decreased cerebral perfusion, metabolic acidosis, and accumulated toxins from renal and liver failure)	• Hypoxemia. • Agitation or restlessness, withdrawal, increasing drowsiness, confusion. • May be unconscious during final hours. • May speak of visions (persons or objects) not visible to others. • Deterioration of hearing and vision acuity. Remember that hearing is one of the last senses to diminish before death.
Musculoskeletal system	• Extreme muscle weakness and fatigue. • May be unable to reposition self or toilet self. • Difficulty swallowing; may be unable to cough effectively and clear secretions.
Renal system (decreased renal function)	• Decreased urine production. • Sphincters relax and incontinence can occur.
Gastrointestinal system	• Decreased oral fluid intake and anorexia are common. • Sphincters relax and bowel incontinence can occur.

Assess the family for coping skills and need for social supports. Identify any cultural or spiritual traditions, rituals, and beliefs related to loss and grieving that may provide comfort to the family.

Examples of nursing diagnoses that apply to the dying child and family include the following (NANDA-I © 2014):

- ***Fear (Child)*** related to unanswered questions and concerns of abandonment
- ***Anxiety, Death (Child),*** related to own impending death
- ***Grieving (Parents)*** related to imminent death of child
- ***Hopelessness (Parents)*** related to failure of therapies to prolong life

Planning and Implementation

Nursing care for the dying child and the family includes providing comfort, assisting the child in a peaceful death, assisting the child and family with coping strategies, and facilitating grief.

PHYSIOLOGIC CARE

A major goal in care of the dying child is to promote comfort and keep the child pain free. Opioids may be prescribed to promote optimal pain relief. Oral, transdermal, or rectal analgesia is available for families who choose to withhold IV fluids. Complementary therapies for comfort and pain management can be used by the nurse and family members (see Chapter 15).

If dyspnea, or air hunger, occurs, position the child to maintain the airway and promote breathing. Open a window or use a circulating fan to ease the child's distress. An opioid may be prescribed for air hunger or tachypnea as its action dilates the pulmonary vessels, reduces oxygen consumption, and decreases pulmonary congestion.

Other physiologic care includes keeping the airway clear of secretions, bathing and keeping the skin dry and intact, changing the child's position frequently, and encouraging favorite foods and liquids as tolerated. Decrease excessive stimulation and reduce unnecessary activities. Involve the parents in physical care and encourage them to hold and comfort the child.

COMMUNICATING WITH THE CHILD ABOUT HIS OR HER IMPENDING DEATH

The dying child may be aware of impending death before being told, and parents may not understand this. When the child has no opportunity to talk about death, the child may feel isolated and distressed. The child may believe that initiating the conversation about an awareness of death and related fears will add to the family's emotional burden.

Some parents wish to protect the child from bad news and avoid talking to the child about the child's serious illness and potential death. Parents often do not know how to talk with their child about dying. Some parents feel emotionally unable to answer the child's questions about dying. They may fear that talking about the impending death will take away the child's hope. A professional who has special training in bereavement counseling can assist children and families with the discussion. When the family is ready to talk with the child about the child's death, suggest some developmentally appropriate words to use. Emphasize to the parents that the child may actually need to hear the word *dying* in order to understand. Strategies for talking with a dying child are described in Table 13–3. Families who have talked with their child about dying report they have rarely regretted having the discussion (Gaab, Owens, & MacLeod, 2013).

Provide the child with opportunities for fantasy play, drawing, and storytelling, without emphasizing or reinforcing death themes. Listen to what children tell you about themselves and their lives. **Death imagery**, references to death or death-related topics (going away, separation, funerals), may be a theme of their stories.

Some dying children want to leave a legacy so they will be remembered or to express their good-byes through photography, journals, poetry, writing letters, or music. Some children choose to make crafts or a memory box for others, or to give away special possessions.

When caring for adolescents, outbursts of frustration and anger are common, but these are not personally directed at the nurse. Provide activities to help adolescents channel their feelings. Continue providing support in spite of their behavior. This approach may encourage adolescents to accept comforting without losing face. Be available to listen when the adolescent wants to talk and express feelings and frustrations. Promote friendships with other adolescents who have similar interests or problems.

FAMILY SUPPORT

Parents need to be present when possible as the child is dying, a pivotal event in their parent–child relationship. Work closely with the family when the child's death is imminent; they will remember the experience and words spoken for the rest of their lives. Prepare the family for changes in the child's appearance and behavior. Providing the parents with a room to be alone with the child ensures privacy at this extremely personal time.

TABLE 13–3 Strategies for Communicating With Dying Children

- Be receptive when dying children initiate a conversation, or look for opportunities to talk with them, such as when their physical health or behavior is changing.
- Ask dying children what they know. Correct any misunderstood information with language appropriate for their age. Ask what they want to know. Be honest when answering questions, but do not provide more information than requested.
- Encourage dying children to talk about what worries them. Allow them to express their feelings and to be upset. Empathize with these children's feelings.
- Ask dying children what is most important to them with the time they have left.
- Offer opportunities for nonverbal expression of feelings, such as art, music, and writing. Ask what the art represents.
- Let dying children know they will not be abandoned and that any suffering they may have will be treated.
- Let dying children know they will always be loved and remembered.

Source: Data from Evan, E. E., & Cohen, H. J. (2011). Child relationships. In J. Wolfe, P. S. Hinds, & B. M. Sourkes (Eds.), *Textbook of interdisciplinary pediatric palliative care* (pp. 125–134). Philadelphia, PA: Elsevier Saunders; You, J. J., Fowler, R. A., & Heyland, D. K. (2014). Just ask: Discussing goals of care with patients in hospital with serious illness. *Canadian Medical Association Journal, 186*(6), 425–432; MacPherson, C. F. (2013). The final chapter. *Clinical Journal of Oncology Nursing, 16*(5), e190–e191.

Ask the family what is important to them in the final moments and hours of the child's life and what will be important to them in the grief process. Each culture has its own way of defining, addressing, and acknowledging death. Customs, ceremonies, religious laws, and beliefs are strongly connected with dying (see Table 13–4 for rituals regarding dying and after death). Accommodate desired spiritual or cultural practices when possible. Holding the child is a universal request and should be permitted, along with touching, stroking, kissing, and talking soothingly.

Many families find that saying good-bye as a group is helpful. Families need to cry together and to tell each other how much they will miss each other. Assure them that the vigil with the child prevents the child from feeling isolated or abandoned as death approaches. The dying child should never be left alone when dying is imminent.

TABLE 13–4 Spiritual Traditions Regarding Dying and After-Death Rites

RELIGIOUS GROUP	RITUALS YOU MIGHT OBSERVE
American Indians	• Beliefs and practices vary widely among tribes • Autopsy is generally acceptable
Buddhism	• Family presence is important • Last-rite chanting at bedside • Cremation is common
Catholicism	• Sacrament of the sick, baptism of newborn • Obligated to take ordinary but not extraordinary means to prolong life • Burial is common
Christian Science	• No medical help is sought to prolong life • No donation of body parts; disposal of body and parts decided by family
Hinduism	• Family presence with chanting, prayers, and singing • Final rites by a religious leader; a thread tied around neck or wrist signifies a blessing; do not remove • Autopsy if required by law; organ donation may be acceptable • Cremation is common.
Islam	• Deathbed should be turned to face Mecca, reading from the Qur'an stressing hope and acceptance • Body is washed 3 times, only by Muslim of the same gender • Autopsy only for medical or legal reasons; organ donation is acceptable • Burial as soon as possible
Jehovah's Witness	• Prayer and reading the Bible • Organ donation is forbidden • Autopsy acceptable for legal reasons • Burial determined by family preference
Judaism	• Autopsy if required by law and organ donation in some cases • Prefer natural death rather than technologic support • Body ritually washed, and a living person is always with the body after death • Burial occurs as soon as possible; all body parts buried together • Seven-day mourning period
Mormonism	• If death inevitable, promote a peaceful and dignified death; laying on of hands, anointing with oil • Organ donation is an individual choice • Burial in "temple clothes"
Protestantism	• Variable rituals, laying on of hands, anointing with oil, communion, final blessing • Organ donation, autopsy, and burial or cremation are individual decisions • Means to prolong life is individual decision
Seventh Day Adventist	• Prayer, anointing with oil • Prefer prolonging life • Organ donation and autopsy are individual decisions • Disposal of body and burial are individual decisions

(2014). *Guide to culturally competent health care* (3rd ed.). Philadelphia, PA: F. A. Davis; Wiener, L., McConnell, D. G., Latella, L., & Ludi, E. (2013). Cultural and religious considerations in pediatric palliative care. *Palliative and Supportive Care, 11*, 47–67.

Developing Cultural Competence Diverse Perspectives on Death

Consider cultural differences when working with families who are dealing with the death of a loved one, for example (Evans & Ume, 2012; Purnell, 2014; Weiner et al., 2013):

- African Americans often place great importance on the presence and involvement of their families in their care. They embrace religion and spirituality. They may be less likely to request medications for pain and other symptoms because of an expectation to suffer. They may seek more aggressive care.
- Some Asian families desire to protect the terminally ill from knowledge of their condition, so their final days will be peaceful. Decision making is often collectively decided by the family, and a spokesperson for the family is often the oldest male or head of household. Some families may believe that making plans for the child's death could cause the child's premature death or having a visit by the chaplain may signify an impending death.
- Hispanics generally believe the entire family makes important decisions. They see death as a natural part of life, and they do not want to be a burden for their families. Cultural customs related to grief and loss vary. Crying openly is seen as appropriate. Faith is very important in times of death. The anniversary of a loved one's death is celebrated every year.

TISSUE AND ORGAN DONATION

Healthcare professionals are obligated to ask families about making an anatomic gift. Become familiar with national guidelines for organ collection and donation so you will be better prepared to serve the family of the dying child and potential organ recipients. An organ procurement coordinator collaborates with the healthcare team to help explain the organ donation process to the family, and to assure family members that the organ donation process is totally separate from decisions regarding their child's care. Organ donation costs are paid by the organ procurement organization, but recipients pay transplantation costs.

NEED FOR AUTOPSY

When the exact cause of death is unclear, an autopsy may be suggested. An autopsy may be required by state law for an unnatural or unexpected death, such as suicide, homicide, child abuse, or sudden infant death syndrome. When parents have a choice, they may be hesitant to consent to autopsy because it further invades the child's body. Support the family during the decision-making process by explaining that the autopsy will likely reveal the cause of death or inevitability of death.

POSTMORTEM CARE AND FAMILY SUPPORT

Offer ongoing support after the child dies. Questions like the following may help begin the conversation: "I am sorry for your loss. How can I help?" "What are your traditions when an infant or child dies?" "Is there someone I can call for you?" Nurses should feel free to express their sorrow and grief for the child and family. Crying with families is recognized as an expression of caring and empathy.

Identify the family's wishes for postmortem care before performing any care. Ask before removing any jewelry or other item from the child because cultural and spiritual practices may specify that the article remain on the child after death. Follow the healthcare facility's guidelines for postmortem care. Position the child according to guidelines or cultural/religious practices, clean the room, and remove medical equipment.

After the child's death, allow the family to spend as much time as they need with the child's body. Never rush family members who are saying good-bye to the child. Save all of the child's personal items—especially in the case of an infant. A lock of hair, hand- or footprints, the infant's identification band, the child's weight and height, or a picture of the infant can be sources of comfort and remembrance for families. Ask for permission before cutting a lock of hair, as some cultural and religious groups prohibit it. Seal the last clothes or patient gown used by the child, or the infant's blanket, in a plastic bag to retain the child's scent. Use a special remembrance box or container for this purpose. If parents refuse to take the items, give them to another family member or retain them. Document the collection of the mementos and who received them in case parents ask for them at a later time.

Clinical Tip

When a sudden violence-related death of a child or adolescent occurs, steps to preserve forensic evidence are taken. Removal of medical equipment is not permitted. Follow facility guidelines for evidence collection (e.g., child's clothing, sheet used during resuscitation) and the chain of possession prior to giving evidence to law enforcement authorities. The child may be swaddled in a clean sheet for family member access. Depending on the injuries and circumstances, the family may not be permitted to have physical contact with the child's body (O'Malley et al., 2014).

When a newborn or young infant has died, wrap the baby in a blanket and offer the mother and other family members the opportunity to hold the baby. Parents may want to bathe and dress the infant. The family experiencing the death of a newborn may appreciate an offer to take pictures of the baby and family together, if picture taking is not prohibited by religious or cultural traditions. Some families may feel uncomfortable taking pictures and refuse the offer. The nurse should question the family about baptism or other ritual requests for the newborn, and facilitate arrangements for a religious or spiritual leader at the family's request. Ensure that the mother experiencing the death of a newborn receives information about lactation suppression or milk donation options if she has been breastfeeding.

A bereavement folder should be provided to parents with information that includes resources available to help with a memorial service or funeral and potential sibling responses. Include grief counseling resources and support groups and encourage the family to use these resources for the first year after the child's death. Inform parents that certain dates, such as the day of the week the child died, the child's birthday, or family holidays, will be difficult and may trigger intense sadness. Parents may benefit from keeping a journal of their thoughts and memories, or writing letters or poems to or about their child. Follow-up phone calls from healthcare providers are appreciated by families.

Evaluation

Expected outcomes of caring for the dying child and family may include the following:

- The child is pain free and comfortable, and the child's physiologic needs are met.
- The cultural and spiritual needs of the dying child and family are met.
- The dying child and family receive support during the dying process.
- The family receives continued support after the child's death.

Bereavement

Parents' Reactions

The death of one's child is likely the most traumatic event a parent will experience. Grief, an individual's feelings and behaviors in response to death or loss, is painful, individualized, and exhausting. Many factors influence the parents' grief responses, including their perception of whether the death could be prevented, the suddenness and other circumstances of the death, the nature of their attachment to the child, previous losses, spiritual or religious orientation, and culture.

Sudden Death of a Child

An estimated 25% of child and adolescent deaths each year are related to complex chronic conditions (Klein & Saroyan, 2011). The majority of child and adolescent deaths are sudden and unexpected, such as from sudden infant death syndrome, injury, illness, suicide, or violence. Parents need additional support to deal with the sudden and unexpected death of their child and with their surviving children.

Death of a Newborn or Young Infant

In 2013, in the United States, 29,138 infants died shortly after birth or during their first year of life (Centers for Disease Control, National Center for Health Statistics, 2015). The death of a newborn forces the parents to experience their child's entire life cycle in a short period of time, and they are faced with overwhelming grief at a time when they anticipated the experience of joy. Refer parents to a perinatal bereavement program or support group.

Clinical Tip

The following strategies can assist the nurse in working with parents whose child dies suddenly and who are not present during the resuscitation:

- Identify a spokesperson for the medical team to keep the family informed during resuscitation efforts. Call support resources (e.g., chaplain service, social worker, or interpreter).
- Create time for families to assimilate the child's worsening status by providing two to three updates during the resuscitation. Prepare them for what is to come.
- Ensure that the right family members are present for discussions after the death, or have a family support member for a single parent. Provide a private space with telephone access.
- Turn off your phone and beeper, sit close, and make eye contact. If the family arrived after resuscitation ended, ask them what they know about what happened. Prepare them by saying you are sorry to give them this bad news. Verify that the child (use the child's name) has died. Let the family know that everything possible was done to save the child, but the injuries or illness complications were too severe to survive.
- Allow the family time to absorb the information. Accept whatever emotions family members express. Let the family be first to talk. Answer any questions asked. Be prepared to repeat information.
- Offer to telephone family or friends.
- After the death, prepare the body for viewing in a private place, covering disfiguring wounds. Escort the family to the body and explain any tubes or lines that must remain in place. Allow them time to say goodbye.
- Convey information to the family about the cause of death, autopsy, funeral preparations, and the normal grief process. Provide contact information for the family in case of questions.
- Arrange for family follow-up to see how they are responding to the child's loss and to review autopsy findings.

Grief and Bereavement

Although parents progress through distinct stages of grief, as described previously in this chapter, the timeline and nature of the grief process differ for each individual. The intense pain and shock initially felt by parents gradually give way to feelings of anger, guilt, depression, and loneliness. Very slowly, and with much support, energy returns and parents again begin to enjoy life experiences. Parents may experience friction due to differing intensities of grief and coping processes. Additional support may be needed to prevent a sense of loneliness and isolation.

Let parents know that caring for themselves physically and mentally is important, even though the period surrounding their child's death is difficult. Refer parents to local support groups for bereaved parents and siblings (e.g., Compassionate Friends, First Candle, and SHARE Pregnancy and Infant Loss Support), and provide books and articles for later use. Some facilities and most palliative care programs have formal follow-up programs for bereaved parents to encourage a healthy progression through the grieving process.

Siblings' Reactions

Siblings experiencing the death of a brother or sister grieve and require supportive and compassionate care. Siblings anticipating the addition of a new baby to the family will also feel the loss. The siblings may have received less attention from parents during the child's illness. Depending on their development, they may fear that they caused their brother's or sister's illness or injury, or worry that their bad thoughts caused the illness. Table 13–5 highlights children's understanding of death at different developmental stages, some of the possible behavioral responses, and nursing considerations for family education.

TABLE 13–5 Children's Understanding of Death, Their Potential Behaviors, and Nursing Management

UNDERSTANDING OF DEATH	POTENTIAL BEHAVIORS	NURSING MANAGEMENT
Infant		
Cognitive stage: Sensorimotor Senses emotions of caregivers and altered routines Senses separation	Resists cuddling and eats less May have feeding problems Cries excessively, clingy Sleeps more than usual	Provide a sense of security by holding and hugging and a soothing voice by a caring person if the parent is too distraught. Try to return to usual routines.
Toddler		
Cognitive stage: Preoperational No understanding of true concept of death Aware someone is missing—separation anxiety Unable to distinguish death from temporary separation or abandonment	Regresses to younger stage of development Clingy; does not want to let parent out of sight Whiney, irritable, may show distress by biting, hitting, tears Problems eating and sleeping Sleep disturbances Fearfulness	Encourage parents to hold and cuddle the toddler to help reduce the fear of separation. Follow familiar routines. Be tolerant of regressive behaviors. Use distraction (toys, games, videos) when the child is fussy or clingy.
Preschooler		
Cognitive stage: Preoperational Believes death is temporary and the dead person will return Experiences magical thinking (believes own thoughts or actions potentially caused the death) Confuses death with being away or asleep Has beginning experience with death of animals and plants	Regression to earlier developmental stage, problems with bowel and bladder control, tantrums, may withdraw from activities, disobedience May fear going to sleep, has nightmares, afraid of the dark, separation anxiety Crying spells Seems morbidly fascinated with death Asks when deceased will return Asks many questions Complaints of abdominal pain	Provide honest and consistent responses to the child's questions; say the person is not coming back. Try to follow usual routines. Be tolerant of regressive behaviors; provide play activities. Keep memories alive with pictures and items that remind the child of the loved one. Participate in rituals, e.g., going to the cemetery, releasing helium balloons, and planting flowers.
School-Age Child		
Cognitive stage: Concrete operations Understands difference between temporary separation and death By 6 years, knows death is permanent. By 9–10 years, understanding of death is same as adult May have guilt or assume blame for the death May not realize that death can occur at any age	Crying, moody, may become more withdrawn and distant, may have angry outbursts or disruptive behaviors, may dwell on absence of loved one Decreased concentration for schoolwork, may refuse to go to school Psychosomatic complaints—stomachache or headache May try to comfort parents by taking over tasks May fear another loved person will die	Listen to the child and answer questions honestly. Return to usual routines and activities. Have the parent let the child know when parents will return and a how to contact them. Keep memories alive through activities such as art, music, creating a memory book, sewing a quilt, and planting a garden. Share Internet resources; suggest coping support groups. Encourage the family to seek faith-based support.
Adolescent		
Cognitive stage: Formal operations Intellectually capable of understanding death Recognizes all people and self will die Understands the association between illness and death Sense of invincibility conflicts with fear of death Able to recognize effect of death on others	May have severe depression, mood swings, withdrawal from friends, may feel angry or guilty Girls may seek comfort from friends Eating and sleeping problems May act-out or display risk-taking behaviors May assume responsibility for family well-being Uses abstract and philosophical reasoning to try to make sense of life	Be available and encourage open communication. Share your own grief and feelings with the adolescent. Keep memories alive with pictures and items that remind the teen of the loved one. Access counseling and support groups; share Internet resources. Encourage the child to seek support from the family's faith group.

Source: Data from Evan, E. E., & Cohen, H. J. (2011). Child relationships. In J. Wolfe, P. S. Hinds, & B. M. Sourkes, Textbook of interdisciplinary pediatric palliative care (pp. 125–134). Philadelphia, PA: Elsevier Saunders; You, J. J., Fowler, R. A., & Heyland, D. K. (2014). Just ask: Discussing goals of care with patients in hospital with serious illness. Canadian Medical Association Journal, 186(6), 425–432; MacPherson, C. F. (2013). The final chapter. Clinical Journal of Oncology Nursing, 16(5), e190–e191.

When possible, siblings should have the opportunity to visit when the child is dying so that they feel nothing was hidden from them. Memories about the death process are part of the grieving process (Lancaster, 2011). Nurses and other support personnel can assist the surviving children to adapt to their parents' distraction, grief, and increased protectiveness of them. The siblings need to hear that the parents' grief in no way diminishes the love felt for them.

When talking to the siblings of a child who has died, be honest and answer questions truthfully. Provide information about the child's death in a manner they can understand. Use developmentally appropriate terms, such as, "Adam's heart will never beat again," "He will never get cold or hungry," and "He will never come home again." Reassure siblings that they did not cause their brother or sister to die (unless they did contribute to the child's death) and that death was not a punishment for wrongdoing. Allow the siblings to ask questions and acknowledge the emotions they are feeling. Emphasize that it is okay for them to be sad, angry, frightened, or tearful. Use the same amount of energy and concern to acknowledge the sibling's and the adult's grief.

Encourage the parents, if appropriate, to allow siblings to participate in planning the child's memorial or funeral service. A funeral service director can be supportive to provide family time for the sibling to say good-bye. Attending the service assists the sibling to grieve, and being able to grieve as a family provides a sense of connectedness to parents and security at a vulnerable time. When siblings attend the funeral, they should be prepared for what to expect, such as an open casket and the behaviors of mourners. Suggest that parents designate a family member or close friend to monitor the siblings' needs while the parents attend to other matters. Keep the family together as much as possible.

As with parental bereavement, sibling bereavement is intense and a lifelong process. Sad feelings may return repeatedly as understanding about death increases. Be open and available when children wish to talk about a dead sibling to support their grieving. Encourage parents to make sure other caregivers and teachers know about the sibling's loss. Books for the family that might help children with grief include *Tell Me, Papa: Answers to Questions Children Ask About Death and Dying* by M. Johnson, J. Johnson, and A. C. Blake; *What Happens When Someone Dies: A Child's Guide to Death and Funerals* by M. Mundy and R. W. Alley; and *A Complete Book About Death for Kids* by E. Grollman and J. Johnson.

Staff Reactions to the Death of a Child

Caring for dying children is especially stressful and demanding for healthcare professionals. Some nurses cope by distancing themselves socially from the dying child and family to maintain composure and a professional demeanor. Nurses with young children may have more difficulty caring for the dying child. They tend to identify with the child, making it more difficult to recognize the dying child's anxiety and fears because of their own personal defenses against a sense of helplessness to alter the course of the child's disease.

When the child dies, the bond that was developed with the child and family is lost, and feelings of helplessness or powerlessness may be related to failed efforts to relieve suffering (Duvall, 2011). Nurses may feel extreme sadness and helplessness in association with a child patient's death and the grief observed among the child's family members. Nurses may alternate between dealing with their grief and suppressing it, which permits them to avoid becoming consumed by the loss.

Nurses who work with terminally ill children and their families need special preparation to care for children and families and to manage personal stress simultaneously. Mentoring by experienced hospice nurses, as well as additional educational experiences, may be helpful. Nurses must learn to cope effectively with grief and develop empathy, competence, and confidence in their ability to provide more humane and effective nursing care. Nurses should feel free to express their sorrow and grief for the child and family. Some nurses attend funeral and memorial services when invited by the patient's family.

Nurses working in emergency departments caring for children who die suddenly or in hospice settings and hospital units that care for terminally ill children need support systems to help balance the stresses of working with dying children. An important support system often gives an opportunity to discuss the experience with a supportive peer (Figure 13–7). Many facilities offer debriefing group sessions with mental healthcare professionals to discuss feelings and concerns, as well as resources to help nurses learn about self-care activities, relaxation techniques, and how to maintain a balance between their work and personal lives.

Figure 13–7 **Nurses need to express grief in a supportive environment after a child's death. Sharing the sadness and grief or futility of resuscitation efforts with colleagues can often help nurses continue to provide supportive care to the next families who need compassionate care.**

Chapter Highlights

- A life-threatening illness or injury places intense emotional and physical demands on the child and family due to the unfamiliar environment of the emergency department or intensive care unit, frightening or invasive procedures, and an uncertain outcome.
- Defense mechanisms displayed by children in stressful situations such as a life-threatening illness or injury include regression (return to an earlier behavior), denial, repression (involuntary forgetting), postponement, and bargaining.
- Nursing interventions to promote a child's psychologic health include permitting parents to be present, preparing children for procedures, using play to help the child manage anxiety, and allowing the child some choices to gain a sense of control.
- Parents typically progress through the stages of shock and disbelief, anger and guilt, deprivation and loss, anticipatory waiting, and readjustment or mourning when their child has a life-threatening illness or injury.
- A family-centered approach will help meet the needs of families, minimize stress, and enhance family coping. Appropriate nursing care includes providing information and building trust, promoting family involvement (including presence during invasive procedures and resuscitation if desired), encouraging parents to meet physical and emotional needs, facilitating effective communication, and maintaining family support systems.
- The nurse should ensure siblings receive information about their critically ill or injured brother or sister in preparation for a visit, and they should support the parents to provide regular messages to help them control feelings of jealousy, guilt, fear, and insecurity. Allowing the siblings to visit the child may help them cope.
- Palliative care is a service for persons with life-limiting conditions that provides therapies to reduce suffering, to improve the quality of remaining life, to facilitate decision making regarding end of life, and to coordinate care. Hospice is one category of palliative care.
- The families of dying children face many decision-making issues such as when to begin palliative and/or hospice care, advance care planning, the withholding or withdrawal of treatments, and DNR requests.
- One commonly accepted definition of death in the United States is brain death, or the irreversible cessation of all functions of the brain, including the cerebral cortex and brainstem.
- Children with life-threatening illnesses often learn about death and their own illness through exposure to other ill and dying children. Children recognize that their condition is worsening when receiving extra treatments, feeling ill, and noticing cues from their parents, even if they are not told they are dying.
- It is essential to work closely with the family when a child's death is imminent, helping to provide the support and services most important to them in the last moments or hours of their child's life.
- The nurse caring for the dying child and family offers physiologic and psychosocial support during end-of-life care.
- Bereavement support must be provided to the family, making sure that siblings are not overlooked. Allow siblings to participate in planning the memorial service. Encourage parents to allow siblings to express their emotions.
- Caring for a dying child is difficult, and nurses need special preparation to meet the needs of the child and family, and to manage their own responses when a child they cared for dies.

Clinical Reasoning in Action

Kelly is a premature baby weighing 500 g (1.1 lb) when born at 24 weeks' gestation after her mother had premature rupture of membranes. Her parents, Shawn and Lori, are of Navajo Indian descent. Kelly's condition is extremely critical and she is on life support. You know that any amount of touch can be extremely stressful for newborns this small and in critical condition. The mother has been pumping and freezing breast milk for future use. The parents are encouraged to assist the nurse in any way they can, but they are not able to touch Kelly. Although the parents know how critical Kelly's condition is and have learned about the machines and medications being used, they are still confused and uncertain about the situation. They have not left the hospital at all. The grandparents have been helping care for Roseanne, Kelly's 7-year-old sister, and she has visited her sister once. On her third day of life, Kelly gained weight and started to show an increase in activity. The parents thought this could be a positive sign, but the nurse explained that swelling caused the weight gain and the increased activity was from agitation as Kelly struggled to breathe. When the parents were at the bedside, Kelly started to become cyanotic and her oxygen saturation level dropped to the 60s. The healthcare team tried to save her but were unsuccessful. This was a devastating loss for the family and all the medical personnel involved.

1. What are some of the stressors Kelly experienced while in the hospital?
2. What are the stages of grief Kelly's family is likely to experience?
3. What are some strategies that can be used to help Roseanne deal with the loss of her sister?
4. What are some of the strategies for supporting Kelly's parents?

Chapter 14
Infant, Child, and Adolescent Nutrition

Ryan McVay/Getty Images

It is exciting to see Joey progressing into the school setting. Being with children his age will really help him develop in many ways. We're just worried because he needs to get only foods he can chew and swallow so he does not choke. He also needs his tube feedings during school to be sure he gets enough energy to do well.

—Mother of Joey, 11 years old

Learning Outcomes

14.1 Discuss major nutritional concepts pertaining to the growth and development of children.

14.2 Describe and plan nursing interventions to meet nutritional needs for all age groups from infancy through adolescence.

14.3 Integrate methods of nutritional assessment into nursing care of infants, children, and adolescents.

14.4 Identify and explain common nutritional problems of children.

14.5 Develop nursing interventions for children with nutritional disorders.

Adequate nutrition is an essential component of growth and development. The child's nutritional status begins before birth and is related to the mother's nutritional state. All children must be assessed for nutritional status, followed by teaching or other interventions to enhance health. Nurses are instrumental in giving parents information about normal nutritional needs of infants, children, and adolescents. Common techniques to assess nutrition, such as measuring growth and monitoring hematocrit, provide needed information about whether intake of nutrients is adequate.

All children and their parents can benefit from information about nutritional needs, but some children have additional concerns that must be considered. The nurse recognizes the special requirements of children with conditions such as feeding disorders, food allergies, cystic fibrosis, cerebral palsy, or diabetes. Nutrition monitoring is provided throughout childhood so that dietary counseling can be integrated with other teaching to promote development. How can the nurse bridge the various settings in which children's nutritional needs are met? These might include the home, childcare settings, schools, and hospitals. How can the nurse help the family prepare for meeting the nutritional needs of a child who has special needs during car or plane travel?

Some children have unique nutritional needs due to their social environments. Parents may not be knowledgeable about the nutritional requirements of children. Perhaps the family is vegetarian and needs extra help to ensure intake of essential nutrients. If finances are limited, the family may need resources such as food stamps, food banks, or budget planning. The nurse considers the high rate of childhood obesity and common nutritional deficits when applying concepts of health promotion with families. Whatever the nurse's setting, knowledge of nutrition must be integrated within nursing care.

General Nutrition Concepts

Nutrition refers to taking in food and assimilating it metabolically for use by the body. It is an essential component of life and therefore an important body of knowledge to consider in discussions of child growth and development. The body

requires a wide array of nutrients. **Macronutrients**, or the major building blocks of the body, are carbohydrates, protein, and fat. Vitamins and minerals are **micronutrients**, or substances needed in small quantities for healthy body functioning. The need for nutrients is dependent on activity level, state of health, and the presence of disease or other stress-related and age-related requirements.

The **Dietary Reference Intakes (DRIs)** are a set of values established by the Food and Nutrition Board of the Institute of Medicine (IOM) and the National Academy of Science that can be used to assess and plan intake for individuals of different ages (Institute of Medicine, 2011). They commonly include the Estimated Average Requirement, or EAR (intake needed to meet requirements of 50% of the population); Recommended Dietary Allowance, or RDA (intake needed to meet requirements of 97% to 98% of the population); Adequate Intake, or AI (used when data to support EAR are not available); and Upper Intake, or UI (maximum level unlikely to pose health risk). Although the DRI approach is used in the United States, other countries have developed their own approaches to dietary standards. For example, Canada uses Adequate Intake and Reference Nutrient Intake, while the United Kingdom uses Recommended Daily Nutrient Intakes. The aims of these standards are to provide a method to evaluate individual and population diets and to plan nutrition programs and education. DRIs are generally specific to males and females in several age categories. See Appendix C for a list of DRIs for children and adolescents.

Although the DRIs provide useful information when evaluating diets, their use can be time consuming. What "quick check" can provide feedback about the daily diets of children? The nurse should be familiar with the U.S. MyPlate food guide and hang posters that illustrate its healthy choices in schools, clinics, and hospitals. It is a fast way to examine children's intakes for 1 day and evaluate whether they meet most requirements. Instead of calculating amounts of nutrients ingested, the MyPlate program focuses on categories of foods, which readily reflects the actual intake. The numbers of servings from various categories stay constant throughout childhood, while the serving sizes increase as the child gets older. See Figure 14–1 for MyPlate, and consult the U.S. Department of Agriculture (USDA) website for ethnic/cultural food guides for vegetarians and those from various ethnic groups, such as Hispanic and Native American.

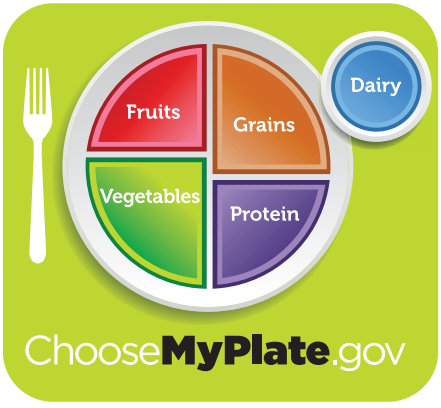

Figure 14–1 The U.S. MyPlate food guide is used to provide teaching about amounts of foods recommended for daily intake.

Nutritional Needs

Nutritional needs evolve during all of infancy and childhood. They support growth and development and influence the progression of the child along the developmental path. Nutritional intake helps maintain the health of the child and fosters a state of maximal potential or health promotion. Specific needs during each developmental stage are discussed in this section.

Infancy

FLUID AND MACRONUTRIENTS

Fluid requirements during the neonatal period are high (140 to 160 mL/kg/day) because of the newborn's decreased ability to concentrate urine and increased overall metabolic rate. Although the infant's total body water content is high (75% to 80%) compared with that of an adult (60%), the infant has an increased surface area to mass ratio and decreased renal absorptive capacity that makes the infant more susceptible to dehydration from insufficient fluid intake or increased fluid loss caused by diarrhea, vomiting, or another source of fluid loss. Parents and caretakers should be aware of the signs of dehydration. See Chapter 18 for further information about fluid needs in infancy.

The basal metabolic rate (BMR) refers to the energy needed for thermoregulation, cardiorespiratory function, cellular activity, and growth. A newborn requires 100 to 115 kcal/kg/day at age 1 month. In breast milk, the primary carbohydrate is lactose. In addition to providing energy, lactose also functions to enhance the absorption of calcium, magnesium, and zinc. Human milk also contains other carbohydrates such as glucosamines and nitrogen-containing oligosaccharides. Glucosamines are one of the building blocks for connective tissues. Oligosaccharides promote the growth of *Lactobacillus bifidus,* which promotes an intestinal acidic environment that is hostile to harmful bacteria, making it difficult for them to thrive (Lawrence & Lawrence, 2011).

Infants receive approximately 50% of their calories from fat. Fats also help the body absorb the fat-soluble vitamins A, D, E, and K. Fats are a precursor of prostaglandins and other hormones. Fatty acids are a key component to brain development. Their derivatives, docosahexaenoic acid (DHA) and arachidonic acid (ARA), are long-chain polyunsaturated fatty acids (LCPUFAs) needed for myelination of the spinal cord and other nerves, and for development of visual acuity and cognitive and behavioral functions (Cloherty, Eichenwald, & Stark, 2012).

Approximately 98% of human milk fat is in the form of triglycerides, and a small amount is from cholesterol. Cholesterol levels in breast milk may also stimulate the production of enzymes that lead to more efficient metabolism of cholesterol, thereby reducing its harmful long-term effects on the cardiovascular system.

Fat content is the most variable component in breast milk, ranging from 30 to 50 g/L. It is influenced by maternal parity, duration of pregnancy, the stage of lactation, diurnal regulation, and changes in fat content even during a single feeding. Multiparous mothers produce milk with a lower content of fatty acids than primiparous women. Mothers of preterm infants have a greater concentration of LCPUFAs in their milk compared with mothers of term infants. By receiving this preterm breast milk, preterm infants receive the increased concentrations of DHA and ARA intended for their growth (Lawrence & Lawrence, 2011).

Phospholipids and cholesterol levels are higher in colostrum compared with mature milk, although overall fat content is higher in mature breast milk compared with colostrum. Fat content is

generally higher in the evening and lower in the early morning. Within a single feeding session, an infant initially receives the low-fat foremilk before receiving the higher calorie, high-fat hindmilk. Finally, the fat content of breast milk is also affected by maternal diet and maternal fat stores. Mothers on low-fat diets have increased production of medium-chain fatty acids (C6–C10), and mothers with high levels of body fat produce breast milk with a higher fat content (Lawrence & Lawrence, 2011).

The fats in milk-based formulas are modified in an attempt to parallel the fat profile of breast milk by removing the butterfat from cow's milk and adding vegetable oils. The different blends of fats all provide a fatty acid profile that is similar to breast milk in terms of amount of saturated, monounsaturated, and polyunsaturated fats present. Since 2002, infant formulas have been supplemented with DHA and ARA. However, breast milk also contains 167 other fatty acids of uncertain function that are absent from formula (Cloherty et al., 2012).

Proteins are the building blocks for muscle and organ structure. They are key to the body's metabolic processes including energy metabolism, cell signaling, growth, and immune function. Milk proteins are often grouped into casein and whey proteins. Whey protein is the predominant dietary protein in human milk. During digestion this type of protein creates soft curds that are easily and quickly broken down. Because of this, breastfeeding babies digest their meals in 90 minutes and need to feed often, receiving about 8 to 12 feedings per day. Casein is the major phosphoprotein found in milk. Cow's milk contains a high amount of casein (a low ratio of whey to casein—approximately 20:80) compared with mature human milk (60:40 whey:casein). Because of its tendency to form curds, milk with high amounts of casein is less easily digested. Cow's milk–based formulas are usually modified to get closer to the whey:casein ratio of human milk.

MICRONUTRIENTS

The fat-soluble vitamins (vitamins A, D, E, and K) are found in both cow's milk–based formula and breast milk. After absorption via the lymphatic system, vitamins enter the blood and are transported to the various tissues. Excessive amounts of fat-soluble vitamins may result in toxicity, and there is general agreement that no routine fat-soluble vitamin supplementation is needed with the exception of vitamin D. See *Families Want to Know: Supplements for Breastfed Babies* for recommendations regarding vitamin D and other nutrients.

The vitamin B complex and vitamin C are water-soluble vitamins that pass readily from serum to breast milk. However, mothers who follow a strict vegetarian or macrobiotic diet may have insufficient vitamin B_{12} in their milk. In that case, the exclusively breastfed infant should receive vitamin B_{12} supplementation. Formula is fortified with adequate amounts of the water-soluble vitamins to meet the DRIs. Unlike fat-soluble vitamins, any excess water-soluble vitamins ingested are simply excreted and the threat of toxicity is low (Lawrence & Lawrence, 2011).

Figure 14–2 Early childhood caries. This child has had major tooth decay related to sleeping as an infant and toddler while sucking bottles of juice and milk.

SOURCE: Everst/Alamy.

Both human milk and infant formulas contain several major and trace minerals to satisfy the needs of the growing infant. The mineral content of breast milk does not appear to be influenced by maternal diet.

DENTAL HEALTH

Early childhood caries, the presence of one or more decayed, lost, or filled tooth surfaces in a primary tooth from birth to 6 years of age, can occur when a young child is allowed to breastfeed or drink from a bottle for long periods, especially when sleeping (AAP Committee on Nutrition, 2013; Colak, Dulgergil, Dalli, et al., 2013) (Figure 14–2). The milk, juice, or other fluid pools around the upper anterior teeth, salivary flow decreases, and acid buffering is decreased, resulting in tooth decay. Nurses should teach parents to avoid putting the child to bed with a bottle and encourage pacifier use or a bottle of water instead. The child should not walk around with a bottle during the day. Mothers who breastfeed should also be cautioned to limit feeding to specific times rather than letting the infant breastfeed every few minutes (sometimes done when infant and mother co-sleep) so that milk will not pool in the mouth during sleep. When sleepy, the infant does not swallow well and the milk is in constant contact with the teeth where milk sugars can decay erupting teeth.

Parents can be taught beginning dental care for the infant, which includes wiping the teeth off daily once they erupt with a piece of moist gauze or a small infant toothbrush. Some pediatric dentists like to see the child for a first dental visit at about 1 year of age; others wait until the child is older. The nurse should encourage the parents to select and establish contact with a dental provider when the child is nearing the end of infancy.

Families Want to Know

Supplements for Breastfed Babies

1. Each baby receives a vitamin K injection after birth to promote adequate blood clotting. After that, no further vitamin K is needed since children manufacture this vitamin in the gut once they begin eating.
2. Vitamin D is recommended at a minimum of 400 International Units/day for all infants (American Academy of Pediatrics [AAP] Section on Breastfeeding, 2012).
3. Iron is not needed unless the infant is not eating food containing iron by 4 to 6 months of age. The baby may need an iron source earlier if the mother was anemic during pregnancy or while breastfeeding.
4. Fluoride 0.25 mg is given after 6 months of age if water is not fluoridated to a level of 0.6 part per million (ppm), or if the baby is not drinking any water (American Association of Pediatric Dentistry, 2014).

WEANING

Weaning is the term used when infants stop breastfeeding or bottlefeeding and obtain most liquids by cup. At about age 8 to 9 months, a cup should be offered to the infant with assistance being provided so that learning about drinking from a cup can begin. By about 1 year of age, infants are usually able to drink most liquids from a cup with a lid, so bottles can be slowly withdrawn and replaced by cups.

The decision to wean the baby from the breast may be made for a variety of reasons, including family or cultural pressures, changes in the home situation, pressure from the woman's partner, or a personal opinion about when weaning should occur. Some infants wean themselves spontaneously despite the wishes of the mother. For the woman who is comfortable with breastfeeding and well informed about the process, the appropriate time to wean her infant will become evident if she is sensitive to the child's cues, such as increased interest in other foods and decreased frequency of feeding (Centers for Disease Control and Prevention [CDC], 2011a). The infant who is weaned before age 12 months should be given iron-fortified infant formula rather than cow's milk.

Healthy People 2020

(MICH-21) Increase the proportion of infants who are breastfed

- Ever: target 81.9%
- At 6 months: target 60.6%
- Exclusively through 3 months: target 46.2%
- Exclusively through 6 months: target 25.5%

If weaning is timed to respond to the child's cues, and if the mother is comfortable with the timing, it can be accomplished with less difficulty than if the process begins before mother and child are ready emotionally. Nevertheless, weaning is a time of emotional separation for mother and baby; it may be difficult for them to give up the closeness of their nursing sessions. The nurse who understands this possibility can help the mother see that her infant is growing up and plan other comforting, consoling, and play activities to replace breastfeeding. A gradual approach is the easiest and most comforting way to wean the child from breastfeeding.

During weaning, the mother should substitute one cup feeding or bottlefeeding for one breastfeeding session over a few days to a week so that her breasts gradually produce less milk. Eliminating the breastfeedings associated with meals first facilitates the mother's ability to wean the infant because satiation with food lessens the desire for milk. Over a period of several weeks she can substitute more cup feedings or bottlefeedings for breastfeedings. The slow method of weaning prevents breast engorgement, allows infants to alter their eating methods at their own rates, and provides time for psychologic adjustment.

INTRODUCTION OF COMPLEMENTARY FOODS

When should other foods be added to the infant's diet? Although some parents add other foods when the infant is only days or weeks old, and such practices are often culturally derived, it is best to take cues from the infant's developmental milestones. The American Academy of Pediatrics recommends introducing complementary foods at about age 6 months (AAP, 2014a). At this age, the extrusion reflex (or tongue thrust) decreases and the infant can sit well with support. The infant is also developing the ability to appreciate texture and swallow nonliquid foods

TABLE 14–1 Introduction of Solid Foods in Infancy

RECOMMENDATION	RATIONALE
Introduce rice or other single-grain baby cereal at about age 6 months.	Single grains are easy to digest and have low allergenic potential, and baby preparations contain iron.
Introduce fruits or vegetables at 6–8 months of age. Some healthcare providers recommend vegetable introduction before fruits.	Fruits and vegetables provide needed vitamins. Vegetables are not as sweet as fruits; introducing them first may enhance acceptability to the infant.
Introduce meats at age 8–10 months.	Meats are harder to digest, have high protein load, and should not be fed until close to 1 year of age.
Use single-food prepared baby foods rather than combination meals.	Combination meals usually contain more sugar, salt, and fillers.
Introduce one new food at a time, waiting at least 3–4 days to introduce another. Delay feeding eggs, strawberries, wheat, corn, and fish until close to 2–3 years of age. Consult a pediatrician or an immunologist about the best timing to introduce peanut and other nut products.	If a food allergy or intolerance develops, it will be easy to identify. The foods listed are those most commonly associated with food allergies.
Avoid carrots, beets, squash, beans, and spinach (especially if prepared at home) before 6 months of age. Have well water evaluated for nitrates (the recommended level is less than 10 mg/L).	Nitrates in these foods and in water near agricultural runoff can be converted to nitrite by young infants, causing methemoglobinemia. Commercial baby foods are adjusted for nitrates, so levels are lower than in foods prepared in the home.
Infants can be fed mashed portions of table foods such as peas, corn, rice, and potatoes.	This is a less expensive alternative to jars of commercially prepared baby food; it allows parents of various cultural groups to feed ethnic foods to infants.
Avoid adding sugar, salt, and spices when preparing baby foods at home.	Infants need not become accustomed to these flavors; they may get too much sodium from salt or develop gastric distress from some spices.
Avoid honey until at least 1 year of age.	Infants cannot detoxify *Clostridium botulinum* spores sometimes present in honey and can develop botulism.

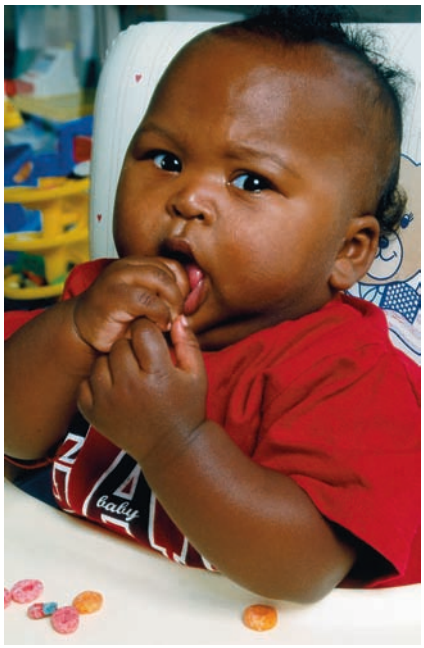

Figure 14–3 **Introducing finger foods. The baby who has developed the ability to grasp with thumb and forefinger should receive some foods that can be held in the hand.**

and can indicate desire for food or turn away when full. At 6 to 12 months, complementary foods are offered in addition to the intake of breast milk or formula rather than replacing that essential nutrient (AAP, 2014a) (see Table 14–1).

The first complementary food added to the infant's diet is often rice or other single-grain cereal. The advantages of introducing cereal first is that it provides iron at an age when the infant's prenatal iron stores begin to decrease, it seldom causes allergy, and it is easy to digest. A tablespoon or two is fed to the infant once or twice daily just before formula or breastfeeding. The infant may appear to spit out food at first because of normal back-and-forth tongue movement. Parents should not interpret this early feeding behavior as indicating dislike for the food. With a little practice the infant becomes adept at spoon feeding.

Once the infant eats 1/4 cup of food twice daily, usually at 6 to 8 months of age, vegetables or fruits can be introduced, at a rate of one new food every several days (Table 14–1). By 8 to 10 months of age, most fruits and vegetables have been introduced and strained meats or other protein (e.g., tofu, cheese, mashed cooked beans) can be added to the infant's diet. Finger foods are introduced during the second half of the first year as the infant's palmar and then finger grasp develops and as teeth begin to erupt (Figure 14–3). Infants enjoy toast, O-shaped cereal, finely sliced meats, cheese, yogurt, tofu, and small pieces of cooked, softened vegetables. Certain foods are associated with choking and should be avoided.

SAFETY ALERT!

Advise parents to use caution when providing finger foods to the infant. Hard foods and some soft and malleable ones slip easily into the throat and may cause choking. Avoid hot dogs, hard vegetables, candy, and chunks of peanut butter. Infants and other young children should always be supervised while eating. Be sure parents are familiar with techniques for airway obstruction removal and have emergency numbers clearly listed on their phones.

TABLE 14–2 Infant Nutritional Patterns

AGE	PATTERN
Birth–1 month	• Eats every 2–3 h, breast or bottle • 2–3 oz (60–90 mL) per feeding
2–4 months	• Has coordinated suck–swallow • Eats every 3–4 h • 3–4 oz (90–120 mL) per feeding
4–6 months	• Begins baby food, usually rice cereal, 2–3 T, twice daily • Consumes breast milk or formula 4 or more times daily • 4–5 oz (100–150 mL) per feeding
6–8 months	• Eats baby food such as rice cereal, fruits, and vegetables, 2–5 T, 3 times daily • Consumes breast milk or formula 4 times daily • 6–8 oz (160–225 mL) per feeding
8–10 months	• Enjoys soft finger foods 3 times daily • Consumes breast milk or formula 4 times daily • 6 oz (160 mL) per feeding • Uses cup with lid
10–12 months	• Eats most soft table foods with family 3 times daily • Uses cup with or without lid • Attempts to feed self with spoon though spills often • Consumes breast milk or formula 4 times daily • 6–8 oz (160–225 mL) per feeding

Certain foods are more commonly associated with development of food allergies, and avoiding them in infancy may decrease allergy incidence. Typically, recommendations for infants at risk due to family history of allergy are to delay feeding of cow's milk until age 1 year, eggs until age 2 years, and peanuts, nuts, fish, and shellfish until age 3 years (AAP, 2014a). However, a recent study found that children at risk of peanut allergy due to manifestation of food allergy in infancy or a family history of allergy have a lowered risk of having peanut allergy at age 5 years if they consume peanuts frequently within the first year of life (Du Toit et al., 2015). When infants have allergies to some foods or have a family history of allergy, refer them for current management to a pediatrician and/or an immunologist.

As food and juice intake increase, formula-feedings or breastfeedings decrease in amount and frequency (Table 14–2). If breastfeeding is not chosen, or if supplemental feedings are provided, only iron-fortified infant formula should be used during the first year of life. Cow's milk (including evaporated milk) can lead to bleeding and anemia (see sections on iron and anemia in this chapter), can interfere with absorption of some nutrients, and has a high solute load, which immature kidneys can have difficulty excreting. Iron-fortified formula should always be used when the infant under 12 months old drinks formula. When breastfed babies are not eating foods with iron by age 6 months, supplemental iron may need to be added. Careful dietary assessment and discussion of intake by the nurse at health visits helps the practitioner decide if supplemental iron is needed.

Parents who want to make baby foods at home can be encouraged and instructed to do so. Some commercially prepared foods have unnecessary additives such as salt, sugar, and food starch, and they may be costly for some families. Parents can easily blend fruits and vegetables the family is eating without adding salt, sugar, or seasoning. Prepared foods should be used promptly and stored in the refrigerator between feedings. Foods can also be placed into ice cube trays and frozen; a cube or two can be defrosted at mealtime. Nurses should caution parents to avoid certain home-prepared vegetables and not to use honey in foods for infants as it can lead to infant botulism because infants cannot detoxify the *Clostridium botulinum* spores sometimes present in honey (see Table 14–1). If foods or fluids are microwaved, they should be shaken, stirred, and checked for temperature so that hot areas in the food do not burn the infant.

Toddlerhood

Why do parents of toddlers frequently become concerned about the small amount of food their children eat? Why do toddlers seem to survive and even thrive with minimal food intake? The toddler often displays the phenomenon of **physiologic anorexia**, which occurs when the extremely high metabolic demands of infancy slow to keep pace with the more moderate growth rate of toddlerhood. Although it can appear that the toddler eats nothing at times, intake over days or a week is generally sufficient and balanced enough to meet the body's demands for nutrients and energy.

Parents often need knowledge about the types of foods that constitute a healthy diet. The nurse can offer fresh food alternatives with lower sodium content to replace hot dogs, microwave meals, or fast foods by providing information about easy preparation of sliced meats, cheese, tofu, fruits, and vegetables. Healthy snacks for young children include yogurt, cheese, milk, slices of bread with peanut butter, thinly sliced fruits, and soft vegetables.

Healthy People 2020

(NWS-19) Reduce consumption of sodium in the population aged 2 years and older

Parents should be advised to offer a variety of nutritious foods several times daily (three meals and two snacks) and let the toddler make choices from the foods offered. They should offer foods only at mealtimes and have the child sit in a high chair or on a special seat at the table to eat (Figure 14–4). Small portions are most appealing to the toddler. A general guideline for food quantity at a meal is one tablespoon of each food per year of age.

The toddler should drink 16 to 24 oz (1/2 to 3/4 L) of milk daily; whole milk is recommended from age 1 to 2 years, and after 2 years of age 2% is appropriate. Parents should be cautioned against giving the toddler more than a quart (1 L) of milk daily since this interferes with the desire to eat other foods, leading to dietary deficiencies. Recall that the child should not be put to bed with a bottle or allowed to carry a bottle of milk or juice around during the day on account of the risk of early childhood caries (see earlier discussion). In addition, parents should be advised to use only 100% fruit juice and to limit consumption of this juice to 4 to 6 oz daily for children ages 1 to 6 years to decrease the likelihood of becoming overweight, developing dental caries, or experiencing abdominal discomfort (AAP, 2011). Unpasteurized juice should never be used since it may contain pathogens particularly harmful to young children. Drinking water and eating whole fruits, which provide fiber, are healthier alternatives. Avoid more than one meal weekly from a fast-food restaurant because such meals generally are high in fat and sugar and low in fiber.

Figure 14–4 Fostering healthy eating habits. Toddlers should sit at a table or in a high chair to eat to minimize the chance of choking and to foster positive eating patterns.

Growth and Development

Toddlers generally eat three meals and two to three snacks daily. Toddlers can drink 2% milk or "follow-up" formula, starting at 2 years of age. Follow-up formula contains less fat than infant formula, and some parents prefer its convenience, although it is not necessary; 2% milk is appropriate to use at that age. Cups are recommended, and bottle use should be discontinued. Drinks should be consumed at mealtimes and for snacks while sitting at a table; carrying cups during the day while playing or at other activities is not recommended. The child is learning to use utensils but may prefer fingers, and still needs small serving sizes.

Learning how to eat with others is an important task of toddlerhood. The toddler displays characteristic autonomy or independence during mealtime. Advise parents to provide opportunities for self-feeding of food with fingers and utensils and to allow some simple choices, such as type of liquid or cup to use. Young children should eat at a table with others, not be allowed to run and play while eating, and eat at specified meal and snack times. Toddlers should be taught to brush teeth after each meal, and care providers should offer assistance and supervision. A dental visit should occur during toddlerhood.

Because social skills are developing, the hospitalized toddler may eat better if allowed to have meals with parents or other hospitalized children. See Chapter 11 for further suggestions about management of nutrition in hospitalized children.

Preschool

The diet of the preschooler is similar to that of the toddler, but mealtime is now a more social event. Preschoolers like the company of others while they eat, and they enjoy helping with food preparation and table setting (Figure 14–5). Involving them in these tasks can provide a forum for teaching about nutritious foods and principles of preparation, such as the need for refrigeration, safety around stoves, and cleanliness. Visits to fast-food restaurants should be limited to about once weekly, and parents can use the opportunity to assist the child in making wise choices of nutritionally adequate foods in that setting.

Although the rate of growth is slow and steady during the preschool years, the child may have periods of **food jags**

Figure 14–5 **Preschoolers learn food habits by eating with others. Engaging them in food preparation enhances knowledge of food and promotes intake at meals.**

(eating only a few foods for several days or weeks) and greater or lesser intake. Parents should be advised to assess food intake over a 1- or 2-week period rather than at each meal to obtain a more accurate impression of total intake. Food jags can be handled by providing the desired food along with other foods to foster choice. The child who chooses not to eat at snack time or mealtime should not be given other foods in between. The child will become hungry and get accustomed to eating when food is provided. Three meals and two or three snacks daily are the norm. Fruit juice should be limited to 8 to 12 oz daily, and begin teaching the "5-a-day" program that supports having five servings of fruits/vegetables each day.

The preschool period is a good time to continue encouraging good dental habits. Children can begin to brush their own teeth with parental supervision and help to reach all tooth surfaces. Fluoride supplements should be used when the water supply is not fluoridated (fluoride concentration below 0.7 mg/L) (U.S. Department of Health and Human Services [USDHHS], 2015). If the child has not yet visited a dentist, the first dental visit should be scheduled so the child can become accustomed to the routine of dental care.

School Age

The school-age years are a period of gradual growth when energy requirements remain at a steady level, although at some point during these years most children experience a preadolescent growth spurt. Girls may begin a growth spurt by 10 or 11 years, and boys a year or so later. Nutritional needs increase dramatically with this spurt, with large numbers of calories and increased amounts of other nutrients being required (see Appendix C for Dietary Reference Intakes).

School-age children are increasingly responsible for preparing snacks, lunches, and even some other meals. These years are a good time to teach children how to choose nutritious foods and plan a well-balanced meal. Because school-age children operate at the concrete level of cognitive thought, nutrition teaching is best presented by using pictures, samples of foods, videos, handouts, and hands-on experience.

Generally, school-age children prefer the types of food eaten at home and may be resistant to new food items. A hospitalized child may refuse to eat, slowing the recuperative process. Nurses should encourage family members to bring favorite foods from home that meet nutritional requirements. This can be especially helpful when the hospital serves food only from the dominant cultural group. A child accustomed to a diet of rice, tofu, and vegetables may not enjoy a hospital meal of hamburger and fries. By school-age, food has become strongly associated with social interaction, so it is beneficial to have children eat together or to invite family members to take the child off the unit to eat or to bring in food from home and eat with the child. Many hospitals allow children to plan a pizza night or sponsor other events to encourage eating in a social atmosphere.

Most children consume at least one meal daily in school. While children may bring lunches to school, most participate in school lunch programs and perhaps school breakfast programs. Nurses should become familiar with the policies of school districts in their areas for providing foods, snacks, and reduced-price food to students in need. During the past decade, many school systems in the United States have allowed vending machines for carbonated sweetened beverages and snacks to be installed in public schools. Part of the profits from these machines has enabled revenue-strapped school districts to enhance their incomes. Today, however, schools are increasingly challenged about the presence of the machines, especially in light of the growing problem of overweight among youth. Some school districts have now limited the number of machines or the hours during which they can be used by students, and some have removed all sweetened beverages from vending machines. Nurses are able to provide information for districts about the problems of obesity and the need for healthy foods for youth. Nurses are also involved in planning for nutritional maintenance when children have special needs in the school setting, such as diet or tube feedings.

Healthy People 2020

(NWS-14) Increase the contribution of fruits to the diets of the population aged 2 years and older

(NWS-15) Increase the variety and contribution of vegetables to the diets of the population aged 2 years and older

The loss of the first deciduous teeth and the eruption of permanent teeth usually occur at about 6 years, or at the beginning of the school-age period. Of the 32 permanent teeth, 22 to 26 erupt by age 12 years, and the remaining molars follow in the teenage years. See Chapter 5 for the typical sequence of tooth eruption and Chapters 8 and 9 for dental care needs during childhood. The school-age child should be closely monitored to

Professionalism in Practice The National School Lunch Program

The National School Lunch Program is a federally assisted meal program operating in over 100,000 public and nonprofit private schools and residential childcare institutions. It provides nutritionally balanced lunches to more than 31 million children on each school day at free or reduced cost. Recently, increased access to fruits, vegetables, and whole grains, along with decreased foods high in sodium content, have been mandated. Specific nutritional and caloric requirements are in place for grades K to 5, 6 to 8, and 9 to 12 (U.S. Department of Agriculture [USDA], 2013b). Nurses can ensure that parents are aware of the program and have assistance to translate or complete the application forms if needed. Nurses also work with school administrators for seamless integration of all children into the school food program so that no student is aware of those who are eligible for this service.

Clinical Reasoning The Child With Special Nutritional Needs

The opening quote in this chapter is from the mother of Joey, a young boy with cerebral palsy who has a gastrostomy feeding tube to assist him in ingestion of adequate nutrients (see the *Clinical Skills Manual* SKILLS for the process of gastrostomy feeding). Joey is attending school and the teacher has been taught to administer his tube feedings. Nurses often assist families who have children with special needs to integrate them into the school environment. How might the nurse plan for Joey to participate in school lunchtime with peers? Since he can eat some soft foods by mouth, what types of foods are commonly available at school that he might be able to enjoy?

ensure that brushing and flossing are adequate, that fluoride is taken if the fluoride concentration in the water supply is below 0.7 mg/L, that dental care is obtained to provide for examination of teeth and alignment, and that loose teeth are identified before surgery or sports participation.

Adolescence

Most adolescents need well over 2000 calories daily to support the growth spurt, and some adolescent boys require nearly 3000 or more calories daily. When teenagers are active in a variety of sports, these requirements increase further. Because adolescents prepare much of their own food and often eat with friends, they need to be taught about good nutrition. Developing a diet that includes a large number of calories, meets vitamin and mineral requirements, and is acceptable to the teen may be a challenge.

The pregnant adolescent has even more challenging nutrient requirements. Increased need of calories, calcium, iron, folic acid, and other nutrients may provide challenges for the adolescent who is pregnant. An adolescent who is hospitalized and does not like the hospital lunch might ask a friend who visits to bring a soft drink and chips; however, the teen may be receptive to offers of juice and pizza, a more nutritious meal. Small improvements should be viewed positively because they may lead to further changes. See *Evidence-Based Practice: Adolescents and Nutritional Choices.*

EVIDENCE-BASED PRACTICE | Adolescents and Nutritional Choices

Clinical Question

Adolescents are largely independent in their food choices. They often eat "on the run" and are influenced by peers and the media. At the same time, rates of obesity are on an escalating upward trajectory. How can nurses understand and apply evidence-based practices for influencing eating behaviors in adolescents?

The Evidence

The HEALTHY study found that a middle school–based intervention program resulted in significant positive changes in students' fruit and water intake (Siega-Riz et al., 2011). Another middle school program with young adolescents, the TEAMS study, asked parents, youth, and school officials to identify barriers to health as well as solutions for healthier environments. Students had knowledge deficits but identified low access to healthy foods and busy schedules as barriers, while teachers tended to believe parents frequently did not provide healthy food options and parents identified teens' preferences for unhealthy foods as an important barrier (Bindler et al., 2012). School boards are instrumental in establishing school wellness policies (USDA, 2014). Achieving healthy weight by adolescents should include nutrition and activity teaching, technology-based approaches, and peer modeling. The community can be engaged in healthy weight goals by introducing measures to monitor weight, nutrition, and activity at all health visits. One tool called Passport to Health was developed and implemented successfully by nurse practitioners in a pediatric practice setting (Vaczy, Seaman, Peterson-Sweeney, et al., 2011).

Best Practice

Child and adolescent eating patterns set an important example for life. Family eating patterns, school setting, and community influences must all be examined to identify risk and protective factors in the adolescent diet. Barriers to adolescent healthy eating include lack of accurate information, availability of "junk food" snacks, lack of parental involvement in the lives of teens, peer influence, and media messages about food consumption.

Clinical Reasoning

1. What developmental stages of the adolescent provide both challenges to healthy eating and ability to make wise food choices?
2. Construct a list of questions about family food patterns that will help you identify risk and protective factors of the family.
3. Visit a local high school and then travel 1/2 mile in each direction from the school. Record the number of fast-food restaurants, billboards about foods, and any other food-related resources or media. Watch 2 hours of television at 3 to 5 p.m., the time at which adolescents frequently arrive home. Record the number of food-related messages, what types of foods are advertised, and other observations.
4. How can you integrate knowledge about adolescent nutrition into your potential role as a school nurse at a high school?

Fast food represents a significant intake for many adolescents. It is commonly high in fat, calories, and sodium while being low in essential nutrients such as calcium, folic acid, riboflavin, vitamins A and C, and fiber. Many schools are redesigning cafeterias and food programs to entice more teens to eat at school rather than nearby fast-food restaurants. Adding fruits and salads and allowing choices can enhance the quality of food intake. School nurses play a vital role in helping to tailor a healthy school nutrition program and teaching teens about the healthiest choices at their favorite fast-food restaurants.

Peer group influence is important to teens, so group sessions in which adolescents eat lunch together can provide a forum for influencing food habits. What other methods might encourage positive nutritional habits among teens?

Nutritional Assessment

What is the best indication that a child's nutrition is adequate? Which data collection methods provide the most accurate information about a child's dietary intake? The nurse plays an important role in assessing the diets of children and in seeking additional evaluation from dietitians and nutritionists in complex situations.

Physical and Behavioral Measurement

GROWTH MEASUREMENT

A common method of evaluating the adequacy of diet is measurement of growth. **Anthropometric measurement** is the term used to refer to assessment of various parts of the body. Anthropometry of young children commonly includes weight, length, and head circumference. Standing height is substituted for length once the child can stand. Head circumference, also known as *occipital-frontal circumference (OFC),* is measured during infancy and into early years when there are growth concerns. Additional measurements that may be included in special circumstances include chest circumference, mid–upper arm circumference, and skinfold measurement at sites such as triceps, abdomen, and subscapular regions. Grids are available for each measurement and assist in providing a thorough nutritional assessment when weight and height are abnormally high or low. The accompanying *Clinical Skills Manual* SKILLS presents techniques for accurate measurement of weight, length, height, chest circumference, and head circumference.

After collecting the measurements, the nurse plots them on the appropriate standardized growth curves for weight, length to height, head circumference, and body mass index (Figure 14–6). **Body mass index (BMI)** is a calculation based on the child's

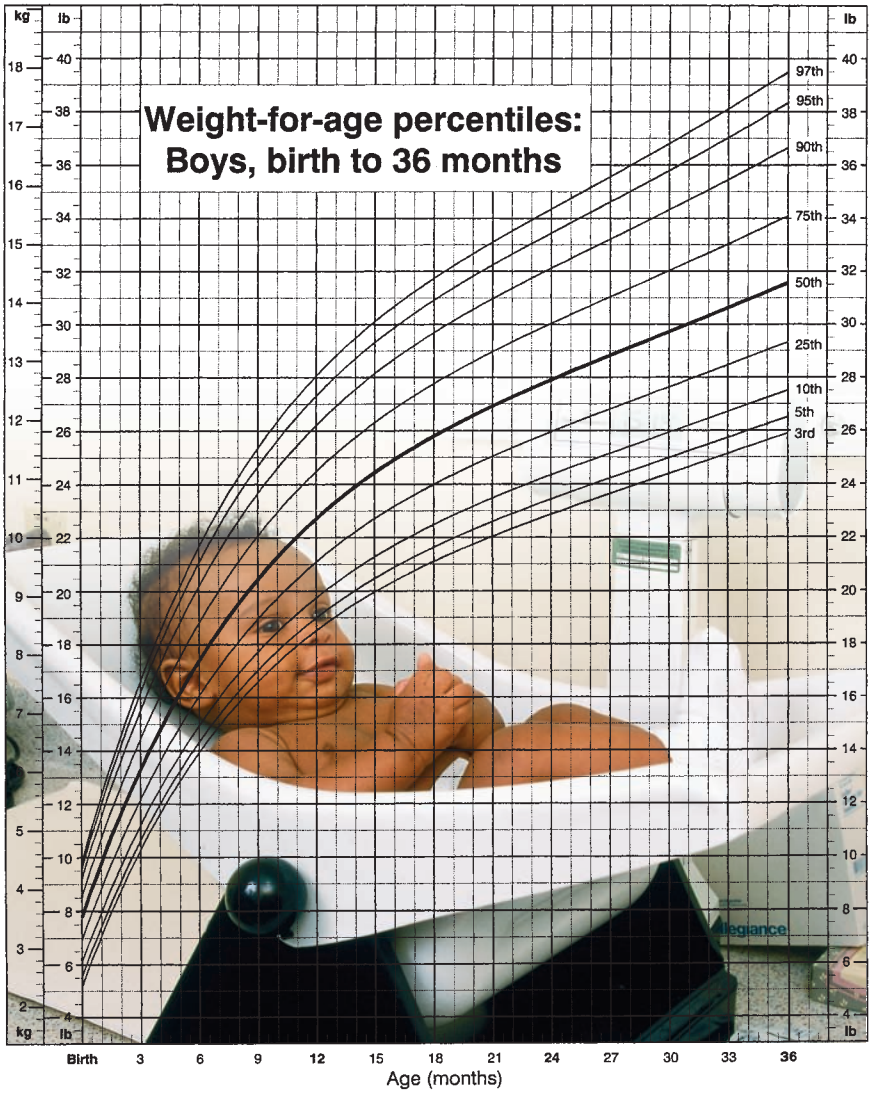

Figure 14–6 **Plotting measurements on the growth curve. The nurse accurately measures the child and then places height and weight on appropriate growth grids for the child's age and gender.**

weight and height, or length, and is calculated as kilograms of weight per square meter of height. This is a useful calculation for determining if the child's height and weight are in proportion and identifies which percentile the child falls in for each measurement. Children normally fall between the 10th and 90th percentiles. A measurement below the 10th percentile, especially for BMI, may indicate undernutrition, and one over the 90th percentile can indicate overnutrition. However, it is important to look at the differences between measurements. An infant in the 90th percentile for length, weight, and head circumference is proportional and may be a naturally large baby. On the other hand, a child who is consistently in the 10th percentile for all measurements, but is growing steadily and is at a normal development level, may simply be a small child. Much cultural and individual variation exists in size. See Appendix A for standardized growth curves by gender and age for infants, children, and adolescents. Visit the Centers for Disease Control and Prevention (CDC) website (www.cdc.gov) to find specialized growth grids for children with conditions such as Down syndrome.

Developing Cultural Competence **Growth Patterns Among Immigrant Children**

The revised growth grids now in use were standardized using a cross section of the U.S. population. However, children from some other countries or cultures may fall outside of these curves. For example, new immigrants or adoptees may be in lower percentiles and may "catch up" over several months or years. Children of immigrants from developing countries tend to be larger than their parents. Even when children are small, they should follow normal growth patterns.

The nurse should plot measurements on the same growth curve with earlier percentiles for the child. When measurements follow the same percentile over time, growth is generally normal for the child and nutrition is likely adequate. However, a sudden or sustained change in percentile may indicate a chronic disorder, emotional difficulty, or a nutritional intake problem. Further assessment of physical status and dietary intake will be needed.

ADDITIONAL PHYSICAL MEASUREMENTS

Many observations from the physical assessment provide clues to nutritional status. Dietary intake can affect every body system, and a combination of certain symptoms may suggest specific nutritional problems. Some common physical manifestations of nutritional status are outlined in Table 14–3.

Laboratory measurements can provide useful information when nutritional status is questionable. Some common studies include hematocrit and hemoglobin, serum glucose and fasting insulin, lipids and lipoproteins, and liver and renal function studies. Adding some further measurements such as chest circumference and skinfolds (measurement of fat at certain body sites such as triceps, scapular, and abdominal areas) may also be useful (Lee & Nieman, 2013).

TABLE 14–3 Clinical Manifestations of Dietary Deficiencies/Excesses

NUTRIENT	DEFICIENCY MANIFESTATION	EXCESS MANIFESTATION
Vitamin A	Night blindness Skin dryness and scaling	Headache Drowsiness Hepatomegaly Vomiting and diarrhea
Vitamin C	Abnormal hair (coiled shape) Skin abnormalities (dermatitis and lesions) Purpura Bleeding gums Joint tenderness Sudden heart failure	Usually none—excess is excreted in urine
Vitamin D	Rib deformity Bowed legs Bone and joint pain Muscle weakness Periodontal disease Increased rates of respiratory and skin infections/irritation	Drowsiness
B vitamins	Weakness Decreased deep tendon reflexes Dermatitis	Usually none—excess is excreted in urine
Protein	Hepatomegaly Edema Scant, depigmented hair	Kidney failure
Carbohydrate	Emaciation Decreased energy Retarded growth and development	Overweight
Iron	Lethargy Slowed growth and developmental progression Pallor	Vomiting, diarrhea, abdominal pain Pallor Cyanosis Drowsiness Shock

Dietary Intake

The nurse should obtain detailed information about the child's dietary intake when there is a potential for nutritional deficiency due to disease, knowledge deficit, or socioeconomic status. The mother's dietary intake during pregnancy may provide information about the child's nutritional state and it can be assessed for pertinent information. After the information is collected, the dietary intake should be compared to the recommended levels for a child of that age and gender (see Figure 14–1 for the U.S. MyPlate food guide; see Appendix C for Recommended Dietary Allowances). The 24-hour recall of intake, a food frequency questionnaire, and a dietary screening history (Tables 14–4 and 14–5) provide a good overview of the infant's or child's intake and eating patterns. A food diary provides precise information about the child's food intake.

TWENTY-FOUR–HOUR RECALL OF FOOD INTAKE

The 24-hour diet recall is frequently used to assess the adequacy of the diet. People can generally remember their intake in the past day, so results are fairly accurate, it is easy to gather the

TABLE 14–4 Dietary Screening History for Infants

Overview Questions
What was the infant's birth weight?
At what age did the birth weight double and triple?
Was the infant premature?
Does the infant have any feeding problems such as difficulty sucking and swallowing, spitting up, fatigue, or fussiness?
If Infant Is Breastfed
How long does the baby nurse at each breast?
What is the usual schedule for breastfeeding?
Does the baby also take any milk or formula? Amount and frequency? What type?
If Infant Is Formula-Fed
What formula is used? Is it iron fortified?
How is it prepared?
Do you hold or prop the bottle for feedings?
How much formula is taken at each feeding?
How many bottles are taken each day?
Does the baby take a bottle to bed for naps or nighttime? What is in the bottle?
If Infant Is Fed Other Foods
At what age did the baby start eating other foods?
Cereal — Finger foods
Fruit/juices — Meats
Vegetables — Other protein sources
Do you use commercial baby food or make your own?
Does the baby eat any table foods?
How often does the baby take solid foods?
How is the baby's appetite?
Do you have any concerns about the baby's feeding habits?
Does the baby take a vitamin supplement? Fluoride?
Have there been any allergic reactions to foods? Which ones?
Does the baby spit up frequently?
Have there been any rashes?
What types of stools does the baby have? Frequency? Consistency?

TABLE 14–5 Dietary Screening History for Children

What types of food or beverage does the child especially like?
What foods or beverages does the child dislike?
What is the child's typical eating schedule? Meals and snacks?
Does the child eat with the family or at separate times?
Where does the child eat each meal?
Who prepares the food for the family?
What methods of cooking are used? Baking? Frying? Broiling? Grilling?
What ethnic foods are commonly eaten?
Does the family eat in a restaurant frequently? What type?
What type of food does the child usually order?
Is the child on a special diet?
Does the child need to be fed, feed himself or herself, need assistance eating, or need any adaptive devices for eating?
What is the child's appetite like?
Does the child take any vitamin supplements (iron, fluoride)?
Does the child have any allergies? What types of symptoms?
What types of regular exercise does the child get?
Are there any concerns about the child's eating habits?

data and analyze results, and only a few minutes are needed. The nurse should ask the parent or child to list all foods eaten during the past 24 hours (Figure 14–7). It is usually helpful to ask for a description of activities in the last day, then start with the most recent event and move backwards, integrating food intake into the daily schedule. For example, the nurse might begin by saying, "You mentioned you got up early to come to the clinic today. What did Sam eat at home before you left? Did he have a snack as you traveled here or after you arrived?" While asking about the foods eaten, the nurse should inquire specifically about the following:

- All meals and snacks
- Amounts of each food item consumed (having various size measuring cups, bowls, and plates available so accurate amounts can be indicated is helpful)
- Types of specific foods used, such as whole milk versus nonfat or 2%, brand names of cereals, specific types of margarine or butter
- Additives used, such as condiments, table salt, spices, milk to mix formula
- Food preparation methods, including adding fats to cook, removal or retention of fats on meats
- Vitamins and supplements, types and doses
- Whether the intake is typical (in situations such as illness or vacation, intake may be different than usual)

Once the 24-hour recall is obtained, the nurse needs to analyze the intake by first doing a quick check to compare servings of various food types with the U.S. MyPlate food guide, as described earlier (see also Figure 14–1). Next the nurse should do a detailed analysis to compute calories, carbohydrate, protein, and fat intake and compare them to recommended amounts. All major vitamins and minerals are also computed and comparisons made to the DRIs. This computation may be done by hand,

Figure 14–7 The 24-hour diet recall. The nurse is interviewing a child about foods eaten in the last day. Note the models of food and dishes for accurate assessment of serving sizes.

using a book of nutrients in common foods, or it may be done on the computer. Several computer programs are available, and the federal government has a website that provides intake levels and comparisons to the RDAs. It may be useful to compute a personal 24-hour recall or that of a child in the clinical setting with the Healthy Eating Index.

FOOD FREQUENCY QUESTIONNAIRE

Food frequency questionnaires are available that can be easily administered to parents or children. Usually, they ask about how often certain types of foods are eaten in a specified period such as a week. Long questionnaires can evaluate a total diet, while short ones focus on specific items such as fruit and vegetable intake. A short questionnaire about milk intake or fruit and vegetable intake may be helpful before planning a teaching project on nutrition to a class of school-age children. Knowing their usual intake of a food item can provide helpful information for planning the project.

DIETARY SCREENING HISTORY

The nurse should ask the parent about the infant's or child's eating habits using the questions listed in Tables 14–4 and 14–5. Responses provide information about the family's eating habits and food beliefs beyond that collected on a 24-hour dietary recall or food frequency questionnaire.

FOOD DIARY

Parents are asked to keep a food diary when the child has a nutrition problem or disorder that requires dietary management, such as malnutrition, obesity, or diabetes. All meals and snacks, with food preparation method and quantities eaten over a 1- to 7-day period, are recorded. Eating patterns change significantly for holidays or family gatherings, so parents should be asked to select typical days for the food diary or to record specific events affecting food intake. Including 1 weekday and 1 weekend day may be helpful. Parents need to be reminded of all the places children might have eaten, such as the childcare center, school, or friends' or neighbors' homes. Food diaries can provide a great deal of helpful information, but they take time and motivation to complete well (Lee & Nieman, 2013). The nurse should be sure instructions are complete and that the form has a place to record amounts, preparation, events occurring, and where food was eaten. The nurse or parent may need to obtain the school lunch menu and talk with the school lunch personnel to add accurate school intake. The nurse completes the nutritional assessment indicated for a child and may consult with or refer the family to a dietitian or nutritionist for additional assessment and teaching.

Developing Cultural Competence **Dietary Intake Varies Among Cultures**

Each culture has eating practices that influence dietary intake. It is important to understand the foods commonly eaten by each cultural group and their contribution to the total nutrition of the child. Depending on the populations nurses work with, they may need to ask about intake of freshly caught fish or wild game such as pheasant and elk. Home-prepared sausages and cheese may be part of diets. Berries and garden produce might be eaten. Foods from ethnic markets may include spices, dried mushrooms, and other products. Some groups do not eat meat or specific types of meats. Using open-ended questions when gathering data will increase the likelihood of obtaining an accurate evaluation of diet.

TABLE 14–6 Food Insecurity Screening

1. Does your household ever run out of money to buy food to make a meal?
2. Do you or members of your household ever eat less than you feel you should because there is not enough money for food?
3. Do you or members of your household ever cut the size of meals or skip meals because there is not enough money for food?
4. Do your children ever eat less than you feel they should because there is not enough money for food?
5. Do you ever cut the size of your children's meals or do they skip meals because there is not enough money for food?
6. Do your children ever say they are hungry because there is not enough food in the house?
7. Do you ever rely on a limited number of foods to feed your children because you are running out of money to buy foods for a meal?
8. Do any of your children ever go to bed hungry because there is not enough money to buy food?

Scoring: 5–8 yes responses = hungry; 1–4 yes responses = risk of hunger. From Washington State Department of Health.

Common Nutritional Concerns

Childhood Hunger

Although most Americans live in a land of plenty, significant numbers of children periodically experience hunger. **Food security** is access at all times to enough nourishment for an active, healthy life. In contrast, **food insecurity** indicates an inability to acquire or consume adequate quality or quantity of foods in socially acceptable ways, or the uncertainty that one will be able to do so; at least 10% of U.S. children live in households that periodically experience food insecurity (USDA, 2013a).

The major cause of hunger in children is poverty, and since, on average, more than one in five children are poor, their families may be unable to provide sustainable nutrition at all times (Children's Defense Fund, 2014). Many single-income families have a head of household moving into the workforce, so incomes are often not sufficient to provide for family food needs (see Chapter 1 for a description of Temporary Assistance for Needy Families). Families may be ineligible for food assistance programs even though they cannot afford enough food for all their members. Children with special nutritional needs are at particular risk since it may be more costly to buy and prepare formula or foods for a child with allergies, diabetes, or an immune disorder.

Children with insufficient dietary intake are at risk for a wide array of health problems. They may become anemic; have a high rate of infectious disease due to a lowered immune response; have slowed developmental maturation, delayed or stunted physical growth, and learning disorders; and be at greater risk of overweight, cardiovascular disease, and diabetes in adulthood (Children's Defense Fund, 2014). Subsequently, the national and individual cost of childhood hunger is great.

Nurses are well positioned to evaluate families for food insecurity in a variety of hospital, clinic, school, and home settings. In addition to the assessment of the individual child's nutritional status, further questions can determine families with potential problems. Nurses should administer a screening tool to identify risk in families (Table 14–6). Most parents go

Families Want to Know

Community Resources for Food

Supplemental Nutrition Assistance Program (SNAP)—Eligibility based on household size and income; refer students and those with low incomes, especially when they have young children; education services often available

Child Nutrition Programs—School lunch, breakfast, and milk programs; free and lowered cost meals in schools; assist parents to apply

Special Child Programs—Summer programs, Head Start, childcare centers, and homeless children programs may provide nutritional support in some communities

Special Supplementary Food Program for Women, Infants, and Children (WIC)—Supplemental foods and nutrition education to pregnant, breastfeeding, and postpartum women and to their young children; assessment of child growth often included

Nutrition Education and Training Program—Nutrition education for teachers and school food service personnel

Community Services—May include food banks, field gleaning (collecting produce from farmers' fields that will not be sold due to excess or small blemishes), community gardens, and other programs

Find out what services are available to provide food and nutrition education in your community. Make a list to use in clinical settings with families.

without food themselves in order to feed their children, so food insecurity may not have directly affected all children. However, anxiety over providing food can be very stressful for families, and diet quality deteriorates as insecurity increases. If families have experienced food insecurity or may be likely to at some time, nurses should be sure to provide them with access to community agencies and programs that can help. What resources are available locally to help families with food insecurity?

Overweight and Obesity

The current incidence of overweight children in the United States is epidemic and is associated with a wide array of health problems, such as type 2 diabetes, stroke, gallbladder disease, arthritis, cardiovascular disease, sleep disturbances, hypertension, dyslipidemia, respiratory problems, certain cancers, interference with physical activity, social stigma, discrimination, depression, and low self-esteem (CDC, 2014a). A historic high of 17% of children and adolescents are at or above the 95th percentile for BMI (obese) and about the same amount fall from the 85th to 94th percentiles for BMI (overweight), designating about one third of U.S. youth as being overweight or obese (CDC, 2014a).

Many reasons are cited for the increase in overweight children. The number of calories consumed is not increasing, but children tend to exercise less, particularly in daily life. They infrequently walk or ride bikes either because of the convenience of driving or because of unsafe neighborhoods. Television viewing is very high among youth; movies, Internet, computer games, social networking, and cell phones are further examples of media commonly used by youth. U.S. children spend, on average, over 7 hours daily on such media (National Heart, Lung and Blood Institute, 2013). Inactive pursuits do not require high caloric energy, leading to an imbalance in intake and demand for calories. Additionally, television viewing is often accompanied by ingestion of high-calorie foods and subjects children to food marketing of unhealthy foods.

The percentage of calories from fat consumed in the United States is among the highest in the world. Although no more than 25% to 35% of calories should come from total dietary fat, and no more than 10% from saturated fat, about 35% of calories consumed in the United States are supplied by fat and over 11% by saturated fat (USDHHS, 2011). Most fats should be supplied from polyunsaturated and monounsaturated fatty acids, but current diets contain low amounts of those fats and high amounts of trans-fatty acids (USDHHS, 2011). The high rate of dietary fat is related to the amount of fast food consumed, and influenced by snacking as well.

Goals of nursing management are to prevent new cases of overweight, identify children who are overweight, and to support youth and families to establish healthy lifestyles that promote weight loss and maintenance of recommended weight. Perform assessment of height, weight, and BMI. Measure blood pressure and determine whether it is within normal limits. Evaluate amount of screen/social activities, sedentary behavior, and physical activity levels. When prevention and behavioral changes have not been successful, some adolescents will have bariatric surgery. Guidelines have been established for adolescents that consider age, physical maturity, BMI, and comorbidities (Brei & Mudd, 2014).

Nurses can help parents and children build good nutritional and exercise habits throughout life, thus decreasing the incidence of overweight and its attendant health risks. Children under 2 years of age should have no exposure to screen activities. Parents should be advised that screen activities by children older than age 2 should be limited to a maximum of 2 hours daily, and that a television, video games, or other screens should not be placed in children's bedrooms (AAP, 2014b). Daily exercise routines of 30 to 60 minutes can be included in the schedules of most families. Aim to meet the current recommendation of 60 minutes daily for children with some activity including muscle strengthening and flexibility. Also, nurses should teach about the MyPlate food guide and its integration into a healthy life. Healthy snacks include fruits, vegetables, grains, and nuts. "Super-sizing" fast foods and eating out often should be avoided.

Risks for poor health often cluster together in individuals and families. Nurses need to be alert for situations in which parents are overweight and children have elevated blood pressure, exercise infrequently, or are in upper percentiles for weight, BMI, or skinfold measurements. Be alert for early menarche, which can help identify overweight girls who need intervention for obesity prevention. The presence of risk factors necessitates further dietary and risk assessment so that a management plan can be implemented. See resources such as "Helping Your Overweight Child" and "Take Charge of Your Health: A Teenager's Guide to Better Health" (http://win.niddk.nih.gov/publications).

Consult the *Nursing Care Plan* in this chapter for further interventions appropriate for the child who is overweight.

Nursing Care Plan: The Child Who Is Overweight

1. Nursing Diagnosis: *Overweight* related to excessive intake in comparison to metabolic needs (NANDA-I © 2014)

GOAL: The child will demonstrate adequate intake of all nutrients without excessive energy intake.

INTERVENTION	RATIONALE
• Perform thorough nutritional assessment of child.	• Assessment assists in identification of dietary risks and strengths as well as health conditions related to nutrition.
• Share results of assessment with child and family by showing weight, height, and body mass index grids.	• Many families do not consider their child overweight. Concrete information about the child's size in comparison with recommendations assists in establishing the importance of weight management.
• Assess access to sufficient nutritious foods for the family at all times.	• Food insecurity promotes inadequate intake alternating with excess intake of high-calorie foods.

• Identify with the child and family 2–3 target areas to begin weight management. Examples might include:
  • Having fast food only once weekly
  • Switching to low-fat dairy products
  • Keeping two more fresh fruits and vegetables in the house and two less snack foods
	• Changing dietary patterns drastically is difficult and may lead to giving up the attempt at weight management. Partnering with the family to set goals enhances chances of success.

• Integrate nutrition information into each visit. Examples of topics include:
  • Dietary requirements for age group
  • Effects of simple sugar and fat intake on weight
  • Beneficial effects of fruits, vegetables, whole grains, and nonfat dairy
  • Reading food labels
  • Healthy choices in fast-food restaurants
  • Calculation of fat content of foods
	• Nutrition information is best learned in an ongoing program.

• Use growth grids to help child and family establish a weight reduction or maintenance goal.	• Goals motivate families to achieve desired health behaviors. The goal for a young child may be weight maintenance so that as the child grows in height, the correct proportion is reached, while weight reduction may be needed for older children or youth who are very obese.

EXPECTED OUTCOME: Child meets all dietary requirements while achieving weight and body mass index goal.

2. Nursing Diagnosis: *Coping: Family, Readiness for Enhanced,* related to need to foster health of family member (NANDA-I © 2014)

GOAL: The family will assist child to manage stressors and to develop new strategies to support weight control goals.

INTERVENTION	RATIONALE
• Include key family members in some of the counseling sessions with the child who is overweight.	• Key members of the family are those who purchase foods, provide support for the child, and participate in decisions about health.
• Encourage the family to eat together at least once daily if possible or to increase number of meals eaten together weekly.	• The family is an important support system in weight loss programs. Eating as a family or in a social situation can provide a chance to promote healthy foods; intake is generally lower fat and calorie than when eating alone.
• Seek a resource for the child to be monitored about twice monthly; this may be a healthcare provider office, nutritionist, school nurse, or other person.	• The resource provides opportunity to monitor the child's progress and to offer support, additional information, and problem-solving techniques.

EXPECTED OUTCOME: Child expresses satisfaction with family understanding and support of weight.

3. Nursing Diagnosis: *Activity Intolerance* related to sedentary lifestyle (NANDA-I © 2014)

GOAL: The child will demonstrate activity tolerance by adequate oxygenation, respiratory effort, and ability to speak during brisk walking, biking, or other activity.

INTERVENTION	RATIONALE
• Establish daily exercise routine beginning with 15–30 minutes daily of walking.	• Starting with brief amounts of exercise makes the child feel comfortable and enhances potential for success.
• Gradually increase activity over 1–2 months until 60 minutes of daily exercise is maintained.	• Gradual increase as the cardiovascular and respiratory systems adapt is generally comfortable for children; 60 minutes of moderate activity daily is recommended for children.
• Use activities enjoyed by the child and suggest options as necessary; refer the family to community resources such as swimming pools, organized sports, and biking groups.	• Activities the child enjoys will be more likely to remain in usual activity patterns; exercising with others in groups increases motivation.
• Have families plan at least 1–2 activities they can do together weekly.	• This fosters family relationships and provides support and motivation for the child.
• Limit screen activities to a maximum of 2 hours daily. • Have child keep a log of hours of television, video games, computer, and other similar activities. Tell child never to snack while doing screen activities.	• Increased use of screen activities is related to poor dietary habits and increased sedentary behaviors and excess weight.
• Ask about use of tobacco in children in fifth grade or higher.	• Most adults who smoke began the habit in childhood; middle school years are the most common age for smoking initiation.
• Inquire about exposure to environmental tobacco smoke at all ages.	• Smoking by others in the household can be harmful to children.
• Perform teaching to discourage tobacco use or offer cessation programs as needed.	• Smoking decreases respiratory reserves and worsens several cardiovascular disease risks.

EXPECTED OUTCOME: Child demonstrates ability to engage in moderate activity for 60 minutes with minimal respiratory discomfort.

4. Nursing Diagnosis: *Self-Esteem, Chronic Low,* related to weight (NANDA-I © 2014)

GOAL: The child expresses positive perception of self-worth and confidence in ability to deal with issues related to weight.

INTERVENTION	RATIONALE
• Facilitate development of a positive outlook by exposing child to others who have been successful with weight loss.	• Increases motivation and feelings of self-efficacy.
• Praise child for weight loss, weight maintenance, increased physical activity, and other achievements. • Help the child establish rewards for meeting goals, such as purchase of new clothing.	• Enhances judgment of self-worth and pride in accomplishments.
• Partner with parents so that they understand the value of praise and never label the child using derogatory words such as "fat."	• Family members are usually the most intimate support system for the child.

EXPECTED OUTCOME: Child speaks positively about accomplishments in weight control management.

Developing Cultural Competence Overweight Causes Health Disparities Among Certain Groups

Overweight is more common among some ethnic and socioeconomic groups. Lack of knowledge about foods and physical activity, limited access to fresh produce and safe places to exercise, and easy access to increasing numbers of fast foods may all constitute risk factors. Lower income, and Hispanic, African American, or Native American ethnic identity are all associated with higher incidence of overweight, especially among women. National goals to eliminate health disparities in income and ethnic groups have been set (USDHHS, 2011).

Food Safety

In the United States, about 48 million people (1 in 6) contract foodborne illnesses every year. Some cases are quite mild, whereas others can be very severe. About 128,000 people are hospitalized, and about 3000 die from these illnesses (CDC, 2014b). Children are at greater risk of severe illness and death from food and water because of their immature gastrointestinal and immune systems. Children who are immunocompromised are at even greater risk. Among the most common pathogens are *Campylobacter, Salmonella, Vibrio, Shigella, Cryptosporidium, Listeria, Yersinia,* and *Escherichia coli* (CDC, 2011b, 2014c). Worldwide, over 3 million people die of illness related to unsafe drinking water each year, and most of those deaths are among children.

Families Want to Know

Food Safety Guidelines

Teach clients to follow these four key food safety practices:

1. *Clean:* Wash hands and surfaces often.
2. *Separate:* Do not cross-contaminate.
3. *Cook:* Cook to proper temperature.
4. *Chill:* Refrigerate promptly.

Source: From Partnership for Food Safety Education. (2011). *Safe food handling*. Retrieved from http://www.fightbac.org/safe-food-handling

Foodborne illness transmission is associated with food preparation and storage practices, lack of adequate training of retail employees about foods and hygiene, and increasing amounts and types of foods being imported from other countries. Some examples of contaminated foods in the past few years include undercooked hamburger meat, cross-contamination of salad bar items from meats, unpasteurized apple cider, green onions, raw spinach, prepackaged salad and delicatessen meat, berries, and sprouts. While most infected persons experience acute diarrhea, some can develop complications such as hemolytic uremic syndrome (Chapter 26) or thrombocytic purpura (Chapter 23). Health personnel should integrate teaching regularly so that families can decrease risks of foodborne illness. Recommend that families avoid consumption of unpasteurized milk, raw or undercooked oysters, raw or undercooked eggs, raw or undercooked ground beef, and undercooked poultry (CDC, 2011b). Check the information regarding outbreaks at www.foodsafety.org.

Food may carry products other than microorganisms that can be harmful. An example is mercury, which may be concentrated in certain types of fish. This metal can cause harm to the developing nervous system of fetuses, infants, and young children when consumed regularly. The U.S. Food and Drug Administration (FDA) and Environmental Protection Agency (EPA) note that fish are an important part of a healthy diet, but that certain recommendations should be followed to lower the risk of experiencing mercury's detrimental effects. Women who may become pregnant, are pregnant or breastfeeding, and young children should:

- Eliminate shellfish, shark, swordfish, king mackerel, and tilefish from the diet.
- Eat 8 to 12 oz (two average meals) a week of a variety of low-mercury fish, such as shrimp, canned light tuna, salmon, pollock, and catfish. Albacore or white tuna has more mercury than light tuna, so limit white tuna to one meal weekly. (Children should have two to three servings per week of low-mercury fish in amounts appropriate for their age and caloric needs.)

Check for local advisories about the safety of fish caught in local waters (U.S. Food and Drug Administration, 2014).

Common Dietary Deficiencies

Dietary deficiencies can occur in children and some are common in selected populations. Children can have deficits in nearly any nutrient, but a number of nutrient deficits are more common in childhood. Limitations in the food supply or patterns of dietary intake cause most deficiencies, while children with certain disease processes, such as metabolic diseases, may have difficulty absorbing or using nutrients ingested. (See Chapter 30 for a discussion of inborn errors of metabolism.) The nutrient deficiencies of a population are a result of genetic factors, characteristics of the food supply, and intake patterns of particular groups.

Developing Cultural Competence Vitamin A Deficiency

Vitamin A deficiency is common in developing countries. The vitamin is found in liver, dairy products, and fish. Provitamin A sources are yellow and dark green vegetables. The vitamin is fat soluble and stored in the liver. When deficient, children develop night blindness, vision loss, and high rates of infection. Public health efforts have been directed at identifying populations of children with low vitamin A status and providing the vitamin in capsule form or in commonly ingested foods.

IRON

Newborns have a store of iron obtained from their mothers in the uterus if the maternal nutritional state was satisfactory and the baby was of normal gestational age. Breast milk contains little iron, but the iron it does contain has high bioavailability. However, by 4 to 6 months of age, the baby's iron stores begin to decrease and a dietary source of iron must be added for the infant. Enriched rice cereal is commonly used to meet these initial iron needs. In babies who do not have adequate stores or do not take in enough iron, **anemia**, or a reduction in the number of red blood cells, can result (Figure 14–8). Feeding cow's milk during infancy can also cause anemia by irritating the gut and leading to small but consistent loss of blood from the gastrointestinal tract; cow's milk should not be fed in the first year of life. When formulas are used, they should be iron fortified to help avoid

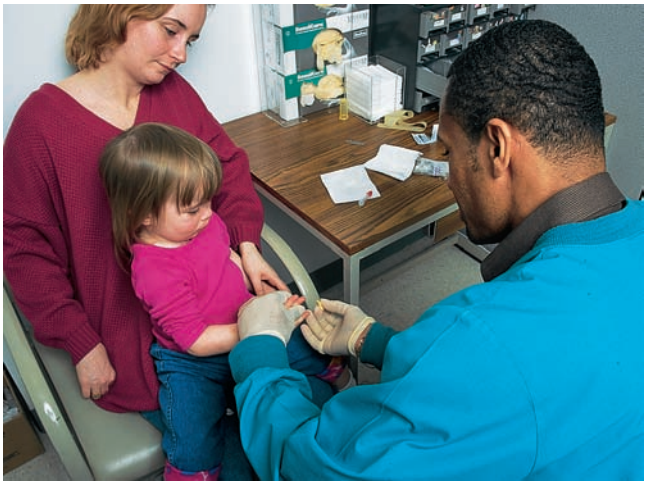

Figure 14–8 **Screening for anemia. Most Head Start centers participate in screening programs to identify children at risk for anemia.**

iron-deficiency anemia. Iron-fortified infant cereals are a good source of the mineral.

Adolescent females comprise another group commonly deficient in iron. Their deficiency is related to loss of blood in menses, metabolic need of the growth spurt, and poor dietary balance due to sporadic dieting. Further discussion of the symptoms and treatment of iron-deficiency anemia can be found in Chapter 23. Encourage intake of good iron sources such as meats, eggs, dried fruits, and iron-fortified cereal. Instruct families on safe iron administration, and ensure follow-up evaluations of iron levels when nutritional supplements are administered.

CALCIUM

Calcium is an essential nutrient for bone development during childhood and adolescence. An increased intake of soft drinks and fruit juices is related to a decrease in calcium intake, especially among adolescents. During the adolescent growth spurt, almost 40% of the adult bone mass is accumulated, and by age 18 years for females and age 20 years for males, 90% of peak bone mass is achieved (National Institute of Arthritis and Musculoskeletal and Skin Diseases, 2012). Inadequate intake puts the person at risk for osteoporosis later in life since it is not possible to make up for earlier deficits. Although genetic variables account for some of the influence on adult bone mass, increasing calcium intake has been shown to promote bone formation. While the recommended daily intake for adolescents is 1300 mg, but the average intake for young males is 870 to 1260 mg and for females is only 750 to 960 mg (only half of the recommended level) (National Institutes of Health, 2013). Nurses should encourage foods such as milk and milk products, egg yolks, grains, legumes, nuts, and fruit juice with added calcium.

Adolescents at highest risk for impaired bone development include female athletes and others who diet excessively to maintain slimness. Teens who exercise excessively may manifest the "female athlete triad" of disordered eating that leads to excessive thinness, excessive exercise, and amenorrhea. A high rate of fractures and osteomalacia can result, in addition to an extreme risk of osteoporosis in adulthood (Ackerman & Misra, 2011). Asking about menstrual patterns as well as exercise and diet can be combined with physical measurements of height and weight to obtain pertinent information about the teen athlete. See the discussion of the eating disorders anorexia nervosa and bulimia nervosa later in this chapter.

VITAMIN D

Vitamin D is needed for bone mineralization. Vitamin D deficiencies were once believed to be rare; however, an increase in cases of vitamin D–deficient rickets has recently been observed. Although vitamin D can be synthesized in the skin when exposed to sunlight, the amount of sunlight needed for manufacture is variable and determined by the amount of skin exposed, the color of the skin, the latitude, and time of the year (Wagner, Greer, Section on Breastfeeding, et al., 2008). Because of this variability and the small amount of vitamin D in breast milk, it is now recommended that all infants from birth to 6 months old receive a minimum intake of 400 International Units daily. All persons 6 months and older should receive 600 International Units daily (Ross, Taylor, Yaktine, et al., 2011). This vitamin is needed to enhance absorption of calcium, so a lack of vitamin D can contribute to calcium deficiency as well. When rickets is suspected, laboratory studies should include 25-OH vitamin D (20–29 ng/mL indicates insufficiency of vitamin D, and below 20 ng/mL is a deficiency state), serum calcium, phosphorus, alkaline phosphatase, creatinine, electrolytes, parathyroid hormone, and hematocrit. Radiographs of extremities should be taken (American Association for Clinical Chemistry, 2014). Encourage parents to discuss vitamin D intake with the healthcare provider at health promotion visits so proper intake can be ensured.

FOLIC ACID

Epidemiologic evidence has linked increasing maternal folic acid (the most common form of folate in the human body) intake with decreased incidence of neural tube defects such as spina bifida in offspring. Folate levels are low among adolescents, putting them at particular risk of birth defects when they have babies (AAP Committee on Nutrition, 2013). The FDA approved fortification of cereals and breads with folate to decrease the population risk of related congenital anomalies. All women ages 15 to 45 years should consume 0.4 mg of folic acid daily, and pregnant women should consume 0.6 mg. In addition to cereals and breads, other good sources of folate include spinach, avocado, green leafy vegetables, beans and peas, liver, and fruits such as oranges and grapefruits.

PROTEIN-ENERGY MALNUTRITION

Although the micronutrient deficiencies described previously are the most common problems in developed countries, macronutrient deficiencies are the most common nutritional problems worldwide. Kwashiorkor indicates protein deficiency and marasmus is a lack of energy-producing calories, but both deficiencies often occur together and are referred to as protein-energy malnutrition (PEM). Protein deficiency manifests with edema, leading to the large abdomens and rounded faces seen in severely malnourished children. Other symptoms include scant, depigmented hair, skin changes, and decreased serum proteins. It can occur following severe diarrhea or other infection in susceptible children. Caloric deficiency results in emaciation, decreased energy levels, and retarded development (see Table 14–3). PEM may occur when a child is weaned in order for the mother to provide breast milk to a new baby. Adoptees and immigrants to developed countries sometimes manifest with at least mild PEM, so careful nutritional assessment is needed to provide adequate nutrition.

Celiac Disease

Celiac disease, or gluten-sensitive enteropathy, is a chronic malabsorption syndrome. About 1 in 133 persons have celiac disease. It is more common among members of the same family and in children with Down syndrome or Turner syndrome (National Institute of Diabetes and Digestive and Kidney Disease [NIDDK], 2012).

Celiac disease is an immunologic disorder characterized by intolerance for gluten, a protein found in wheat, barley, rye, and oats. Inability to digest glutenin and gliadin (protein fractions) results in the accumulation of the amino acid glutamine, which is toxic to mucosal cells in the intestine. Damage to the villi ultimately impairs the absorptive process in the small intestine.

In the early stages, celiac disease affects fat absorption, resulting in excretion of large quantities of fat in the stools (steatorrhea). Stools are greasy, foul smelling, frothy, and excessive. As changes in the villi continue, the absorption of protein, carbohydrates, calcium, iron, folate, and vitamins A, D, E, K, and B_{12} becomes impaired.

Symptoms usually occur when solid foods containing gluten are introduced to the child's diet (generally between 6 months to 2 years of age), although celiac disease is sometimes first diagnosed in adulthood. The classic features of celiac disease in infancy include chronic diarrhea, growth impairment, and abdominal distention. The child also demonstrates poor appetite, lack of energy, and muscle wasting with hypotonia. Atypical features are present in children diagnosed with delayed-onset celiac disease around 5 to 7 years of age. Symptoms include nausea, vomiting, recurrent abdominal pain, bloating, tooth enamel

defects, and aphthous ulcers (Rashid, Zarkadas, Anca, et al., 2011). Other symptoms may include delayed growth, iron deficiency, and abnormal liver function tests.

Diagnosis is confirmed through measurement of fecal fat content, duodenal biopsy, and improvement with removal of gluten products from the diet. Serum screening tests for immunoglobulin (IgA) antiendomysial antibodies and IgA antitissue transglutaminase antibodies are commonly used in the diagnosis of celiac disease (Garcia-Manzanares & Lucendo, 2011; NIDDK, 2012).

Management of celiac disease involves total exclusion of gluten from the diet. This gluten-free diet is a lifetime treatment. Barley, wheat, and rye are completely eliminated; oat products are sometimes tolerated. Symptoms generally improve within a few days to weeks. Supplementation with fat-soluble vitamins, vitamin B_{12}, folic acid, calcium, and iron may be needed depending on the results of serum testing (Daitch & Epperson, 2011).

The intestinal villi return to normal in about 6 months. Growth should improve steadily, and height and weight should reach normal range within 1 year.

Nursing Management

Nursing care focuses on supporting the parents in maintaining a gluten-free diet for the child. Thoroughly explain the disease process to the parents. Emphasize the necessity of following a gluten-free diet. Help parents to understand that celiac disease requires lifelong dietary modifications that should not be discontinued when the child is symptom-free. Discontinuation of the diet places the child at risk for growth retardation and the development of gastrointestinal cancers in adulthood. All children with celiac disease should be seen by a dietitian several times during childhood. Nutritional assessment and continued teaching to maintain a gluten-free diet take place at these visits. Dietary management is made difficult by hidden gluten in many prepared foods, such as chocolate candy, prepared meats, ice cream, soups, condiments, and food starch.

An infant or toddler's diet is easily monitored at home. When the child enters school, however, ensuring adherence to dietary restrictions becomes more difficult. In addition to easily identified gluten-based foods, such as bread, cake, doughnuts, cookies, and crackers, the child must also avoid processed foods that contain gluten as a filler. School-age children and adolescents are often tempted to eat these foods, especially when among peers. Emphasize the need for compliance while meeting the child's developmental needs.

The child's special dietary needs can place a financial burden on the family. Parents need to purchase prepared rice or corn flour products or make their own bread and bakery products. Advise parents that getting a dietary prescription enables them to deduct the cost of these ingredients and commercially prepared products as a medical expense.

Because the entire family must adapt to the diet, parents and siblings need support and management skills. For information and support, refer parents and children to several organizations, including the American Celiac Society, the Celiac Sprue Association/United States of America, and the Gluten Intolerance Group.

Expected outcomes of nursing care include the following:

- The child maintains adequate nutrition to support growth and development needs.
- The child achieves growth and developmental milestones appropriate for age.
- The child and family understand the dietary restrictions and appropriately plan meals.

Feeding and Eating Disorders

Deficiencies in food intake related to available nutrients and safety of the food supply were discussed in the previous section. In addition to these issues of availability, nutrient intake is affected by psychologic issues of individuals as well. Disorders of food intake span the entire developmental spectrum and can affect pregnant women, young children, and adolescents. Some of the most common feeding and eating disorders are discussed in the following sections.

COLIC

Colic is a feeding disorder of infants characterized by paroxysmal abdominal pain and severe crying. The crying generally lasts at least 3 hours and occurs on at least 3 days per week. Crying episodes peak around 6 weeks of age and generally resolve by 3 to 4 months of age (Holt, Wooldridge, Story, et al., 2011). The etiology of colic is unknown. Proposed causes include feeding too rapidly and swallowing large amounts of air.

Characteristically, the infant cries loudly and continuously, often for several hours. The infant's face may become flushed. The abdomen is distended and tense. Often the infant draws up the legs and clenches the hands. Episodes occur at the same time each day, usually in the late afternoon or early evening. Crying may stop only when the child is completely exhausted or after passage of flatus or stool.

The symptoms initially may resemble intestinal obstruction or peritoneal infection. These conditions must be ruled out along with sensitivity to formula. Treatment is supportive; no general medical consensus exists on effective treatments or interventions for colic. Some healthcare providers recommend medications such as simethicone (Mylicon) drops. Some recommend formula change to a soy formula or an elemental formula such as Pregestimil.

Nursing care requires a thorough history of the infant's diet and daily schedule and the events surrounding episodes of colicky behavior. Assessment of the infant's feeding patterns and diet includes type, frequency, and amount of feeding (if breastfeeding, maternal diet history) and frequency of burping. Inquire about onset, duration, and characteristics of cry during colic episodes. Ask the parents what measures are used to relieve crying and their effectiveness.

When possible, observe the feeding method. Parents of infants with colic are often tired and frustrated. They require frequent reassurance that they are not to blame for the infant's condition. Suggest ways of alleviating some of the infant's symptoms and discomfort. These include using a front-carrying sling, swaddling, playing soothing music, using a pacifier, or giving a warm bath or massage of the abdomen. The breastfeeding mother should avoid gas-producing foods and the infant should be burped frequently during feedings. An important consideration is the significant impact of colic on families. Colic can place extreme stress and fatigue on the family, so active support and counseling for the mother and other family members is important.

PICA

Pica is an eating disorder characterized by ingestion of nonfood items or food items consumed in abnormal quantities or forms. Examples of ingested items include starch, peeling paint, paper, soil components, flour, and coffee grounds. Clinical manifestations include zinc and iron deficiencies as well as symptoms of lead or other heavy metal poisoning (see Chapter 17) if these substances are contained in peeling paint or other ingested material. Pica most commonly manifests in pregnancy when women have abnormal cravings for nonfood products, and this can seriously impair the developing fetus. Some children also ingest abnormal amounts of nonfood items and fail to take in adequate nutrients

from food. Treatment for children involves removing access to the substances, ensuring an adequate and nutritious diet, and treating any dietary deficiencies noted.

AVOIDANT/RESTRICTIVE FOOD INTAKE DISORDER (FORMERLY CALLED FEEDING DISORDER OF INFANCY AND EARLY CHILDHOOD OR FAILURE TO THRIVE)

Avoidant/restrictive food intake disorder describes a syndrome in which infants or young children fail to eat enough food to meet requirements for nutrition or energy (American Psychiatric Association [APA], 2013). This disorder accounts for 5% to 10% of pediatric hospitalizations in children under 1 year of age, and many more children are managed in community settings (Kliegman, Stanton, St. Geme, et al., 2011).

Etiology and Pathophysiology. Some disease states can contribute to poor intake, such as congenital AIDS (see Chapter 22), inborn errors of metabolism (see Chapter 30), congenital heart defect (see Chapter 21), neurologic disease (see Chapter 27), and esophageal reflux (see Chapter 25). However, avoidant/restrictive food intake disorder is not attributable to a medical or mental disorder (APA, 2013).

Infants and children whose parents or caretakers experience poverty, depression, substance abuse, intellectual disability, or psychosis are at risk for this disorder. Parents may be socially and emotionally isolated, or may lack knowledge of infant nutritional and nurturing needs. A reciprocal interaction pattern may exist in which the parent does not offer enough food or is not responsive to the infant's hunger cues, and the infant is irritable, not soothed, and does not give clear cues about hunger. Parental neglect is a contributor to the condition. Preterm and small-for-gestational-age babies more commonly have eating disorders (Kliegman et al., 2011).

Clinical Manifestations. The characteristics of this food intake disorder are persistent failure to eat adequately with no weight gain or with weight loss in an infant or child that is not associated with other medical conditions or mental disorders, and is not caused by lack of or unavailability of food. Weight is generally below the 5th percentile, and weight-for-length is less than 80% of ideal weight (Kliegman et al., 2011). Infants with food intake disorder refuse food, may have erratic sleep patterns, are irritable and difficult to soothe, and are often developmentally delayed (Figure 14–9).

Figure 14–9 **Avoidant/restrictive food intake disorder (formerly feeding disorder of infancy and childhood or failure to thrive). Infants with food intake disorder may not look severely malnourished, but they fall well below the expected weight and height norms for their age. This infant, who appears to be about 4 months old, is actually 8 months old. He has been hospitalized for food intake disorder.**

Clinical Therapy. A thorough history and physical examination are needed to rule out any chronic physical illness. The infant or child may be hospitalized so that healthcare providers can establish a routine for feeding and sleeping. The goals of treatment are to provide adequate caloric and nutritional intake, promote normal growth and development, and assist parents in developing feeding routines and responding to the infant's cues of physical and psychologic hunger. Interprofessional teams that include nutrition teaching, home visits, parenting skills information, and other support are most successful (Cole & Lanham, 2011).

Nursing Management

For the Child With Avoidant/Restrictive Food Intake Disorder

Nursing Assessment and Diagnosis

Nursing assessment of the child is essential for establishing the best intervention plan for a child with food intake disorder. Documenting accurate weight and height each time any child is seen for health care provides an important record of growth patterns over time. This helps identify the child with an eating food intake disorder. The child's activity level, developmental milestones, and interaction patterns provide important information. When feeding the child, observe how the child indicates hunger or satiety, the ability of the child to be soothed, and general interaction patterns such as eye contact, touch, and "cuddliness."

Ask parents about stresses in their lives; these may prevent appropriate interaction with the child. Asking about the pregnancy and birth can elicit information about early disturbances in the child–parent relationship. Are there other children in the family, and, if so, do they have eating problems? Observe the child and parent behaviors while they feed the child; cues given by each person and interactional modes such as rocking, singing, talking, and body postures are important.

Some of the nursing diagnoses pertinent for the young child with an eating food intake disorder include the following (NANDA-I © 2014):

- ***Nutrition, Imbalanced: Less than Body Requirements,*** related to inability to ingest proper amounts of food
- ***Development: Delayed, Risk for,*** related to inadequate food intake
- ***Growth: Disproportionate, Risk for,*** related to inadequate food intake
- ***Parenting, Risk for Impaired,*** related to lack of knowledge about the child's nutritional needs
- ***Fatigue*** related to malnutrition

Planning and Implementation

Nursing care focuses on performing a thorough history and physical assessment, observing parent–child interactions during feeding times, and providing necessary teaching to enable parents to respond appropriately to their child's needs. The child is often hospitalized initially and evaluated for potential organic causes while staff members feed the child. Tube feedings may be

needed temporarily until normal intake can be ensured. Accurate weights, nutritional assessments, and developmental evaluation should be done to see if the child grows more normally. Additional diagnostic tests may be carried out at this time to rule out organic causes of poor growth.

Once a diagnosis of nonorganic food intake disorder is confirmed, parents become involved in feeding the child. Observations of feeding and continued careful physical assessments are needed. Carefully record the child's intake at each meal or feeding. Teach parents how to understand and respond to the child's cues of hunger and satiety. Teach them to hold, rock, and touch the infant during feedings and establish eye contact with infants and older children.

Developing Cultural Competence Height and Weight Growth Standards

Each child should maintain a height and weight growth pattern similar to the population standard. Asian American children may normally be below the 5th percentile on growth charts and not have an eating food intake disorder. Suspect a food intake disorder when the infant or child falls 1 standard deviation below the prior achieved growth curve and either fails to gain weight or loses weight over several months.

Upon discharge, referral to an agency that can continue monitoring of the home situation is needed. This provides an opportunity to observe feeding during a home visit and evaluate stresses and behavior patterns among family members. Frequent growth measurement and development must be ensured so the child is adequately nourished. Parents may need referral to community resources to help them manage stressful situations in their lives and to enhance their parenting skills.

Evaluation

Expected outcomes of nursing care include the following:

- Adequate growth and normal development of the infant is achieved.
- An improved parent–child relationship is established.

ANOREXIA NERVOSA

Anorexia nervosa is a potentially life-threatening eating disorder that occurs primarily in teenage girls and young women. An estimated 3% of adolescents in the United States are affected by anorexia nervosa or a related eating disorder, with females affected nearly three times more than males (National Institute of Mental Health [NIMH], 2011). The typical client is White and from a middle-class to upper-middle-class family. Age at onset varies from 8 years onward, with 19 years as the most common age at onset (NIMH, 2011).

Etiology and Pathophysiology. Many causes are believed to contribute to the onset of anorexia. Cultural overemphasis on thinness may contribute to the excessive concern with dieting, body image, and fear of becoming fat that is experienced by many adolescents. Chemical changes have been found in the brain and blood of individuals with anorexia, leading to theories about a biologic cause. Often a significant life stress, loss, or change precedes the onset of anorexia. Stress hormones are commonly elevated in adolescents with anorexia, and immune system function may be disturbed.

Many experts view family issues as contributory to anorexia. Intrafamilial conflicts and dysfunctional family patterns may occur when parents are overly controlling and perfectionistic. The adolescent's eating behaviors may be an attempt to exercise independence and resolve internal psychologic conflicts.

The adolescent may engage in lengthy and vigorous exercise (up to 4 hours daily) to prevent weight gain. Laxatives or diuretics may be used to induce weight loss. As the disorder progresses, the adolescent perceives the ever-thinner body as becoming more beautiful. Youths may share weight loss techniques with friends who are anorectic and search out Internet sites that are positive about anorexia. The body responds to the abnormal eating behaviors as if starvation were occurring. Leukopenia, electrolyte imbalance, and hypoglycemia develop as a result of PEM. Once the body mass decreases below a critical level, menstruation ceases.

The adolescent who has anorexia and becomes pregnant is at risk for disturbances in prenatal care and outcomes as well as potential harm to the baby.

Clinical Manifestations. Adolescents with anorexia are characterized by extreme weight loss accompanied by a preoccupation with weight and food, excessive compulsive exercising, peculiar patterns of eating and handling food, and distorted body image. They may prepare elaborate meals for others but eat only low-calorie foods. Characteristically, the fear of becoming fat does not decrease with continued weight loss. Accompanying signs and symptoms of depression, crying spells, feelings of isolation and loneliness, and suicidal thoughts and feelings are common. The disorder is often associated with mental illness such as obsessive-compulsive disorder, anxiety disorders (see Chapter 28), and history of abuse.

Physical findings include cold intolerance, dizziness, constipation, abdominal discomfort, bloating, irregular menses, and malnutrition (Figure 14–10). Hypothalamic suppression can lead to disturbances of gynecologic function, osteoporosis, decreased bone density, and fractures. Lanugo (fine, downy body hair) may be present. Fluid and electrolyte imbalances, especially potassium imbalances, are common. The child or adolescent is usually energetic despite significant weight loss. Extreme weight loss often leads to cardiac arrhythmias (bradycardia).

Clinical Therapy. Diagnosis is based on a comprehensive history, physical examination revealing characteristic clinical manifestations, and the criteria listed in Table 14–7. Diagnostic tests commonly include hematocrit and hemoglobin, serum electrolytes, and serum vitamins and vitamin precursors.

Figure 14–10 **Anorexia nervosa. Note the loss of subcutaneous tissue in the back, arms, and pelvis.**

SOURCE: Sally and Richard Greenhill/Alamy.

TABLE 14–7 *DSM-5* Diagnostic Criteria for Anorexia Nervosa

A. Restriction of energy intake relative to requirements, leading to a significantly low body weight in the context of age, sex, developmental trajectory, and physical health. *Significantly low weight* is defined as a weight that is less than minimally normal or, for children and adolescents, less than that minimally expected.

B. Intense fear of gaining weight or of becoming fat, or persistent behavior that interferes with weight gain, even though at a significantly low weight.

C. Disturbance in the way in which one's body weight or shape is experienced, undue influence of body weight or shape on self-evaluation, or persistent lack of recognition of the seriousness of the current low body weight.

Specify whether:

- *Restricting type:* During the last 3 months, the individual has not engaged in recurrent episodes of binge eating or purging behavior (i.e., self-induced vomiting or the misuse of laxatives, diuretics, or enemas). This subtype describes presentations in which weight loss is accomplished primarily through dieting, fasting, and/or excessive exercise.
- *Binge-eating/purging type:* During the last 3 months, the individual has engaged in recurrent episodes of binge eating or purging behavior (i.e., self-induced vomiting or the misuse of laxatives, diuretics, or enemas).

Specify if:

- *In partial remission:* After full criteria for anorexia nervosa were previously met, Criterion A (low body weight) has not been met for a sustained period, but either Criterion B (intense fear of gaining weight or becoming fat or behavior that interferes with weight gain) or Criterion C (disturbances in self-perception of weight and shape) is still met.
- *In full remission:* After full criteria for anorexia nervosa were previously met, none of the criteria have been met for a sustained period of time.

Specify current severity:

The minimum level of severity is based, for adults, on current body mass index (BMI) (see below) or, for children and adolescents, on BMI percentile. The ranges below are derived from World Health Organization categories for thinness in adults; for children and adolescents, corresponding BMI percentiles should be used. The level of severity may be increased to reflect clinical symptoms, the degree of functional disability, and the need for supervision.

- *Mild:* BMI $\geq$ 17 kg/m^2
- *Moderate:* BMI 16–16.99 kg/m^2
- *Severe:* BMI 15–15.99 kg/m^2
- *Extreme:* BMI $<$ 15 kg/m^2

Bone density examination for females with lengthy amenorrhea is recommended (Mehler, Cleary, & Gaudiani, 2011).

The goals of treatment are to restore a healthy weight, address the psychologic issues associated with the condition, and reduce behaviors that lead to inadequate intake and relapse (NIMH, 2011). A firm focus is placed on reaching a targeted weight with a gradual weight gain of 2 to 3 lb/week in those hospitalized or 0.5 to 1 lb/week in outpatient care (Agency for Healthcare Research and Quality, 2014). Enteral feedings or total parenteral nutrition (TPN) may be necessary to replace lost fluid, protein, and nutrients, although the adolescent often perceives these feedings as a punitive measure.

Individual treatment and family therapy are used to address dysfunctional family patterns and assist the family to accept and deal with the adolescent as an independent and less-than-perfect individual (Brewerton & Costin, 2011; Lock, 2011). Family involvement is crucial to effect a lasting change in the adolescent. Nurses, psychologists, family therapists, and dietitians commonly partner to plan and implement therapy.

Long-term outpatient treatment, in either an individual or a group setting, is frequently necessary. Counseling that engages self-help techniques may be continued for 2 to 3 years to ensure that weight gain and self-image are maintained. Antidepressant drugs such as imipramine (Tofranil) or desipramine (Norpramin) may be prescribed for coexisting conditions such as depression, anxiety, or obsessive-compulsive disorders. However, they are not generally useful in the primary treatment of the disorder (Flament, Bissada, & Spettique, 2011).

Indications for hospitalization include loss of 25% to 30% of body weight or being at 85% or less of healthy weight, fluid and electrolyte imbalances, cardiac arrhythmias, hypotension, or the need to provide a more intense period of therapy if outpatient treatment fails to produce improvement. Behavior modification techniques are used extensively in combination with counseling and other methods in the care of the hospitalized adolescent with anorexia.

Nursing Management

For the Child With Anorexia Nervosa

Nursing Assessment and Diagnosis

Obtain a thorough individual and family history. Ask about usual eating patterns, daily caloric intake, exercise patterns, and menstrual history. Ask about medication use; include prescription, nonprescription, and herbal products. Is there a family history of eating disorders? Assess for signs of malnutrition. Obtain height and weight measurements and compare with norms for the general population. Because the client with anorexia often wears layers of clothes when being weighed, strive to obtain an accurate measurement. Mid–upper arm circumference, skinfold thickness, waist-to-hip ratio, and body composition measurement may all be obtained (Mattar, Godart, Melchior, et al., 2011).

Nursing diagnoses for the adolescent with anorexia nervosa include the following (NANDA-I © 2014):

- ***Nutrition, Imbalanced: Less than Body Requirements,*** related to inadequate food intake
- ***Fluid Volume: Deficient, Risk for,*** related to inadequate fluid intake or fluid volume loss from overuse of laxatives and diuretics
- ***Body Temperature, Imbalanced, Risk for,*** related to excessive weight loss and absence of subcutaneous fat
- ***Constipation*** related to inadequate food intake and overuse of laxatives
- ***Body Image, Disturbed,*** related to distorted perception of body size and shape
- ***Self-Esteem, Chronic Low,*** related to dysfunctional family dynamics
- ***Coping: Family, Compromised,*** related to parental tendency to be overly controlling and perfectionistic

Planning and Implementation

Nursing care focuses on meeting nutritional and fluid needs, preventing complications, administering medications, supporting psychologic interventions, and providing referral to appropriate resources. Specific treatment measures vary depending on physical complications, length and degree of illness, emotional symptoms accompanying the disorder, and family dynamics. Resistance to treatment is common, and nurses who care for adolescents with anorexia must deal with their own feelings of frustration and anger.

PROVIDE PSYCHOLOGIC SUPPORT

Care for the adolescent with anorexia necessarily includes psychologic support as an important component. The nurse will refer the family to a specialist who can counsel and recommend further treatment. Families of a youth with anorexia should be involved in support groups and should also receive information about the condition and the youth's plan of care. The adolescent is often treated with individual counseling and encouragement to participate is needed. Interventions that improve self-concept and lead to a realistic body image are needed. They may include encouragement for participation in sports, praise for participation in the treatment plan, and immediate referral for relapses as treatment progresses.

MEET NUTRITIONAL AND FLUID NEEDS

Monitor nutritional and fluid intake, encourage consumption of food, and observe eating behaviors at mealtime. Elimination patterns may be altered as a result of increased intake during hospitalization. Monitor for possible problems, including abdominal distention, constipation, or diarrhea. Daily monitoring of serum electrolytes is necessary.

If TPN is administered, watch for complications such as circulatory overload, hyperglycemia, or hypoglycemia. Use strict aseptic technique when changing tubing or dressings.

ADMINISTER MEDICATIONS

Monitor vital signs if the adolescent is receiving antidepressants. Watch for signs of hypertension and tachycardia. Administer medications after meals because it helps to prevent gastric irritation. Be alert for substance abuse. People with anorexia often use excessive laxatives or products such as ephedra (also known as *ma huang*) to induce weight loss. Changes in the central nervous system, vital signs, and other findings may indicate over-the-counter or herbal drug use.

PROVIDE REFERRAL TO APPROPRIATE RESOURCES

Refer parents and other family members to the American Anorexia and Bulimia Association, National Eating Disorders Organization, and National Association of Anorexia Nervosa & Associated Disorders for further information about the disorder and a list of support groups in their area.

Evaluation

Expected outcomes for nursing care include recommended level of weight gain, maintenance of adequate fluid volume and balanced electrolytes, maintenance of normal blood pressure and heart rhythm, beginning of positive sense of self-esteem, intake of nutritionally balanced diet, and use of psychologic counseling to understand the disorder.

BULIMIA NERVOSA

Bulimia nervosa is an eating disorder characterized by **binge eating** (a compulsion to consume large quantities of food in a short period of time). Usually the episodes of bingeing are followed by various methods of weight control (purging), such as self-induced vomiting, large doses of laxatives or diuretics, or a combination of methods. Persons are overly concerned with body shape and weight (APA, 2013). Bulimia affects 1% of the general population, with prevalence in young women about 3 times that in men (NIMH, 2011). Like anorexia, it affects adolescent and young adult females more commonly than males. The disorder usually begins in middle to late adolescence at an average age of 20 years.

Etiology and Pathophysiology. Causes of bulimia nervosa are similar to those of anorexia nervosa: sensitivity to social pressure for thinness, body image difficulties, and long-standing dysfunctional family patterns. Families may be chaotic and distant rather than overinvolved as seen in the person with anorexia. Many individuals with bulimia experience depression. It is not clear whether the depression is a cause or a result of the individual's inability to control the bingeing and purging cycles. An adolescent with bulimia often binges after any stressful event.

Bingeing usually occurs in secret for several hours until the individual is stopped by abdominal discomfort, by another person, or by vomiting. At first, the episodes of binge eating are pleasurable. Immediately following the binge episode, however, feelings of guilt, shame, anger, depression, and fear of loss of control and weight gain arise. As these feelings intensify, the adolescent with bulimia becomes increasingly anxious. This usually initiates the purge behaviors.

Purging eliminates the discomfort from bloating and also prevents weight gain. This relieves the feelings of depression and guilt, but only temporarily. Adolescents with bulimia commonly practice the binge–purge cycle many times a day, losing their ability to respond to normal cues of hunger and satiety.

Clinical Manifestations. Bulimia is often called a "silent" disorder since it is easily concealed from healthcare providers and families. Only about 6% of those with the condition are believed to receive treatment. Adolescents with bulimia are preoccupied with body shape, size, and weight. They may appear overweight or thin and usually report a wide range of average body weight over the years. Physical findings depend on the degree of purging, starvation, dehydration, and electrolyte disturbance. Erosion of tooth enamel, increased dental caries, and gum recession, which result from vomiting of gastric acids, are common findings. Vomiting-induced calluses may be seen on the back of an affected individual's hand. Abdominal distention is often seen. Esophageal tears and esophagitis may also occur.

Clinical Therapy. A comprehensive history is necessary because most adolescents with bulimia appear normal in weight or only slightly underweight. Diagnostic tests include hematocrit, hemoglobin, and serum electrolytes; they may identify signs of altered electrolyte and hematologic status. Lowered potassium levels are related to repetitive vomiting since gastric contents have a high potassium level. The diagnosis is confirmed by the presence of specific criteria (Table 14–8).

Treatment includes management of physiologic problems and cognitive-behavior therapy. Medications, such as fluoxetine 60 mg/day for adolescents, may be prescribed (Hay & Claudino, 2011). Management involves a variety of healthcare providers such as physicians, nurses, and therapists. Behavior modification focuses on modifying the dysfunctional eating patterns and restoring normal patterns. Until the episodes of bingeing and purging are under control, feelings of discouragement and hopelessness prevail. Thus the focus early in treatment is on initiating

TABLE 14–8 *DSM-5* Diagnostic Criteria for Bulimia Nervosa

A. Recurrent episodes of binge eating. An episode of binge eating is characterized by both of the following:
- Eating, in a discrete period of time (e.g., within any 2-hour period), an amount of food that is definitely larger than what most individuals would eat in a similar period of time under similar circumstances.
- A sense of lack of control over eating during the episode (e.g., a feeling that one cannot stop eating or control what or how much one is eating).

B. Recurrent inappropriate compensatory behaviors in order to prevent weight gain, such as self-induced vomiting; misuse of laxatives, diuretics, or other medications; fasting; or excessive exercise.

C. The binge eating and inappropriate compensatory behaviors both occur, on average, at least once a week for 3 months.

D. Self-evaluation is unduly influenced by body shape and weight.

E. The disturbance does not occur exclusively during episodes of anorexia nervosa.

Specify if:
- *In partial remission:* After full criteria for bulimia nervosa were previously met, some, but not all, of the criteria have been met for a sustained period of time.
- *In full remission:* After full criteria for bulimia nervosa were previously met, none of the criteria have been met for a sustained period of time.

Specify current severity:

The minimum level of severity is based on the frequency of inappropriate compensatory behaviors (see below). The level of severity may be increased to reflect other symptoms and the degree of functional disability.
- *Mild:* An average of 1–3 episodes of inappropriate compensatory behaviors per week.
- *Moderate:* An average of 4–7 episodes of inappropriate compensatory behaviors per week.
- *Severe:* An average of 8–13 episodes of inappropriate compensatory behaviors per week.
- *Extreme:* An average of 14 or more episodes of inappropriate compensatory behaviors per week.

Source: Used with permission from American Psychiatric Association. (2013). *The diagnostic and statistical manual of mental disorders* (5th ed.). Washington, DC: Author. Copyright © 2013 American Psychiatric Association.

an immediate behavioral change. Once initial interventions have been successful, group therapy sessions work well for people with anorexia or bulimia. Specific treatment measures may include the following:

- Educating the adolescent about good nutrition (including food choices and caloric content)
- Encouraging the adolescent to keep a log or food journal and assisting the adolescent to make connections between emotional states, stress, and the impulse to binge or purge
- Setting up a daily dietary routine of three meals and three snacks a day (using the same foods for each meal and snack every day to change misconceptions about the weight-gaining potential of certain foods and to decrease anxiety about what food must be eaten at the next meal)

Once these initial measures have been taken, the underlying psychosocial issues are explored. The goals of therapy are to provide the adolescent with bulimia with adaptive coping skills and to improve self-esteem.

Most adolescents with bulimia do not require hospitalization. Serious abnormalities in fluid and electrolyte levels caused by uncontrollable cycles of bingeing and vomiting, accompanied by depression or suicidal activity, are indications of the need for hospitalization. The prognosis is good with long-term therapy.

Nursing Management

For the Child With Bulimia Nervosa

Nursing Assessment and Diagnosis

Obtain a thorough individual and family history, including daily dietary intake and weight fluctuations. Inquire about problems such as abdominal pain or distention, which may indicate an abnormal eating or elimination pattern. Assess the oral mucosa for signs of damage to tooth enamel caused by purging; examine hands for evidence of vomiting-induced calluses.

Following are nursing diagnoses that may be appropriate for the adolescent with bulimia nervosa (NANDA-I © 2014):

- ***Nutrition, Imbalanced: Less than Body Requirements,*** related to disordered food intake
- ***Fluid Volume, Deficient, Risk for,*** related to fluid volume loss
- ***Tissue Integrity, Impaired,*** related to chemical effects of vomited gastric acids on mucous membranes
- ***Knowledge, Deficient (Adolescent),*** related to health risks of excessive use of laxatives and diuretics
- ***Anxiety*** related to discomfort with weight and eating patterns
- ***Self-Esteem, Chronic Low,*** related to dysfunctional family dynamics
- ***Coping, Ineffective,*** related to life stressors

Planning and Implementation

Nursing care includes monitoring nutritional intake and elimination patterns, preventing complications, and providing appropriate referrals.

During hospitalization the client should keep a food diary. Be alert to the adolescent who hides, gives away, or discards food from the tray or who exits to use the bathroom after meals. The adolescent should be monitored for at least 30 minutes after meals by remaining in a central area in the company of the nurse or other responsible individuals. Withdrawal from laxatives and diuretics is managed with careful observation for alterations in fluid and electrolyte status. Cardiac monitoring may be necessary if potassium levels are seriously altered. Esophageal tearing or esophagitis is treated to promote mucosal healing. Medications such as antidepressants may be administered. Encourage continuation of group and other therapy sessions.

Adolescents with bulimia and their families can be referred to organizations such as those listed earlier in the section on anorexia for assistance and information about the disorder.

Evaluation

Expected outcomes for nursing care for the adolescent with bulimia include healthy mucous membranes and skin, adequate intake of fluids and food, balanced food intake, maintenance of normal weight, adequate support and healthy psychologic balance, and absence of bingeing and purging.

Food Reactions

Food reaction encompasses any adverse reaction to foods or substances ingested in foods. The most common food reaction is **food intolerance**, an abnormal physiologic response to a food that is not immunoglobulin E (IgE)–mediated. Examples include indigestion or flatulence when eating certain foods, a sweating reaction to some spices, rhinitis, and hives with urticaria (Mansoor & Sharma, 2011). See the discussion of lactose intolerance that follows. Milk and grain products are common causes of food intolerance. Chemical additives, antibiotics, preservatives, and food colorings also can cause food-sensitivity reactions.

The most serious type of reaction is **food allergy**, an IgE-mediated reaction that is potentially systemic, characteristically rapid in onset, and may be manifested as swelling of the lips, mouth, uvula or glottis, generalized urticaria, and in severe reactions, anaphylaxis. Food allergies are the most common cause of anaphylaxis and are more prevalent in children with a family history of allergic reactions to various substances and foods (**atopy**). The foods that most commonly cause allergy are fish, shellfish, peanuts, tree nuts, eggs, soy, wheat, corn, strawberries, and cow's milk products. About 0.6% of children have an allergy to peanuts, and the incidence has increased in the past two decades (National Institute of Allergy and Infectious Diseases [NIAID], 2011). A majority of the 150 deaths from food allergies that occur annually in the United States are due to peanut allergy.

Children who have both food allergy and asthma are most at risk of death from anaphylaxis due to a food allergy. Allergic individuals need to be aware of hidden substances in prepared foods. For example, the child allergic to nuts will experience a reaction to a food if nut extracts are used in its preparation. Note that certain foods can cause either allergy or intolerance so accurate diagnosis is needed. An example is cow's milk, which can cause an allergy with IgE-mediated systemic reaction, or an intolerance from gastrointestinal response to milk proteins (diarrhea, vomiting, abdominal pain) as a result of lack of the enzyme lactase in the gastrointestinal tract.

Delayed hypersensitivity reactions are attributed to digestive products of food and require a thorough diet history over several days to identify the offending food. These reactions are more difficult to diagnose, since the reaction can occur up to 24 hours after ingestion of the food. There may also be biphasic reactions that occur 1 to 30 hours after an initial anaphylaxis. Such reactions can be severe and life threatening. Therefore, every child with a food allergy who ingests the allergen should be promptly treated with epinephrine and transported to an emergency facility for further management and monitoring.

Diagnostic tests to identify suspected food allergies include measurement of serum IgE levels, scratch tests, and the **radioallergosorbent test (RAST)**, in which radioimmunoassay measures IgE antibodies to specific allergens. (See Chapter 22 for further information about these tests.) In cases of past allergic response, the food is absolutely avoided. In food intolerance, a diet diary is kept, noting date, type of foods eaten, and reaction, if any. Foods should be eaten singly for several days to determine whether they cause a reaction.

Treatment consists of eliminating the offending foods from the child's diet. Collaborative care involving the child, parents, school, and healthcare providers is needed to ensure that the child with food allergies does not get exposed to the offending allergen, and that all children with food reactions can avoid contact with foods to which they are allergic or intolerant. When the child is exposed to the food, epinephrine should be administered and transport to a treatment center should be immediate. Treatment in the hospital may include additional measures as needed such as bronchodilators, antihistamines, and oxygen therapy (NIAID, 2011).

Nursing Management

Prevention is the first step. Instruct parents of infants to introduce new foods at a rate of not more than one new food every 3 to 5 days. If food intolerance is noted, the causative food can be easily identified. Discuss any changes in diet or preparation of formula. Reassure parents that the child's symptoms will disappear when the offending foods are removed from the diet.

Be alert for skin, respiratory, and other characteristic manifestations of food allergy in children. Immediately call 9-1-1 for care. All such cases should be referred to an allergist for diagnosis. If an allergy is identified, help the family identify and remove the offending foods. Emphasize the importance of reading food labels for hidden foods that can trigger an allergic response. The child, family, school, and other settings should be prepared at all times for immediate response to food allergy.

SAFETY ALERT!

Children with food allergies should wear an alert bracelet and carry emergency medication such as an EpiPen. Nurses in schools and offices must instruct families, schoolteachers, and others about the child's allergy and what to do in case of accidental ingestion of the food product. Assist them to set up prevention and emergency treatment plans.

Refer the family to the Food Allergy Network. Recognize that food allergies can be stressful for children and families, as they worry about exposure in daily life.

The child with food intolerance needs to avoid the food to ensure comfort and an absence of the annoying symptoms associated with it. Although, unlike with an allergic reaction, intolerance is not life threatening, the family needs to learn about hidden sources of the food product so that it can be avoided and alternative foods can be suggested for their use.

Lactose Intolerance

Lactose intolerance is the inability to digest lactose, a disaccharide found in milk and other dairy products. It results from a congenital or acquired deficiency of the enzyme lactase. Congenital lactase deficiency of infancy is a rare disorder. Lactose intolerance is considered a biologic norm, occurring in 50% to 100% of African Americans, Native Americans, Asian Americans, and Hispanics, and only 15% of White Americans (National Dairy Council, 2011).

Abdominal pain, flatulence, and diarrhea occur shortly after birth when the infant is unable to hydrolyze lactose. Diarrhea develops rapidly after the child ingests milk and milk products. Some children are able to tolerate small ingestions of lactose but have symptoms when larger amounts are consumed. Incidence of lactose intolerance increases with advancing age throughout childhood.

Diagnosis is based on a thorough history and a hydrogen breath test, which measures the amount of hydrogen left after fermentation of unabsorbed carbohydrates. Implementing a lactose-free diet for a period of time may eliminate the symptoms, thus confirming the diagnosis. Treatment for infants includes switching to lactose-free formula. For older children, eliminating lactose-containing foods is recommended. Lactase enzyme tablets can be added to milk or sprinkled on foods to aid digestion.

Nursing Management

Nursing care is primarily supportive. Carefully explain dietary modifications to parents and discuss alternative sources of calcium. Discuss the need for supplementation of calcium and vitamin D to prevent deficiencies. Teach families how to read food labels to find hidden sources of lactose. For example, milk solids may be found in breads, cakes, candies, salad dressings, margarine, and processed food. Suggest lactase tablets for children who want to eat some dairy products.

Nutritional Support

Sports Nutrition and Ergogenic Agents

Regular physical activity should be encouraged for all children, with at least 60 minutes of activity recommended daily. However, during vigorous or prolonged exercise, or during hot weather, child and adolescent athletes may have special nutritional needs. A well-balanced diet, reflective of recommended foods, is needed. A wide variety of fresh fruits and vegetables, grains, and complex carbohydrates usually provides for adequate caloric intake. When the child is hungry, extra calories should come from the food groups listed here rather than from increased intake of fat. When the child or teen is very active, sports bars or drinks can provide the additional needed calories in a nutritionally balanced manner. As always, the height, weight, and BMI percentiles are the best assurance that the child is growing adequately over time. Adequate energy to perform the sport as well as be attentive and productive at school and for other activities should also be considered.

Water should be increased during activity both to minimize chance of dehydration and also to maximize performance. About 1 hour before vigorous exercise, the child should drink 1 to 2 glasses (8 to 16 oz) of water and should repeat the same amount of fluid just before the exercise begins. Young children may not feel thirsty and should be encouraged to drink 13 mL/kg during activity and exercise with rest periods every 15 to 20 minutes (Rowland, 2011). Water is usually the best replacement, but during extended exercise, sports drinks may be a good alternative for some of the fluid intake. Frequent or excessive intake of caloric sports drinks and those with caffeine should be discouraged (AAP Committee on Nutrition and the Council on Sports Medicine and Fitness, 2011). Additional water is needed for the first 2 hours after activity. Weight loss of 1 lb indicates a loss of about 1/2 quart of fluid, and weight loss of 1% of body weight can influence performance. The nurse should be sure the child takes in fluid to replace all losses.

Some common nutrients that may be deficient in all teens, but even more often in the athlete, are calcium and iron. The increased blood volume common in the well-conditioned person necessitates greater intake. Calcium-rich foods such as milk products and dark green vegetables, and iron-rich foods such as meats and grains, can guard against deficiencies. While many adolescents believe that they need extra protein during athletic season, most Americans eat adequate protein to meet even the increased needs of sports. On the other hand, the vegetarian child or adolescent may need help to plan a diet with adequate protein.

Many teens take a wide variety of dietary supplements, believing that they act as **ergogenic aids**, or products that enhance performance during sports by influencing energy, alertness, or body composition. Most of the claims of these products are unproven, and their safety has not usually been investigated, especially in the young. Effects on youth whose bodies are still developing are particularly unknown and the risks are high for permanent interference with some normal growth patterns. Offer guidance and help the family and teen investigate claims before choosing to use a product. If youth use supplements, they should be instructed about doses, desired effects, and potential side effects. Some sports and coaches may encourage small size and dieting, or encourage use of dietary supplements to increase weight and muscle. Children and adolescents in activities such as ballet, wrestling, track or running, and horse racing may have health risks associated with inconsistent or inadequate intake.

Approximately 3.2% of U.S. high school students (4.0% of males and 2.2% of females) report taking illegal anabolic steroids; up to 8.8% in some communities report use (CDC, 2014d). These products can have a wide array of side effects. They may stop growth of long bones, lead to endocrine imbalance, and cause increased tendon rupture. They are also illegal in sporting events. Andro and DHEA are steroidal hormones used by some athletes. They can cause masculinization of females, disruption of glucose balance, insulin sensitivity, dyslipidemia, decrease in potential height, bone and joint abnormalities, and aggressive behavior (O'Malley, 2013).

Some common amino acid nutritional supplements include creatine, carnitine, and glutamine. Although the side effects of these substances are minimal, their possible enhancement of performance is temporary and outcomes of long-term use are unknown. Increasing protein intake to meet needs during periods of high activity is a better alternative. Creatine has been studied more than most supplements; it is made by the body and is present in many protein sources. Supplemental creatine increases the creatine level in muscle and may help to increase performance in short bursts of activity, while not affecting endurance sports. The increase in muscle mass that can occur is actually due to water and is lost quickly when the supplement is discontinued.

Minerals such as chromium, iron, and calcium are used by some youths. Ask about the athlete's social group and whether ergogenic aids are used; this is a strong predictor of their adoption and is reason for additional counseling. The nurse should ask careful and sensitive questions such as, "Many athletes take supplements to aid in performance in sports. What supplements do you take or are you considering?" Information should be provided to enhance the youth's understanding of nutrition and sports performance. Generally, a balanced diet with adequate carbohydrate, protein, and fat will meet the needs of most athletes and lead to maximal sport performance. School nurses can work with physical education teachers and coaches to plan appropriate programs for youth to prevent use of ergogenic aids.

Herbs, Probiotics, and Prebiotics

Many families use food products to promote health and treat diseases. These include herbal products that may be acquired from health food stores or the Internet. Herbs are not tested nor regulated by the government, so amounts of ingredients are often not known. Ask families about what herbal products they use regularly or to treat disease. Learn about the herbs and any research that has been conducted with children.

Another type of food product is a **probiotic**, a food supplement containing a live microorganism that alters the balance of gut microflora, thereby providing a health benefit. Common probiotics include *Lactobacillus* and *Bifidobacterium*, which are commonly found in the human gastrointestinal tract, are enhanced by eating yogurt with live cultures, and may be helpful in treating diarrhea or atopic dermatitis. Daily intake of pasteurized yogurt with live cultures can safely be encouraged for children.

A **prebiotic** is a nondigestible food ingredient that can stimulate growth or activity of probiotic bacteria (Mitsuoka, 2014). For example, oligosaccharides enhance proliferation of the beneficial *Bifidobacterium.*

Inquire about the family's treatment of common childhood disorders. Include questions about food and nutritional supplements at all well-child visits. Provide information for the family as needed.

Health-Related Conditions

Many health conditions influence the child's nutritional state. Conversely, the child's nutritional state can influence the state of health. See *Pathophysiology Illustrated* for examples of some common conditions that influence nutritional needs. These conditions are discussed in various chapters throughout the text. Discuss with classmates how to adjust normal nutritional assessment and teaching due to the presence of a healthcare concern. Which conditions influence absorption of nutrients? Which cause changes in nutritional intake requirements? Some children benefit from special dietary aids, such as eating utensils and cups that are easy to grasp. Therapists can evaluate and make recommendations about devices that can assist the child at meals.

Vegetarianism

Some families choose to eat vegetarian diets and can be helped and encouraged in their endeavors. Several variations in intake occur. **Vegetarians** eat no poultry, meat, or fish. **Lacto-ovovegetarians** eat eggs and dairy products, whereas **lactovegetarians** eat dairy products but not eggs. In contrast, **vegans** are strict vegetarians and eat no animal products. When someone says he or she is vegetarian, it is best if the nurse asks specific questions about what the individual will and will not eat.

The vegetarian diet is healthy, easy to follow, and may even provide extra health benefits (Academy of Nutrition and Dietetics, 2013). Some deficiencies may exist; assessment and planning can ensure that they do not develop. Vegans should be sure to include adequate dietary vitamins D and B_{12}, zinc, iron, calories, protein, and fat. Completing a 24-hour diet recall for pregnant or lactating women and vegetarian children, with analysis for RDAs, can be helpful. The nurse should be sure to routinely assess growth and other nutritional measures, as well as provide ideas of various foods to meet nutritional needs and perform other general nutritional teaching. When a vegetarian child is hospitalized, the nurse should plan with the nutrition department and the child's family to meet intake needs.

Figure 14–11 **Enteral therapy. This child has returned to school following surgery. He has difficulty chewing and swallowing food due to cerebral palsy. The school nurse has taught his teacher how to safely administer some enteral feedings during school hours.**

Growth and Development

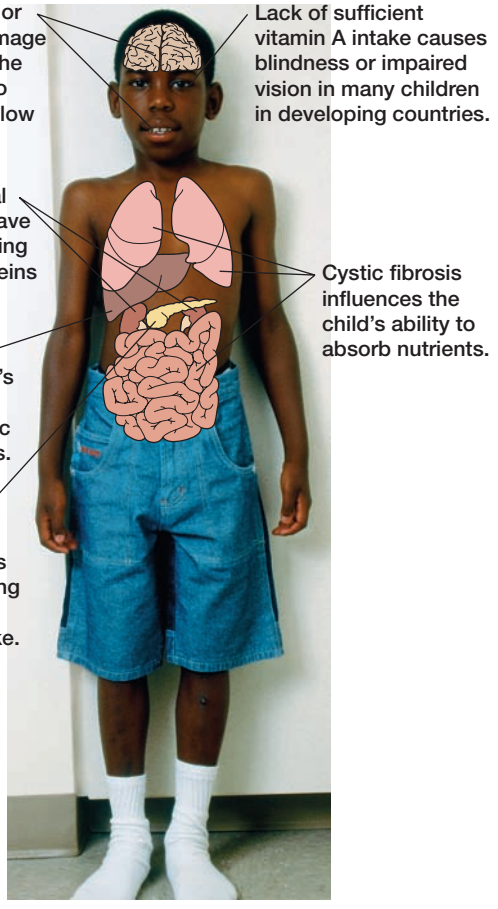
When a pregnant teen follows a vegetarian diet, she needs additional help to encourage adequate nutrition. A 24-hour or 2-day diet diary helps identify nutritional needs. Consider additional pregnancy needs for energy, protein, omega-3 fatty acids, iron, vitamin D, and calcium; note that vitamin B_{12} is recommended as a supplement. Use the vegetarian food guide available through the Academy of Nutrition and Dietetics.

Enteral Therapy

Enteral therapy is a form of nutritional support provided when a child cannot take in enough food orally to sustain health. Since it is the closest form of nutritional support to the natural method of eating, it has the least untoward effects and greatest rate of success. Some children who use enteral therapy are those with cerebral palsy or other neurologic conditions that lead to weakness of the throat and mouth, those with neoplasm or immune dysfunction, and those in acute states of recovery from accidents or illness (Figure 14–11).

Although a tube can be inserted into the nasal opening and placed through the esophagus into the stomach (nasogastric tube),

Pathophysiology Illustrated: **Conditions That Influence Nutritional Needs**



a tube surgically placed into the stomach through an abdominal opening, a jejunal or gastric tube, is preferred for long-term use. As long as the child can absorb and use nutrients, enteral therapy can be successful in providing calories and essential nutrients. Commercially prepared formulas are available, and specially formulated solutions can be adapted for children with specific dietary needs. Nursing care includes care of the gastrostomy tube and entry site to prevent infection and skin breakdown. Ensure that a nasogastric tube is correctly placed before each tube feeding. For both nasogastric and gastric feedings, an empty syringe is often used to check residuals or the amount of fluid not absorbed since the previous feeding. Teach families enteral feeding techniques when they will perform the process at home and arrange for periodic evaluation of technique. Perform regular nutritional assessments. See Chapter 25 for suggestions on management of nursing care during tube feedings. See the accompanying *Clinical Skills Manual* SKILLS.

Total Parenteral Nutrition (TPN)

Total parenteral nutrition (TPN) makes it possible to provide intravenous nutritional support for people who cannot eat or are unable to absorb nutrients from the intestinal tract in a normal manner and are at risk of severe malnutrition. Examples of children who benefit from this method of nutrition are those with congenital malformation of the gastrointestinal tract, brain injury, or severe burns; it may also be used for support after bone marrow transplant, sepsis, or other critical conditions.

A catheter is inserted so that a sterile nutrition solution is infused directly into the bloodstream. A central venous catheter is used to promote safe infusion. Fluids usually contain glucose; electrolytes such as sodium, potassium, calcium, magnesium, phosphate, and chloride; vitamins; and proteins. Lipid emulsions are another type of TPN used in some children. Meticulous care is needed, whether in the hospital or at home, to ensure safe TPN infusion and treatment. The nurse performs initial assessment, ongoing evaluation, and monitoring of treatment; verifies the solution type and rate of administration; ensures that solution storage recommendations are followed; and administers the solutions in the hospital or other settings. See the *Clinical Skills Manual* SKILLS for the protocols for TPN management.

Clinical Reasoning The Child With Special Nutritional Needs

Joey was diagnosed with cerebral palsy early in life. He is now 11 years old and has recently been enrolled in school. Part of the healthcare plan being implemented in the school involves fostering a positive nutritional state. Joey has limited ability to swallow, related to muscle weakness of cerebral palsy, and is therefore unable to ingest enough calories by mouth to ensure his optimal growth and development. Joey had a feeding tube inserted into his stomach at an early age and receives some of his nutrition by this method.

The school nurse has met with Joey's parents and his home health nurse to learn about the amount and type of tube feedings he receives, as well as the texture of oral feedings he can manage. The nurse will plan the feeding schedule at school to facilitate adequate nutrition in that setting. In addition, careful ongoing nutritional assessment will be needed to evaluate if Joey is getting the calories and other nutrients he needs for growth and development. The school nurse is also educating the classroom teachers and other school personnel about Joey's unique nutritional requirements.

How will you organize Joey's care and educate teachers and other staff if you are the case manager for his integration within the school system?

Chapter Highlights

- Adequate nutritional intake is necessary for the normal growth and development of children.
- Children with medical or psychosocial conditions require additional nutritional support.
- Dietary intake patterns vary throughout childhood. As the child grows, the child is able to metabolize different types of food and gain greater gross and fine motor control.
- Nutritional assessment is an essential part of nursing care and may involve approaches such as growth measurement and intake records.
- Common nutrition concerns in childhood include hunger, overweight, foodborne illness, celiac disease, and dietary deficiencies.
- The child with avoidant/restrictive food intake disorder requires comprehensive assessment and ongoing management to foster parent–child interaction and adequate nutritional intake.
- The most common eating disorders of adolescents are anorexia nervosa and bulimia nervosa.
- A combination of behavioral management, counseling, and medication is often used in treatment programs for eating disorders.
- Food allergy represents a life-threatening condition for children, whereas food intolerance can lead to uncomfortable but non-life-threatening symptoms.
- Children engaging in sports, and those who eat vegetarian diets, may need guidance to meet nutrition needs.
- Some children require alternative feeding methods, such as enteral and parenteral feedings.

Clinical Reasoning in Action

A mother is seeing the pediatric nurse practitioner you are working with for her son Jonathan's 3-month, well-baby checkup at the local community health clinic. The baby is in the 90th percentile for weight and in the 50th percentile for length and is fed Similac formula with iron. According to the medical history, Jonathan had respiratory syncytial virus (RSV) when he was 1 month old and there are smokers in the house (see Chapter 20 for more information on RSV). The nurse practitioner has asked you to educate the mother about feeding her 3-month-old baby. The mother has raised concerns that the baby is not sleeping through the night, and the baby's grandmother has suggested adding cereal to his bottle at night to help him sleep. Jonathan has met all developmental milestones and has not yet developed teeth.

1. What type of advice can you give the mother about adding cereal to the bottle?
2. Why is rice cereal recommended as the first food to introduce when Jonathan is able to start solid foods?
3. What is the reason only iron-fortified formula or breast milk is recommended the entire first year of life for Jonathan rather than cow's milk?
4. Based on Jonathan's length and weight percentiles on the growth chart, his mother wonders if he should be put on a "diet." What would be the appropriate response to her concern?

Chapter 15
Pain Assessment and Management in Children

Kevin Peterson/Getty Images

Felicia must be in pain so soon after her surgery. I know I would have pain if it were me. Can she get pain medicine without getting another needle?

—Mother of Felicia, 5 years old

Learning Outcomes

15.1 Summarize the physiologic and behavioral consequences of pain in infants and children.

15.2 Analyze the behaviors of an infant or a child to assess for pain.

15.3 Assess the developmental abilities of children to perform a self-assessment of pain intensity.

15.4 Plan the nursing care for a child receiving an opioid analgesic.

15.5 Examine the role of nonpharmacologic (complementary) interventions in effective pain management.

15.6 Plan nursing care for a child in acute pain that integrates pharmacologic interventions and developmentally appropriate nonpharmacologic (complementary) therapies.

15.7 Develop a nursing care plan for the child with a chronic painful condition.

15.8 Develop a nursing care plan for assessing and monitoring the child having sedation and analgesia for a medical procedure.

Every child has an individual perception of pain. A neurologic response to tissue injury, **pain** is an unpleasant sensory and emotional experience associated with actual or potential tissue damage. Much of the acute pain infants and children feel associated with medical conditions and procedures can be prevented or greatly relieved. Effective pain management is every child's right.

Pain

Pain may be either acute or chronic. **Acute pain** is sudden, of short duration, and may be associated with a single event, such as surgery, injury, or an acute exacerbation of a condition such as a sickle cell crisis. An immediate pain response occurs at the time of tissue damage, and the inflammatory response

that follows causes a sustained pain response that decreases as healing occurs.

Chronic pain is persistent, lasting longer than 3 months, and generally associated with a prolonged disease process such as juvenile idiopathic arthritis or cancer. Chronic pain affects the entire central nervous system, and the child has increased neuron responsiveness to painful and nonpainful stimuli (American Pain Society [APS], 2012). Chronic pain may be nociceptive or neuropathic. **Nociceptive pain** is the normal processing of pain stimuli caused by tissue injury or damage. **Neuropathic pain** is an abnormal processing of pain stimuli by the peripheral or central nervous system. It may be initiated or caused by a primary lesion or dysfunction of the nervous system. Chronic pain is discussed more fully later in this chapter.

Pain transmission to the brain occurs through specialized nerve fibers (see *Pathophysiology Illustrated: Pain Perception*). The pain signal may be modified depending on the presence of other stimuli, either from the brain or from the periphery.

If pain is untreated or poorly treated, neurons become hyperexcited by the N-methyl-D-aspartic acid receptor system, which sensitizes the central nervous system. This leads to initiation of a pain memory and potentially to permanent alterations in pain pathways of young infants that may result in chronic pain syndromes (Rosen & Dower, 2011; Tobias, 2014a).

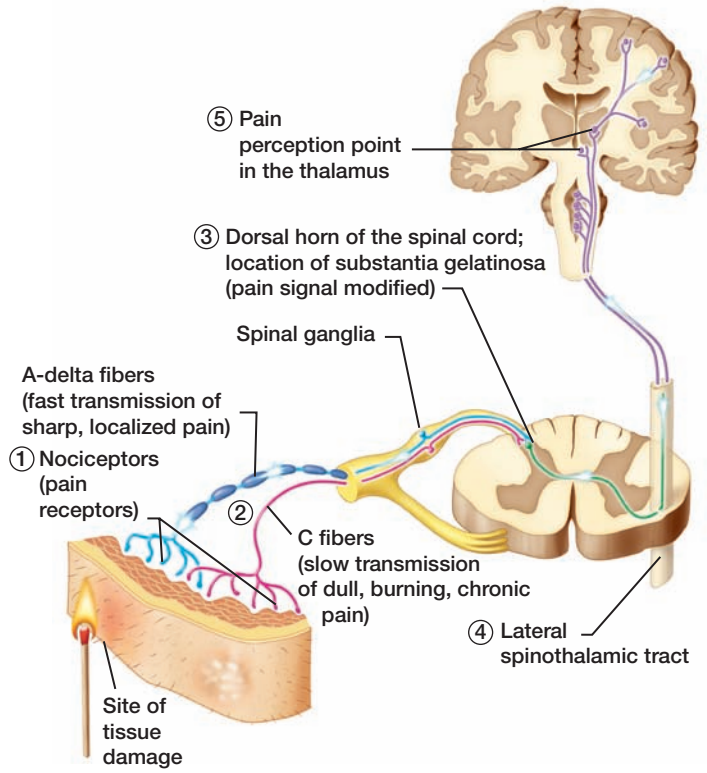
Misconceptions About Pain in Children

Healthcare professionals once believed that children feel less pain than adults. Undertreatment of pain was based on these attitudes about pain and the difficulty and complexity of pain assessment in children. Healthcare professionals now recognize that infants and children of all ages feel pain, just as adults do. For a review of past myths and the contrasting reality, see Table 15–1.

Developmental Aspects of Pain Perception, Memory, and Response

Although every infant and child perceives pain, their understanding, response to pain, and memory of painful events change as they develop. A number of factors influence the pain perceived by the child, including maturation of the nervous system, the child's developmental stage, and previous pain experiences.

Pathophysiology Illustrated: **Pain Perception**



1. Nociceptors (free nerve endings at the site of tissue damage that are able to detect and respond to chemical, mechanical, and thermal stimuli) transmit information via specialized nerve fibers to the spinal cord.
2. Unmyelinated C fibers slowly transmit dull, burning, diffuse pain as well as chronic pain. Large, myelinated A-delta fibers quickly transmit sharp, well-localized pain. Inflammatory mediators (e.g., bradykinin, prostaglandins, leukotrienes, serotonin, and substance P) are produced in response to tissue damage. These substances help move the pain impulse from the nerve endings to the spinal cord.
3. After the sensory information reaches the substantia gelatinosa in the dorsal horn of the spinal cord, the pain signal may be modified depending on the presence of other stimuli. Nonpainful touch, vibration, or pressure at the periphery and endogenous opioids from the brain can interfere with and reduce the transmission of pain to the brain.
4. The pain signal is then transmitted through the lateral spinothalamic tract to the thalamus of the brain where perception occurs.
5. Once the sensation reaches the brain, interpretation of pain occurs, and emotional responses may increase or decrease the intensity of the pain perceived.

TABLE 15–1 Misconceptions About Pain in Infants and Children

MYTH	REALITY
Newborns and infants are incapable of feeling pain. Children do not feel pain with the same intensity as adults because a child's nervous system is immature.	The anatomic, physiologic, and neurochemical structures for pain transmission are well developed at birth, even in preterm infants (Huether, 2014, p. 495). Children feel a similar amount of pain as adults postoperatively (Tobias, 2014a).
Infants are incapable of expressing pain.	Infants express pain with both behavioral and physiologic cues that can be assessed.
Infants and children have no memory of pain.	Children remember painful episodes, fear procedures that cause pain, and may have increased pain responses during future procedures (Fein, Zempsky, Cravero, et al., 2012).
Parents exaggerate or aggravate their child's pain.	Parents know their child and are able to identify behaviors associated with pain.
Children are not in pain if they can be distracted or if they are sleeping.	Children use distraction to cope with pain, but they soon become exhausted when coping with pain and fall asleep.
Repeated experience with pain teaches the child to be more tolerant of pain and cope with it better.	Children who have more experience with pain respond more vigorously to pain. Experience with pain teaches how severe the pain can become.
Children recover more quickly than adults from painful experiences such as surgery.	Children heal quickly from surgery, but they have the same amount of tissue injury and pain from surgery as an adult.
Children tell you if they are in pain. They do not need medication unless they appear to be in pain.	Children may be too young to express pain or afraid to tell anyone other than a parent about the pain. The child may fear treatment for pain will be worse than the pain itself.
Children without obvious physical reasons for pain are not likely to have pain.	The cause of pain cannot always be determined. The feeling of pain is subjective and should be accepted.
Children run the risk of becoming addicted to pain medication when used for pain management.	Children may develop physical dependence and tolerance after prolonged use of opioids for a serious injury, but addiction is uncommon (Galinkin, Koh, & Committee on Drugs and Section on Anesthesiology and Pain Management, 2014).

See Table 15–2 to learn more about the child's understanding of pain as well as the behavioral and verbal responses to pain at each age.

Children's responses to acute or chronic pain are influenced by factors such as memory of a past painful experience, their temperament, their ability to control what will happen, their use of a pain-coping mechanism, and emotions such as fear or anxiety. Pain may be expressed as anger, anxiety, feeding problems, and sleep disturbances (Rosen & Dower, 2011).

Depending on their developmental stage, children use different coping strategies to deal with pain, such as escape, postponement or avoidance, diversion, and imagery. Children may not complain of pain for several reasons:

- Young children cannot give a description of their pain because of a limited vocabulary or few pain experiences.
- Some children believe they need to be brave and not worry their parents.
- Preschoolers and adolescents may assume the nurse knows they have pain.
- Some children are afraid it will hurt more to have the pain treated.

Cultural Influences on Pain

Pain sensitivity is believed to vary by race and ethnicity, with evidence that Blacks and Latinos perceive greater pain than Whites (Sadhasivam et al., 2012). In addition, culture and social learning greatly influence the child's expression of pain. Children observe family members in pain and try to imitate their responses. Through the process of parental approval and disapproval, they learn how to behave when in pain, how much pain should be tolerated, how much discomfort justifies a complaint, how to express a complaint of pain, and who to approach for pain relief. See *Developing Cultural Competence: Examine Your Own Experience*.

Developing Cultural Competence **Examine Your Own Experience**

Think about your childhood pain experiences and how your family encouraged you to be stoic or to express pain. Such childhood experiences often contribute to a health professional's attitudes about the pain experienced by children. For example, some healthcare providers may believe that being in pain for a little while is not so bad, that pain helps build character, or that using pain medication is a sign of a weak character. However, all nurses need to acknowledge the child's right to pain management because it is the standard of care.

Many ethnic groups, such as Irish, Japanese, Russian, Amish, and Appalachian, encourage a stoic response with a diminished expression of pain. Other ethnic groups, such as people of Puerto

TABLE 15–2 The Child's Understanding of Pain, Behavioral Responses, and Verbal Descriptions by Developmental Stage

AGE GROUP	UNDERSTANDING OF PAIN	BEHAVIORAL RESPONSE	VERBAL DESCRIPTION
INFANT			
0–6 months	Has no understanding of pain; is responsive to parental anxiety	Generalized body movements, chin quivering, facial grimacing, poor feeding	Cries
6–12 months	Has a pain memory; responsive to parental anxiety	Reflex withdrawal to stimulus, facial grimacing, disturbed sleep, irritability, restlessness	Cries
TODDLER			
1–3 years	Lacks understanding of what causes pain and why it might be experienced	Demonstrates fear of painful situations; may resist with entire body or localized withdrawal; aggressive behavior, disturbed sleep	Cries or wails, cannot describe intensity or type of pain Uses common words for pain such as *owie* and *boo-boo*
PRESCHOOLER			
3–6 years (preoperational)	Pain is a *hurt* Does not relate pain to illness; may relate pain to an injury Often believes pain is punishment or someone else is responsible for the pain Unable to understand why a painful procedure will help them feel better	Active physical resistance, directed aggressive behavior, strikes out physically and verbally when hurt, easily frustrated	Has the language skills to express pain on a sensory level Can identify location and intensity of pain, may deny pain, may believe their pain is obvious to others
SCHOOL-AGE CHILD			
7–9 years (concrete operations)	Understands simple relationships between pain and disease Understands the need for painful procedures to monitor or treat disease May associate pain with feeling bad or angry May recognize psychologic pain related to grief and hurt feelings	Passive resistance, clenches fists, holds body rigidly still, suffers emotional withdrawal, engages in plea bargaining	Can specify location and intensity of pain; can describe physical characteristics of pain in relation to body parts
10–12 years (transitional)	Better understanding of the relationship between an event and pain Has a more complex awareness of physical and psychologic pain, such as moral dilemmas and mental pain	May pretend comfort to project bravery, may regress with stress and anxiety	Able to describe intensity and location with more characteristics, able to describe psychologic pain
ADOLESCENT			
13–18 years (formal operations)	Has a capacity for sophisticated and complex understanding of the causes of physical and mental pain Recognizes that pain has both qualitative and quantitative characteristics Can relate to the pain experienced by others	Wants to behave in a socially acceptable manner, shows a controlled behavioral response May immerse self in an activity as a pain distraction May not complain about pain if given cues that nurses and other healthcare providers believe it should be tolerated	More sophisticated descriptions as experience is gained; may think nurses are in tune with their thoughts, so they do not need to tell the nurse about their pain

TABLE 15–3 Physiologic Consequences of Unrelieved Pain in Children

RESPONSES TO PAIN	POTENTIAL PHYSIOLOGIC CONSEQUENCES
RESPIRATORY CHANGES	
Rapid shallow breathing	Alkalosis
Inadequate lung expansion	Decreased oxygen saturation, atelectasis
Inadequate cough	Retention of secretions, pneumonia
NEUROLOGIC CHANGES	
Increased sympathetic nervous system activity and release of catecholamines	Tachycardia, elevated blood pressure, vasoconstriction, and decreased tissue oxygenation
	Increased intracranial pressure, change in sleep patterns, irritability
METABOLIC CHANGES	
Increased metabolic rate with stress response, increased release of hormones, suppressed release of insulin	Increased fluid and electrolyte losses
	Altered nutritional intake, hyperglycemia
IMMUNE SYSTEM CHANGES	
Depressed immune and inflammatory responses	Increased risk of infection, delayed wound healing
GASTROINTESTINAL CHANGES	
Decreased gastric acid secretions and intestinal motility	Impaired gastrointestinal functioning, nausea, poor nutritional intake, ileus
ALTERED PAIN RESPONSE	
Increased pain sensitivity	Hyperalgesia, decreased pain threshold, exaggerated memory of painful experiences

Source: Data from Greenwald, M. (2010). Analgesia for the pediatric trauma patient: Primum non nocere? *Clinical Pediatric Emergency Medicine, 11*(1), 28–40; Huether, S. E. (2014). Pain, temperature regulation, sleep, and sensory function. In K. L. McCance, S. E. Huether, V. L. Brashers, & N. S. Rote (Eds.), *Pathophysiology: The biologic basis for disease in adults and children* (7th ed.,pp. 481–524). St. Louis, MO: Mosby Elsevier; Clark, L. (2011). Pain management in the pediatric population. *Critical Care Nursing Clinics of North America, 23*, 291–301; Tobias, J. D. (2014a). Acute pain management in infants and children—Part 1: Pain pathways, pain assessment, and outpatient pain management. *Pediatric Annals, 43*(7), e163–e168.

Rican, Jewish, and Arabic heritage, are more likely to use both verbal and nonverbal methods (moans and groans) to express pain freely (Purnell, 2014). However, not all members of a cultural group will demonstrate the same pain response. Children will have individualized responses to pain based on past experiences, and younger children have had less time to acquire culturally learned behaviors.

Consequences of Pain

Unrelieved pain is stressful and has many undesirable physiologic consequences (Table 15–3). For example, the child with acute postoperative pain takes shallow breaths and suppresses coughing to avoid more pain. These self-protective actions increase the potential for respiratory complications. Unrelieved pain may also delay the return of normal gastric and bowel functions and cause a stress ulcer. Anorexia associated with pain may delay the healing process. Pain drains the body of energy resources needed for healing and growth.

Pain Assessment

The goal of pain assessment is to provide accurate information about the location and intensity of pain and its effects on the child's functioning.

Pain History

Parents can provide a great deal of information about the child's response to pain, such as the following:

- How the child typically expresses pain. Children and parents use similar terms to describe pain. Knowing the appropriate word to use makes communicating with the child easier. See *Growth and Development.*
- The child's previous experiences with painful situations and reactions.
- How the child copes with and manages pain. The child with several past pain experiences may not exhibit the same types of stressful behaviors as the child with few pain experiences.
- What works best to reduce the child's pain?
- The parent's and child's preferences for analgesic use and other pain interventions.

Growth and Development

Children slowly acquire words for pain over the first 6 years of life. Toddlers and preschoolers use *ouch*, *pinch*, and *hurt* to describe pain. Other pain words include *owie*, *boo-boo*, *ache*, *stinging*, *cutting*, *burning*, *itching*, *hot*, and *tight*. Expressions of pain intensity by young children may include "hurts a lot" or "a really bad hurt" (Rashotte et al., 2013).

Ask older children to give a history of painful procedures. Keep in mind that children may modify their pain descriptions depending on the type of questions asked and what they expect will happen as a result of their response. Examples of questions to ask include the following:

- What kinds of things caused hurt in the past? What made it feel better?
- What do you tell your mother or caregiver when you hurt or are in pain? What do you, your caregiver, or your mother do for the pain?
- What would you like the nurse to do for the hurt? What should the nurse or other caregiver do for your pain?
- Where do you hurt? What does it feel like? What do you think is causing the pain?

Pain Assessment Tools

Various scales and tools are used to assess pain in children. After a pain assessment tool is designed, it must be evaluated for **validity** (accurately measures the concept it was designed to measure) and **reliability** (consistent results are obtained when measured by the same rater or other raters). All of the following pain assessment tools have validity and reliability established.

PAIN BEHAVIOR SCALES FOR NONVERBAL CHILDREN

Physical and behavioral indicators are used to quantify pain in infants and nonverbal children. For example, the Neonatal Infant Pain Scale (NIPS) and the Faces, Legs, Activity, Cry, and Consolability (FLACC) Observational Tool rely on the nurse's observation of the child's behavior (expression, positioning, movement, and crying).

Neonatal Infant Pain Scale (NIPS). The NIPS is designed to measure procedural pain in preterm and full-term newborns up to 6 weeks after birth. The newborn facial expression, cry quality, breathing patterns, arm and leg position, and state of arousal are observed. See Table 15–4.

The Faces, Legs, Activity, Cry, and Consolability (FLACC) Observational Tool. The FLACC scale is designed to measure acute pain in infants and young children following surgery, and it can be used until the child is able to self-report pain with another pain scale. The tool has validity and reliability for evaluation of postoperative pain. See Table 15–5.

Pain Location. Young children (3 years and older) can localize pain if given an outline of the front and back of the body. The child can mark where the pain is located or color the area of pain with crayons. The child should use one color for the place where it hurts the most, and another color for areas with less pain.

ASSESSING CHILDREN WITH INTELLECTUAL DISABILITY

Assessing the pain of a child with severe intellectual disability is challenging. Many children with intellectual disability are able to use simple self-report pain tools. In other cases, behavioral pain assessment tools are appropriate.

The FLACC scale with some modifications can be successfully used by parents and nurses to assess postoperative pain in children with intellectual disability. Before surgery the parent identifies pain behaviors the child displays, such as a specific facial expression, body posture, leg position, and vocalizations to help guide the assessment. These behaviors are added to the descriptors for the scores in each of the FLACC scale categories. This tool has shown good validity and inter-rater reliability for use in this population (Ely et al., 2012).

SELF-REPORT PAIN SCALES

Self-report assessment tools of pain intensity are considered to be the best method of assessing pain in children and adolescents who can use such tools (see the *Clinical Skills Manual* SKILLS). Examples of self-report tools developed for children include the Faces Pain Rating Scale, the Oucher Scale, and the Poker Chip Tool.

TABLE 15–4 Neonatal Infant Pain Scale (NIPS)

CHARACTERISTIC	SCORING CRITERIA
FACIAL EXPRESSION	
0 = Relaxed muscles	• Restful face with neutral expression
1 = Grimace	• Tight facial muscles; furrowed brow, chin, and jaw (*Note:* At low gestational ages, infants may have no facial expression.)
CRY	
0 = No cry	• Quiet, not crying
1 = Whimper	• Mild moaning, intermittent cry
2 = Vigorous cry	• Loud screaming, rising, shrill, and continuous (*Note:* Silent cry may be scored if infant is intubated, as indicated by obvious facial movements.)
BREATHING PATTERNS	
0 = Relaxed	• Relaxed, usual breathing pattern maintained
1 = Change in breathing	• Change in drawing breath; irregular, faster than usual, gagging, or holding breath
ARM MOVEMENTS	
0 = Relaxed/restrained (with soft restraints)	• Relaxed, no muscle rigidity, random movements of arms
1 = Flexed/extended	• Tense, straight arms; rigid; or rapid extension and flexion
LEG MOVEMENTS	
0 = Relaxed/restrained (with soft restraints)	• Relaxed, no muscle rigidity, occasional random movements of legs
1 = Flexed/extended	• Tense, straight legs; rigid; or rapid extension and flexion
STATE OF AROUSAL	
0 = Sleeping/awake	• Quiet, peaceful, sleeping; or alert and settled
1 = Fussy	• Alert and restless or thrashing; fussy

Source: From Lawrence, J., Alcock, D., McGrath, D. P., Kay, J., MacMurray, S. B., & Dulberg, C. (1993). The development of a tool to assess neonatal pain. *Neonatal Network, 12*(6), 61; Taddio, A., Hogan, M. E., Moyer, P., Girgis, A., Gerges, S., Wang, L., & Ipp, M. (2011). TABLE 15–5 FLACC Behavioral Pain Assessment Scale

	SCORING		
CATEGORIES	**0**	**1**	**2**
Face	No particular expression or smile	Occasional grimace or frown; withdrawn, disinterested	Frequent to constant frown, clenched jaw, quivering chin
Legs	Normal position or relaxed	Uneasy, restless, tense	Kicking or legs drawn up
Activity	Lying quietly, normal position, moves easily	Squirming, shifting back and forth, tense	Arched, rigid, or jerking
Cry	No cry (awake or asleep)	Moans or whimpers, occasional complaint	Crying steadily, screams or sobs; frequent complaints
Consolability	Content, relaxed	Reassured by occasional touching, hugging, or being talked to; distractible	Difficult to console or comfort

Instructions: Observe the child for 5 minutes or longer. Observe the legs and body uncovered. Reposition the child or observe activity. Assess body for tenseness and tone. Initiate consoling interventions if needed. Each of the five categories is scored from 0 to 2, resulting in a total score between 0 and 10. A total score of 0 = relaxed and comfortable; 1–3 = mild discomfort; 4–6 = moderate pain; 7–10 = severe discomfort or pain.

Source: Used with permission from Merkel, S. I., Voepel-Lewis, T., Shayevitz, J. R., & Malviya, S. (1997). The FLACC: A behavioral scale for scoring post-operative pain in young children. *Pediatric Nursing, 23*(3), 293–297; Gomez, R. J., Barrowman, N., Elia, S., Manias, E., Royle, J., & Harrison, D. (2013). Establishing intra- and inter-relater agreement of the Faces, Legs, Activity, Cry, Consolability scale for evaluating pain in toddlers during immunization. *Pain Research & Management, 18*(6), e124–e128.

To use pain scales, the child must understand the concept of a little or a lot of pain well enough to tell the nurse and to follow simple directions. Children 2 to 3 years of age can usually understand the concept of "more or less." Only three choices should be offered these children when assessing pain (none, some, a lot). Most children at ages 4 to 5 years can distinguish a larger number from a smaller number or correctly put different sized blocks in largest to smallest order. These children can use a self-report pain rating tool.

Faces Pain Rating Scale. This scale has a series of six or seven cartoonlike faces with expressions from smiling (or neutral) to tearful, depending on the model selected. The Wong-Baker scale is commonly used for children from 3 years through adolescence (Figure 15–1). After explanations about the meaning for each face, the child selects the face that is the closest match to the pain felt. The nurse should not use the tool to compare with the child's facial expression to determine pain level. Older children can use the words associated with the tool to provide a pain rating. The Faces Pain Rating Scale has good validity and reliability for measuring pain intensity (Wood et al., 2011).

Oucher Scale. The Oucher Scale presents a series of six photographs of a child expressing increasing pain intensity in combination with a vertical Visual Analog Scale (Figure 15–2). The tool has been developed and tested in four cultural groups: White, African American, Hispanic, and Asian.

Poker Chip Tool. This tool uses four checkers or poker chips to quantify acute procedural pain. The child is asked to pick the number of chips that best match the pain felt, with one chip being a little pain and four being the most pain one could have.

School-age children and adolescents have better number concepts and language skills, so additional tools can be used to assess their pain. The nurse should ask the child to describe the pain and give its location. Providing some words such as *sharp, dull, aching, pounding, cold, hot, burning, throbbing, stinging, tingling*, or *cutting* can help children describe their pain.

Numeric Pain Scale. This tool, also called the Visual Analog Scale, is a single 10-cm horizontal or vertical line that has descriptors of pain at each end (no pain, worst possible pain). Marks and numbers are placed at each centimeter on the line. The child marks the amount of pain felt, and the numbers on the line are used to score the pain. Younger school-age children often have less understanding of numbers and directions to use this tool.

Word-Graphic Rating Scale. This tool has words rather than numbers describing increasing pain intensity across a

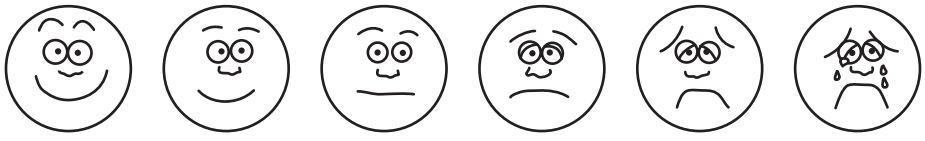

Figure 15–1 **Teach the child to use the Faces Pain Rating Scale by pointing to each face and using the words under the picture to describe the amount of pain felt. Then ask the child to select the face that comes closest to the amount of pain felt. Use the number under the selected face to score the pain.**

SOURCE: Used with permission from Wong, D. L., & Baker, C. M. (1988). Pain in children: Comparison of assessment scales. *Pediatric Nursing, 14*, 9–16.

10-cm Visual Analog Scale without numbers. The child marks the line that is closest to the level of pain felt. A millimeter ruler can be used to quantify the pain and record the pain score (Figure 15–3).

Adolescent Pediatric Pain Tool. This tool includes a human figure drawing, the Word-Graphic Rating Scale, and a choice of descriptive words—for example, *burning, ache, sharp,* and *dull*. Adolescents indicate pain sites on the human figure outline, use the Word-Graphic Rating Scale as described, and use the word choices to characterize the pain felt. This tool may be used to assess acute and chronic pain.

Acute Pain

Children experience acute pain related to a variety of illnesses and injuries, surgery, and invasive procedures. Just as with adults, children must have their pain assessed and managed.

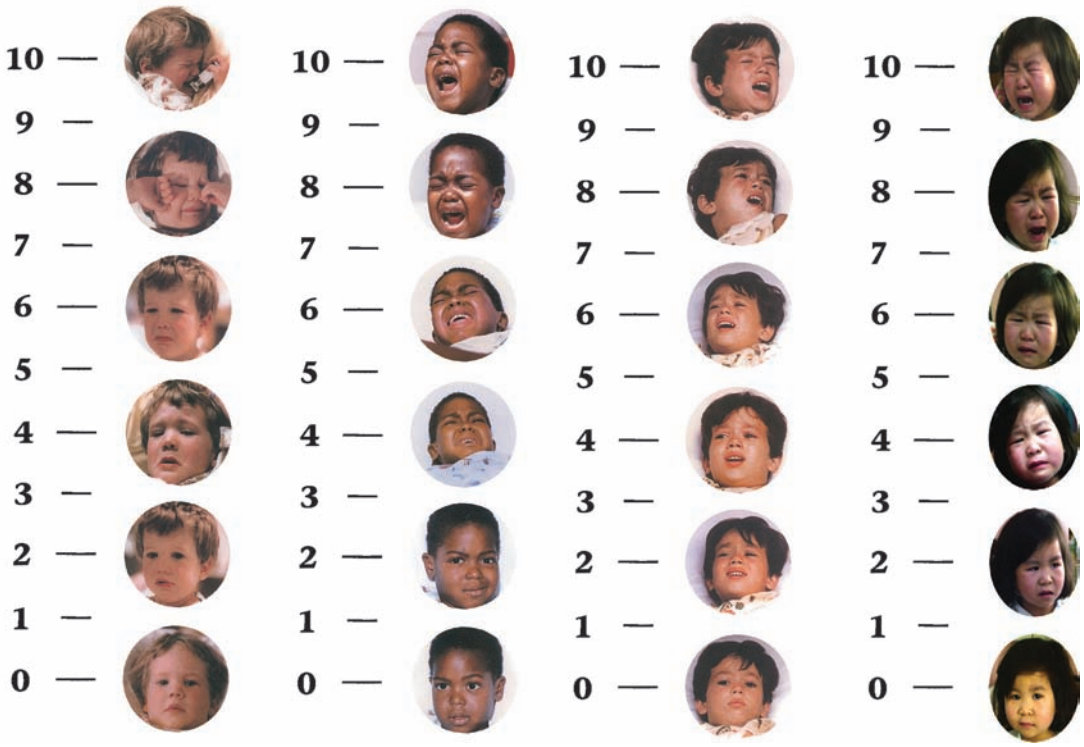

Figure 15–2 **Use the Oucher Scale with the best match for the child's ethnicity. Teach the child to use the scale. Point to each photograph and explain that the bottom picture is "no hurt," the second picture is a "little hurt," the third picture is "a little more hurt," and so on until the sixth picture which is the "biggest or most hurt you could ever have." The young child selects a face that matches the level of pain. The numbers beside the photos are used to score the amount of pain the child reports. The older child can select a pain intensity number between 0 and 10. The nurse should not compare the photos with the child's expression to determine a pain level. See http://www.oucher.org for more information.**

Denyes, RN, PhD, and Antonia M. Villarruel, RN, PhD, 1990. The Hispanic version of the Oucher Scale used with permission from Antonia M. Villarruel, RN, PhD, 1990. The Asian version of the Oucher Scale used with permission from C. H. Yeh, RN, PhD, and C. H. Wang, BSN, 2003.

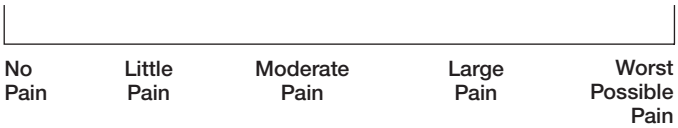

Figure 15–3 **The Word-Graphic Rating Scale has words rather than numbers under the line. Teach the child to use the tool by pointing to the side of the line that is no pain and then to the side that is the worst possible pain. Ask the child to make a mark along the line that matches the amount of pain felt. Use a millimeter ruler to measure from the "no pain" end of the line to the marked location to identify the pain score. Make sure the line is 10 cm each time pain is assessed so comparisons can be made.**

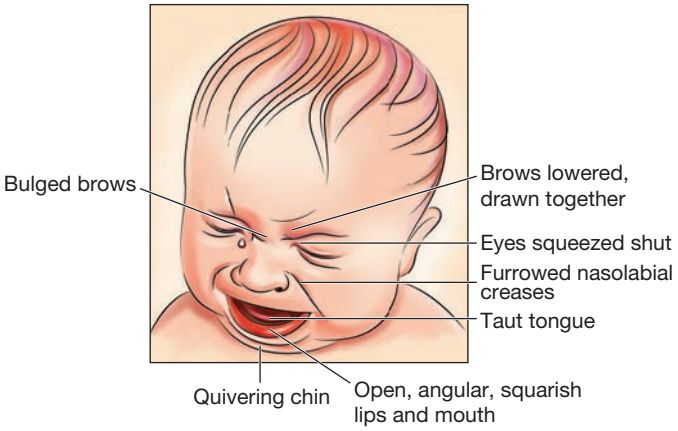

Figure 15–4 Characteristic neonatal pain facial expressions include bulged brow, eyes squeezed shut, furrowed nasolabial creases, open lips, pursed lips, stretched mouth, taut tongue, and a quivering chin.

SOURCE: Adapted from Carlson, K. L., Clement, B. A., & Nash, P. (1996). Neonatal pain: From concept to research questions and the role of the advanced practice nurse. *Journal of Perinatal Neonatal Nursing*, *10*(1), 64–71.

Clinical Manifestations

PHYSIOLOGIC INDICATORS

Acute pain stimulates the adrenergic nervous system and results in physiologic changes, including tachycardia, tachypnea, hypertension, pupil dilation, pallor, increased perspiration, and increased secretion of stress hormones such as the catecholamines and cortisol (Huether, 2014). These signs demonstrate a complex stress response. The body adapts physiologically to acute pain; after several minutes, the vital signs return to near normal and perspiration decreases, so these signs cannot be used for monitoring acute pain. Persistent or continuous chronic pain of long duration permits physiologic adaptation, so normal heart rate, respiratory rate, and blood pressure levels are often seen (Huether, 2014).

BEHAVIORAL INDICATORS

Newborns and infants demonstrate knitted brows, squinted eyes with cheeks raised, eyes closed, crying, jerky or flailing movements, and stiff posture in response to pain. See Figure 15–4. A preterm or sick newborn may have a weaker cry, a less expressive face, or not have the energy to make as many body movements as the well infant (Badr, 2013).

Children in acute pain are often distressed and anxious, especially if they have experienced pain previously. Behaviors that could indicate pain or anxiety in infants and toddlers include crying, restlessness or agitation, hyperalertness or vigilance, sleep disturbances, and irritability. Children and adolescents may demonstrate the following additional behaviors:

- Short attention span (child is easily distracted)
- Posturing (guarding a painful joint by avoiding movement), remaining immobile, or protecting the painful area
- Drawing up knees, flexing limbs, massaging affected area
- Lethargy, remaining quiet, or withdrawal
- Sleep disturbances
- Depression and/or aggressive behavior, especially for those who fear that the discomfort will worsen

Clinical Therapy

Acute pain management includes both drug and nondrug measures. Children need adequate pain medication, but complementary therapies can enhance pain management and ultimately reduce the amount of pain medication needed.

ACETAMINOPHEN AND NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

Nonsteroidal anti-inflammatory drugs (NSAIDs) such as ibuprofen, primarily given orally, are effective for the relief of mild to moderate pain and chronic pain. Acetaminophen is a nonnarcotic analgesic and antipyretic that is used like an NSAID; however, it does not have a systemic anti-inflammatory action. NSAIDs are most commonly used for bone, inflammatory, and connective tissue conditions. An NSAID may be prescribed in combination with an opioid to increase the effectiveness of the opioid drug, and potentially reduce the amount of opioids needed. See *Medications Used to Treat: Pain*.

OPIOIDS

Opioids are analgesics commonly given for severe pain, such as after surgery or a severe injury. Opioids (e.g., morphine) are commonly administered by oral, subcutaneous, intramuscular (IM), and intravenous (IV) routes. Oral and IV routes are preferred for use in children because the intramuscular and subcutaneous routes cause pain and stress at the time of administration.

Oral administration of opioids is as effective as IM and IV routes when the drug is given in an **equianalgesic dose** (the amount of drug needed to produce the same analgesic effect regardless of the route used). The optimal analgesic dose is not specific for age or ethnicity of clients. See *Medications Used to Treat: Pain*. Meperidine is rarely prescribed for children because of adverse effects on the central nervous system, including seizures, agitation, and depressed mood (Tobias, 2014b). Codeine must also be used with caution in children.

SAFETY ALERT!

Codeine acquires its analgesic properties with its conversion to morphine by the liver, and it requires metabolism by the CYP2D6 enzyme. About 10% of White people and varying frequencies in other ethnic groups are poor metabolizers and therefore do not receive adequate pain relief from codeine (Pasero & McCaffery, 2011, p. 330). Children of North African, Ethiopian, and Saudi heritage are more likely to be ultrarapid metabolizers and risk a life-threatening overdose, even at recommended dosages (Watt & Arnstein, 2013). Genetic testing is not currently recommended.

After reports of several pediatric deaths and overdoses associated with codeine, the U.S. Food and Drug Administration issued a boxed warning that contraindicates the use of codeine after tonsillectomy or adenoidectomy (Aschenbrenner, 2013).

Clinical Tip

Analgesics were often withheld from children with acute abdominal pain until surgeons could complete an assessment, as it was believed that analgesia would interfere with diagnosis. Studies involving children with appendicitis revealed that giving morphine did not delay the diagnosis or cause complications associated with opioid use (Fein et al., 2012). Be an advocate for pain management in these children.

Medications Used to Treat: Pain

MEDICATION AND ACTION	NURSING MANAGEMENT
Nonopioid Analgesic	
Acetaminophen (Tylenol), *Oral, Rectal, IV* Inhibits prostaglandin synthesis in the central nervous system (CNS) and blocks pain impulse generation in the periphery	• Use for mild or moderate pain. • Ensure that families avoid liver toxicity by using appropriate dosing. • Avoid using other medications with acetaminophen as an ingredient. • Give with food to decrease gastrointestinal (GI) upset. • Give no more than 5 doses in 24 hours.
Nonsteroidal Anti-Inflammatory Drugs (NSAIDS)	
Acetylsalicylic Acid (Aspirin), *Oral, Rectal* Inhibits prostaglandin synthesis involved in pain synthesis in periphery Ibuprofen (Motrin), *Oral* Cyclooxygenases 1 and 2 (COX-1 and COX-2) NSAID inhibitors that block prostaglandin synthesis Naproxen (Naprosyn, Aleve), *Oral* Inhibits prostaglandin synthesis by inhibiting COX-1 and COX-2 isoenzymes Ketorolac (Toradol), *IV, IM* Inhibits prostaglandin synthesis by decreasing activity of the COX enzyme, which decreases prostaglandin precursors	• Use for short-term management of mild or moderate pain. • Do not use aspirin in children recovering from chickenpox or influenza because of concern about Reye syndrome. • Give with food to decrease GI upset. • Monitor for prolonged bleeding time with extended use. • Run periodic lab tests for blood counts with differential, serum electrolytes, liver function tests with extended use. • Monitor for hypersensitivity reaction, especially if child is allergic to aspirin. • Educate parents about signs of GI bleeding if prescribed for extended use.
Opioids	
Morphine Sulfate, *IV, IM, Subq, Oral* Agonist that binds with mu receptors in the brain and spinal cord to provide analgesia; gold standard for comparison of other analgesics Hydromorphone (Dilaudid) Opiate receptor agonist in central nervous system (CNS) leading to changes in pain perception Levorphanol (Levo-Dromoran) Synthetic morphine derivative with opiate receptor agonist activity, more potent and longer duration of action than morphine Methadone (Dolophine), *Oral, IV* Synthetic narcotic that has increased duration of action with repeated doses	• Use for moderate to severe pain. • Carefully calculate the dosage to be administered and verify with another nurse. • Obtain baseline vital signs before administration for future comparison. • Assess pain regularly for pain relief and duration. • Carefully monitor for signs of respiratory depression, especially during drug-specific peak action time. • Anticipate and provide preventive treatment for constipation. • Monitor for other adverse effects and notify healthcare provider. • For severe pain, administer every 4 hours or continuously to avoid pain breakthrough.
Fentanyl, *IV, Intranasal, Transmucosal, Transdermal* Synthetic and potent narcotic agonist that causes analgesia and sedation, short action time	• May be used for sedation and analgesia for painful procedures. • Monitor vital signs. • Observe the child for thoracic and skeletal muscle rigidity and weakness that may depress respirations. • Respiratory depression effect may last 4 hours longer than analgesic effect; be prepared to support ventilations and give naloxone.

(*continued*)

Medications Used to Treat: Pain *(continued)*

Oxycodone (Roxicodone), *Oral* Semisynthetic derivative of an opium agonist that binds with receptors in the CNS to alter the perception of pain and emotional response to pain	• Use for moderate pain. • Monitor respiratory status for respiratory depression. • Note adverse effects such as nausea, dizziness, and sedation. • Determine child's continued need for medication, as the potential for drug abuse is high.
Codeine, *Oral* Opiate receptor agonist in CNS leading to changes in pain perception	• Use for mild or moderate pain. • Assess pain regularly for pain relief and duration. • Observe for nausea, a common side effect. • See *Safety Alert!*

Source: Data from Taketomo, C. K., Hodding, J. H., & Kraus, D. M. (2014). *Pediatric dosage handbook* (21st ed.). Hudson, OH: American Pharmacists Association; Barnes, S. (2014). Analgesia and sedation. In B. Engorn, & J. Flerlage (Eds.), *The Harriet Lane handbook* (20th ed.). Philadelphia, PA: Elsevier; Wilson, B. A., Shannon, M. T., & Shields, K. M. (2016). *Nurse's drug guide 2016*. Hoboken, NJ: Pearson Education.

Common opioid side effects include sedation, nausea, vomiting, constipation, urinary retention, and itching. These may be treated by rotating the opioids used or with specific therapies as follows:

- *Sedation*—supplement lower opioid dose with nonsedating analgesia or psychostimulant such as methylphenidate (Pasero & McCaffery, 2011, p. 512; Rosen & Dower, 2011)
- *Nausea and vomiting*—antiemetic medication, alternate opioid
- *Constipation*—prophylactic stool softener, a stimulating laxative, and increased fluids and dietary fiber
- *Urinary retention*—place child in bathtub, run water, intermittent catheterization
- *Pruritus*—antihistamine, alternate opioids, or naloxone 0.1 to 0.2 mcg/kg/hr continuous IV infusion (given simultaneously with opioid) (Pasero & McCaffery, 2011, p. 500)

The major life-threatening complication of opioid administration is **respiratory depression** (unresponsiveness and progressively decreasing respiratory rate that may progress to respiratory arrest). Clinical signs that indicate the development of respiratory depression include sleepiness, small pupils, and shallow breathing. Children at higher risk for opioid-induced respiratory depression have an altered level of consciousness, an unstable circulatory status, a history of apnea, a known airway problem such as obstructive sleep apnea, or are receiving another medication that potentiates the CNS effect of the opioid (e.g., benzodiazepines or barbiturates). Starting opioid dosages for these children may be 50% of the recommended dose (Tobias, 2014b). Frequent visual assessments and cardiorespiratory monitoring or pulse oximetry are important safety guidelines when the infant or child is at increased risk for respiratory depression.

SAFETY ALERT!

Respiratory depression is most likely to occur when the child is sleeping and the tongue may obstruct the airway. Carefully monitor the child's vital signs during the drug-specific peak action time to detect respiratory depression. Monitor the respiratory rate because pulse oximetry does not measure ventilation.

If respiratory depression occurs, naloxone is administered at a rate of 1 to 2 mcg/kg every 1 to 2 minutes to gradually reduce the opioid effects without losing analgesia effects (Tobias, 2014b). Continue to monitor the child for respiratory depression because the half-life of naloxone is shorter than the opioid's half-life.

When given opioids over an extended period of time, children develop **physical dependence**, the physiologic adaptation to an analgesic or sedative drug by the peripheral and central nervous systems that may lead to **withdrawal**, the physical signs and symptoms that occur when a sedative or pain drug is stopped suddenly. Physical dependence is not addiction. **Tolerance** is an adaptation to an opioid dosage that results in a shorter duration of drug effectiveness over time. An increasing dosage is needed to produce the same level of pain relief. For example, a child might develop physical dependence or tolerance after being in an intensive care setting long term with pain management for life-threatening injuries, multiple surgeries, and invasive procedures. See Table 15–6 for signs and symptoms of withdrawal. The child is weaned off

TABLE 15–6 Clinical Manifestations of Opioid or Sedative Withdrawal

SYSTEM	SIGNS AND SYMPTOMS
Central nervous system	Anxiety, irritability, increased wakefulness, tremors, increased muscle tone, inability to concentrate, frequent yawning, sneezing, delirium, visual or auditory hallucinations
Gastrointestinal system	Decreased appetite, nausea, vomiting, diarrhea, uncoordinated suck and swallow
Sympathetic nervous system	Tachycardia, tachypnea, increased blood pressure, nasal stuffiness, lacrimation, sweating, fever, increased salivation

opioids over 2 to 4 weeks to prevent withdrawal symptoms. One plan is to switch the child to oral opioids and reduce the daily dose by 10% over several days. The longer the child has been taking the opioids, the longer the tapering should take.

DRUG ADMINISTRATION

Pain from surgery, major trauma, acute episodes such as vaso-occlusive crisis, or cancer is present for predictable periods because of the effects of tissue damage. Pain relief should be provided around the clock. Every effort should be made to give the child analgesics without causing more pain. The preferred routes of administration are intravenous, local nerve block, and oral.

Continuous infusion analgesia is recommended for children with persistent severe pain, as it keeps blood levels constant. Analgesics may also be given intravenously on a scheduled basis (e.g., every 3 to 4 hours). Delays in analgesia administration increase the chances of **breakthrough pain** (pain that emerges as the pain medication wears off, resulting in the loss of pain control) and the subsequent anticipation of pain. Giving analgesics on an as-needed (PRN) basis for acute pain results in the loss of pain control. More medication is often needed to restore pain control than would have been required with continuous infusion analgesia.

Patient-Controlled Analgesia. **Patient-controlled analgesia (PCA)** is a method of administering an intravenous analgesic, such as morphine, using a computerized pump programmed by the healthcare professional and controlled by the child (see the *Clinical Skills Manual* SKILLS). After pain control has been achieved with a continuous IV infusion of morphine (basal dose) by the nurse, the child presses a button to receive a smaller analgesic dose (bolus dose) for episodic pain relief. This method of pain management is especially useful for pain control in the first 48 hours after surgery or until oral pain management is possible. Safety features to prevent overdoses include the ability to set the maximum number of bolus infusions per hour and the maximum amount of drug received in a specific time period. Once oral analgesics can be taken, PCA is discontinued.

Pain-controlled analgesia is prescribed mostly for children age 6 years and older, but may be offered to children as young as 5 years. The child should be able to self-report pain with a pain scale and understand that pushing the button will give them medication to relieve pain. See *Families Want to Know: Patient-Controlled Analgesia (PCA)*. Nurse-controlled analgesia, with the nurse taking responsibility for bolus infusions, is sometimes provided for younger children or those with cognitive impairments. The nurse must assess pain before pushing the device button to reduce risks for adverse events.

SAFETY ALERT!

Pain-controlled analgesia by proxy, such as giving a parent permission to push the PCA button, has been used for some children with disabilities or too young to be responsible. Many facilities no longer permit parents to administer PCA to their child. If permitted, parents must be taught to follow guidelines for pain assessment and PCA use, and adherence to guidelines must be monitored to reduce the risk for an adverse event associated with too much medication.

REGIONAL PAIN MANAGEMENT

Epidural pain control provides selective analgesia for a body region, and it has become more common for postoperative pain management. A catheter is inserted into the epidural space during general anesthesia through which anesthetics and opioids may be administered in small doses. Analgesia may be administered by intermittent bolus, continuous infusion by a small pump, or PCA to maintain pain control for the first 24 to 48 hours after surgery. Urinary retention may be a complication and a urinary catheter may be required for the duration of epidural pain management. Monitor vital signs, pain level, and degree of motor and sensory block.

Regional nerve blocks, such as a popliteal or femoral for the lower extremity, or interscalene (in a muscle of the cervical vertebrae) for the upper extremity, are used for anesthesia and to control pain after surgery. A subcutaneous catheter is inserted into the local area for infusion of the medications. The single dose administered during surgery may last up to 15 hours postoperatively (Guarin, 2013). A continuous infusion may also be given using a pump.

Clinical Tip

Assess the extremity receiving the local nerve block for color, temperature, and capillary refill. Assess motor function by asking children if they can move their legs, wiggle their toes, and lift their buttocks off the bed. Ensure proper positioning of the extremity to prevent nerve damage. Protect the extremity from injury because the child has reduced feeling in the limb. Monitor the child every 2 hours for tingling felt in the fingers or toes of the affected extremity, the first sign that the nerve block is receding. Effective oral analgesia should be initiated to maintain pain control when the nerve block begins to recede.

Families Want to Know

Patient-Controlled Analgesia (PCA)

- What is PCA? *Analgesia* means pain relief: You get to control the amount of medicine you receive by using the PCA machine.
- The machine gives the medicine by passing it through the tube that is connected to your IV line. When you push the button, the machine pumps pain medicine into the IV line to make you feel better.
- The machine limits the amount of medicine you can get to what the healthcare provider prescribes. You can get any amount up to the maximum hourly limit by pushing the button at times during the hour. The push button will not let you make a mistake if you drop it or roll on it.
- Whenever you feel pain, hurt, or discomfort, push the button to get more medicine. You should be the only one to push the button. Do not let another family member push the button.
- No needles for pain shots are needed as long as the IV line is in place.
- The PCA may not relieve all your pain, but it should make you feel comfortable. Let the nurse know if you think your PCA is not working.
- The PCA will be used until you can take pain medicine by mouth.

Nonpharmacologic Methods of Pain Management

Complementary therapies are nonpharmacologic methods used for pain management that can enhance the effect of analgesics and potentially reduce the amount of analgesics needed. One or more of these methods may provide adequate pain relief when the child has low levels of pain.

DISTRACTION

Distraction involves engaging a child in a pleasant activity to help focus attention on something other than pain and the anxiety. Teach the parent to be a distraction coach and suggest developmentally appropriate distraction activities to use. Examples of distraction activities are provided in *Growth and Development: Distraction Activities* later in the chapter. Note that children in severe pain cannot be distracted; do not assume that pain is gone if a child can be distracted.

GUIDED IMAGERY

Imagery is a cognitive behavioral process that encourages the child to relax (often with progressive muscle relaxation techniques) and focus on vivid mental images as if they were real, and to ignore things, such as a painful procedure. For example, help the child visualize and explore a favorite place, do a fun activity, remember a funny story, or be a superhero. Ask the child to think about all the sights, sounds, smells, tastes, and feelings that will enhance the image and experience. Imagery has been used successfully by school-age children to reduce the pain associated with sickle cell disease (Dobson & Byrne, 2014).

RELAXATION TECHNIQUES

Progressive muscle relaxation is used to reduce muscle tension that may worsen pain. Teach children to tense and relax different muscle groups, starting with the hands and feet, and then moving to more central muscles. Ask the child to tense a muscle group for 10 seconds and notice how it feels, and then ask the child to relax the muscle group for 10 seconds and compare the feelings. With practice, the child should be able to detect the difference between tense and relaxed muscles and then to reduce the tension. Relaxation techniques may be combined with rhythmic breathing.

BREATHING TECHNIQUES

Rhythmic deep breaths can be used with distraction or muscle relaxation during a painful procedure or as a mechanism to reduce stress. Ask the child or adolescent to take a deep breath, hold it for 5 seconds, and blow out through the mouth, as if to push the tension out or the needle away. Another breathing technique is patterned, shallow breathing. The young child is encouraged to take shallow breaths in through the nose and blow out through the mouth while thinking of a particular image. For example, the short breaths could be the "toot, toot" of a train horn.

CUTANEOUS STIMULATION

Gently rub the painful area, massage the skin gently, and hold or rock the child. Touching competes with the pain stimuli that are transmitted from the peripheral nerves to the spinal cord and brain and may reduce the pain felt by the child. Swaddling and skin-to-skin contact are methods to reduce neonatal pain responses.

HYPNOSIS

Hypnosis is an altered state of awareness facilitating heightened concentration, decreased awareness of external stimuli, increased relaxation, and increased suggestibility. The hypnotic or positive therapeutic suggestion often uses muscle relaxation and guided imagery, and posthypnotic suggestions are given for the relief of anxiety, tension, and pain. Children more easily respond to hypnosis than adults because of their imaginative powers for fun and fantasy. Hypnosis has been successful in helping children and adolescents manage the stress and pain associated with invasive medical procedures and chronic pain such as daily headaches and surgery (Kohen, 2011; Martin, Smith, Newcomb, et al., 2014).

SUCROSE SOLUTION

A sucrose solution (2 mL of 24% solution) is effective for pain relief during painful procedures (venipuncture, heel sticks, cannulation) in preterm and term newborns up to 1 month of age (Cooper & Petty, 2012). The sweet taste is believed to activate the endogenous opioid pathways, leading to the release of endogenous opioids. The effectiveness of sucrose solution beyond 4 weeks of age for immunizations has not been consistently demonstrated in research (Wilson, Bremmer, Mathews, et al., 2013). Give the solution 2 minutes before the procedure, and the analgesic effect of sucrose lasts approximately 3 to 5 minutes. Allow the infant to continue sucking on a pacifier or to breastfeed during the procedure to enhance the effect of sucrose.

APPLICATION OF HEAT AND COLD

Heat application promotes dilation of blood vessels. The increased blood circulation permits the removal of cell breakdown debris from the site. Heat also promotes muscle relaxation, breaking the pain–spasm–pain cycle. To reduce edema, do not apply heat in the first 24 hours after an injury.

The application of cold is believed to slow the ability of pain fibers to transmit pain impulses to help control pain. Apply ice for 20 to 30 minutes and then remove for about 10 minutes before continuing therapy. Assess the skin for redness or signs of irritation. Discontinue cold applications immediately if the skin alternately blanches and reddens afterwards.

ELECTROANALGESIA

Also known as transcutaneous electrical nerve stimulation (TENS), **electroanalgesia** delivers small amounts of electrical stimulation to the skin by electrodes. This electronic stimulation is stronger than the pain impulses and is thought to interfere with the transmission of pain impulses from the peripheral nerves to the spinal cord and brain. TENS may be used for both acute and chronic pain management. The only known side effect is skin irritation at the electrode site.

ACUPUNCTURE

A traditional Chinese treatment for pain relief, acupuncture has been gaining greater acceptance in Western medicine. Acupuncture is based on the theory that energy, or *chi*, flows along channels through the body (meridians) that are connected by acupuncture points. Placement of acupuncture needles at specific pain points interferes with the transmission of pain impulses to the brain, and it also stimulates the release of endogenous opioids (Chon & Lee, 2013). Limited research has been conducted about the use and effectiveness of acupuncture in children.

Nursing Management

For the Child With Acute Pain

Nursing Assessment and Diagnosis

Nurses have an ethical obligation to relieve a child's suffering. Unrelieved pain has consequences, and appropriate pain management may have benefits such as earlier mobilization,

shortened hospital stays, and reduced costs. Anticipate the presence of pain and recognize the child's right to pain control.

Professionalism in Practice Pain Management

In 2001, the Joint Commission introduced standards for the assessment and management of pain in clients treated in healthcare facilities. Nurses have a responsibility to assess a child's pain during their initial assessment and as appropriate during subsequent care. Pain management should be provided, and children and parents should be educated about managing pain (Joint Commission, 2014).

When assessing pain in children, keep the following questions in mind:

- What is happening in tissues that might cause pain? Assume that children who have had surgery, injury, a vaso-occlusive episode, or illness are experiencing pain since these events also cause pain in adults.
- What external factors could be causing pain? For example, is the cast too tight or is the child poorly positioned in bed?
- Are there any indicators of pain, either physiologic or behavioral?
- How is the child responding emotionally?
- How does the child or parent rate the pain?

Physiologic symptoms such as nausea, fatigue, dyspnea, bladder and bowel distention, and fever may influence the intensity of pain felt by a child. The child's behavior or responses to pain stimuli may also be affected by fear, anxiety, separation from parents, anger, culture, age, or a previous pain experience.

When working with an infant or child, determine which pain scale is the most appropriate for the circumstance and developmental stage. When using a self-report pain assessment tool, *use the same tool each time* you assess for pain or for the evaluation of pain management. This makes comparison of assessment results possible. A chronologic record of the child's pain assessments must be documented along with actions taken to relieve pain in addition to the follow-up assessments to determine the effectiveness of those actions.

Remember that surgery and trauma can result in multiple sites of pain (incision or laceration, cut or bruised muscles, interrupted blood supply, nasogastric tube placement, insertion sites of IV lines). Attempt to evaluate the intensity of pain at each site.

Examples of nursing diagnoses for children in pain include the following (NANDA-I © 2014):

- ***Pain, Acute,*** related to injury and femur fracture
- ***Anxiety*** related to anticipation of pain from an invasive procedure
- ***Mobility: Physical, Impaired,*** related to pain
- ***Nausea*** related to opioids used for pain medication

Other nursing diagnoses are included in *Nursing Care Plan: The Child With Postoperative Pain*.

Planning and Implementation

Nursing management involves the following actions to increase and maintain client comfort: pharmacologic intervention; complementary therapy; monitoring, evaluating, and documenting the

Nursing Care Plan: The Child With Postoperative Pain

1. Nursing Diagnosis: *Pain, Acute (severe abdominal),* related to surgery and injury (NANDA-I © 2014)

GOAL: The child will report relief.

INTERVENTION	RATIONALE
• Have the child select a pain scale and rate the amount of pain perceived before and 30–60 minutes after analgesia is given to ensure pain relief.	• The child's pain rating is the best indicator of pain. Maintenance of pain control requires less analgesia than treating each acute pain episode.
• Assess pain control each hour to ensure that the child's pain is relieved.	• Frequent monitoring identifies inadequate pain control before it becomes significant.
• Reposition the child every 2 hours to maintain good body alignment.	• New positions decrease muscle cramping and skin pressure.
• Provide therapeutic touch or massage. Encourage the parents to read a story or play favorite music.	• Complementary therapy reduces stress and enhances the analgesic action.

EXPECTED OUTCOME: Child will report pain relief after administration of analgesia, repositioning, and complementary therapy, as indicated by a lower level on the pain scale.

2. Nursing Diagnosis: *Sleep Pattern, Disturbed,* related to inadequate pain control (NANDA-I © 2014)

GOAL: The child will experience fewer disruptions of sleep by pain.

INTERVENTION	RATIONALE
• Give analgesia by continuous infusion or every 3–4 hours around the clock.	• Pain breakthrough occurs even during sleep and disturbs its healing effects.

EXPECTED OUTCOME: Child will sleep for age-appropriate number of hours per day, undisturbed by pain.

(*continued*)

Nursing Care Plan: The Child With Postoperative Pain (*continued*)

3. Nursing Diagnosis: *Health Management, Readiness for Enhanced,* related to self-management of pain control and use of nonpharmacologic pain-control measures (NANDA-I © 2014)

GOAL: The child and family will effectively use patient-controlled analgesia (PCA) and complementary therapy pain-control measures.

INTERVENTION	RATIONALE
• Teach the child how the PCA works and when to push the button.	• The child must know that pain can be relieved by pushing the PCA button and how the button works.
• Teach the family and the child how to use age-appropriate complementary therapies for pain management.	• Complementary therapy pain-control measures may reduce the amount of analgesia needed.

EXPECTED OUTCOME: Child's pain rating will stay low. Child and family will independently use complementary therapies for pain control.

GOAL: The child and family will use appropriate analgesia after discharge.

INTERVENTION	RATIONALE
• Explain why managing pain is helpful for the child's healing.	• The family and child may not know the benefits of relieving pain.
• Discuss how to assess the child's pain and ways to manage it at home after discharge.	• The family and child may be anxious about pain management at home.

EXPECTED OUTCOME: Family will understand pain assessment and pain-relief measures and state appropriate dose and frequency for pain medication use at home.

4. Nursing Diagnosis: *Breathing Pattern, Ineffective,* related to opioid overdose (NANDA-I © 2014)

GOAL: The child will maintain adequate ventilations.

INTERVENTION	RATIONALE
• Verify that correct opioid dose is given for the child's weight.	• Respiratory depression is a significant complication when too much opioid medication is given.
• Monitor vital signs and depth of respirations before analgesic is administered and at time of peak drug action. Withhold opioid if vital signs fall within parameters set by the healthcare provider or policy.	• A respiratory depression episode must be identified before it progresses to respiratory arrest. All opioids act on brainstem center, which decreases responsiveness to CO_2 tension.
• Calculate agonist dose prescribed by healthcare provider to be sure it will reverse respiratory depression, but not counteract effect of analgesia.	• Valuable time will be saved if agonist is needed to treat respiratory depression. Complete reversal of analgesia will cause the child to have significant pain.

EXPECTED OUTCOME: Child will not have episodes of respiratory depression associated with analgesia.

5. Nursing Diagnosis: *Constipation, Risk for,* related to opioid administration and decreased motility of gastrointestinal tract (NANDA-I © 2014)

GOAL: The child will have minimal constipation.

INTERVENTION	RATIONALE
• Assess bowel sounds and abdominal distention, and palpate the abdomen.	• Signs of constipation must be anticipated and identified.
• Request healthcare provider order for stimulating laxative and stool softener.	• Opioids increase the transit time of feces and interfere with bile enzymes needed for evacuation.
• Provide fluids of choice to increase fluid intake when IV fluids are decreased.	• Extra fluids will counteract opioid action of increasing the absorption of water from the large intestine.
• Inform family and child that constipation is a side effect of pain medication.	• Parents can become partners in increasing fluid intake and monitoring bowel movements.

EXPECTED OUTCOME: Child will have bowel movements at least every 2 days while on opioid pain control.

EVIDENCE-BASED PRACTICE | Challenges to Adequate Pain Management

Clinical Question

Why does adequate management of children with acute pain continue to be a problem despite the increased knowledge about children's needs for pain relief?

The Evidence

A children's hospital committed to pain management conducted a survey of nurses ($n = 272$) to rate 18 potential barriers to optimal pain management. The five leading barriers identified were inadequate healthcare provider orders, insufficient premedication orders before procedures, insufficient time allowed to premedicate before procedures, low priority given to pain management by medical staff, and parents' reluctance to have children receive medication (Czarnecki et al., 2011).

After implementation of some quality improvement projects related to the identified barriers to optimal pain management, a follow-up survey using the same questions was conducted with nurses ($n = 442$) in the same hospital. Consistency in barriers perceived by nurses was found for four of the five leading barriers. Insufficient time allowed to premedicate before procedures was less of a barrier, perhaps due to development of a hospitalwide procedure guideline. A significant decrease in perceptions related to the barriers of inadequate healthcare provider orders and insufficient premedication orders before procedures was found, both also having been the focus of quality improvement efforts. A new barrier was identified related to the time taken to process and deliver pain medications from pharmacy (Czarnecki, Salamon, Thompson, et al., 2014). Findings revealed that more work is needed.

Thirty nurses working in a general hospital participated in focus groups to identify their perceptions about barriers and facilitators to pediatric pain management and the effectiveness of the facility's 3-year-old pediatric pain practice guideline. One nursing barrier related to knowledge deficiencies about pain management and analgesics and the potential of overdosing a child. The nurses expressed an expectation that parents and children inform them when in pain rather than being proactive in assessing for pain, and they were concerned about parents requesting pain medication when the child's behavior did not reflect pain. It was not evident that all nurses knew about or used the pain practice guideline since participating nurses requested pediatric pain assessment tools and a pain medication flow chart that was part of the practice guideline (Twycross & Collins, 2013).

Best Practice

Pain management is a complex process that requires the nurse to assess the child and make clinical judgments about treatment. The expectations that children must display pain behaviors to have their pain believed or that pain assessment and management is a low nursing priority are ongoing concerns. The facility's structure and culture also have an important influence on pain management. The Czarnecki studies focused on organizational contributors to pain management and efforts to change the system. Findings revealed some improvements but illustrate the challenges of making systemwide improvements, even in a pediatric hospital. System changes to improve pain management require collaboration among healthcare providers and the development of practice guidelines. Hospitals then need to educate healthcare providers about the care expectations in the practice guidelines and evaluate how well they are implemented. Nurses must take responsibility for learning and consistently using the guidelines.

Clinical Reasoning

In the clinical setting, identify the infrastructure supports to promote pain management of children, such as pain assessment tools, pain flow sheets, pain management policies and guidelines, education, and resources for complementary therapies. Identify additional supports that would help you as an inexperienced nurse to gain competence in pediatric pain management.

effectiveness of pain-control measures to provide optimal comfort; and client education. See *Evidence-Based Practice: Challenges to Adequate Pain Management*.

PHARMACOLOGIC INTERVENTION

Give analgesics as ordered by the healthcare provider, ensuring that the dose is appropriate for the child's weight. When administering an opioid by intravenous infusion or PCA, monitor the flow rate and the site for infiltration. Follow facility guidelines for monitoring vital signs, and use a pulse oximeter or cardiorespiratory monitor with audible alarm for children at risk for respiratory depression. Vital signs (heart rate and blood pressure) may not change in response to effective analgesia when infection, trauma, or other stressors keep them elevated. Make sure that naloxone is available in case adverse effects develop. The dose should be precalculated and the medication immediately available when an opioid is used.

Check for the presence of other side effects of analgesics, such as sedation, nausea, vomiting, itching, urinary retention, and constipation. An alternative opioid or medications to treat the side effects may be prescribed when analgesia is needed long term.

Oral NSAIDs, sometimes in combination with an opioid, are generally ordered for less severe pain or chronic pain. These drugs may mask fever. Be alert to the potential complication of gastrointestinal hemorrhage in critically ill children who have increased gastric acids as a physiologic stress response to pain.

Assess the child for pain using a behavioral or self-report pain scale 15 to 30 minutes following intravenous pain medication and 1 hour after oral pain medication to determine if adequate pain control was achieved. Evaluate the child's level of pain frequently to identify any increase in pain intensity. Use information collected from the child and parent. Dramatic reductions in pain should occur, although not all pain may disappear. Be certain to record results of pain-control measures to guide future nursing actions. Use a flow sheet to document assessments, medication administration, complementary therapies, and other comfort measures during the postoperative period.

Many children sleep after receiving an analgesic. This sleep is not a side effect of the drug or a sign of an overdose, but the result of pain relief. Pain interrupts sleep, and once pain is relieved, the child can sleep comfortably. However, sleep does not always indicate pain control. A child in pain may fall asleep in exhaustion. Look for other symptoms of pain, such as excess movement or moaning.

Figure 15–5 **The presence of the parent is an important part of pain management. Children often feel more secure telling their parents about their pain and anxiety.**

Become an advocate for the child when the dose or type of analgesic ordered is inadequate. When the child with severe pain has been taking opioids for several days, tolerance may occur and an increasing amount of the opioid may be needed to produce or maintain the same level of pain relief. The duration of effective analgesia becomes shorter than expected, and breakthrough pain occurs. Review the child's record to verify that the opioid was given at the appropriate dose and frequency before asking the healthcare provider to modify the child's pain medication.

COMPLEMENTARY THERAPY

Complementary therapies can be implemented for all children with discomfort and pain, with or without pain medication. Parents are one of the most powerful nonpharmacologic methods of pain relief available to children (Figure 15–5). When parents are actively participating in the child's care during hospitalization, provide suggestions for some age-appropriate interventions to improve comfort (see *Growth and Development: Distraction Activities*).

Growth and Development Distraction Activities

Children of all ages feel more secure and may have less pain and anxiety when parents are present. Parents can actively participate during their child's care with selection of age-appropriate distraction strategies, such as the following:

- *Infants:* holding, rocking, pacifier, mobiles, music, soft toys, massage
- *Toddlers:* massage, pinwheels, stories, bubbles, touch, holding, rocking, music
- *Preschoolers:* puzzles, action figures and other toys, being a superhero, kaleidoscopes, books, videos
- *School-age children:* rhythmic breathing, muscle relaxation, guided imagery, talking about pleasant experiences, playing games, watching a video, video games
- *Adolescents:* rhythmic breathing, muscle relaxation, guided imagery, having visitors, video games, watching videos, listening to CD player or iPod

Clinical Reasoning **Determining When a Child Is in Pain**

Felicia, who is 5 years old, was struck by a car. Six hours ago, she had surgery to repair a liver laceration, but she also has numerous bruises and abrasions on her body. After spending 3 hours in the postanesthesia unit, she was moved to the pediatric inpatient unit. She has an intravenous line in place, as well as a nasogastric tube attached to low suction. Her abdominal dressing is clean and dry. Felicia has orders for morphine IV every 3 hours around the clock for the first 24 hours.

Felicia's mother is rooming in with her during her hospital stay. Twelve hours after surgery, Felicia is dozing but is responsive to verbal stimuli. Her most recent IV morphine was given 2 hours ago. The nurse attempts to determine how well Felicia's pain is managed. Her facial expression indicates that she is not in pain. Felicia's mother feels that she is resting comfortably.

How do you know whether Felicia is in pain? Can you expect her to tell you if she feels pain? What other pain-relief measures could reduce or help to control her pain in the first 24 hours? What is the appropriate dose of IV morphine for Felicia, who weighs 25 kg? What is the timing of assessments of the response to pain medication and potential side effects? What signs of respiratory distress indicate a need for naloxone administration?

MEASURES TO INCREASE COMFORT DURING PAINFUL PROCEDURES

Make every effort to increase the child's comfort during painful procedures, including the use of complementary therapies. Topical anesthetics can be used to reduce the pain associated with an immunization, other injection, intravenous insertion, venipuncture, heel lance, or the first needlestick of another procedure. Give time for the medication to become effective. Mechanisms for administration of topical anesthetics include the following:

- Vapocoolant sprays can be used for injections. Spray the site or soak a cotton ball and apply to intact skin for about a minute.
- EMLA (eutectic mixture of local anesthetics) cream, an emulsion of 2.5% lidocaine and 2.5% prilocaine, is effective if applied 60 minutes before a needlestick, venipuncture, or circumcision procedure on intact skin in infants and children (Barnes, 2014). The depth of penetration deepens if left on longer.
- L-M-X4, 4%, liposomal lidocaine (formerly called ELA-MAX), is effective if applied 30 minutes before a needlestick. It is available without a prescription. See Figure 15–6.
- The Synera anesthetic patch, containing 70 mg of lidocaine and 70 mg of tetracaine, can be applied to intact skin for 20 to 30 minutes prior to a procedure. It becomes heated on application and results in more rapid anesthesia.
- Buzzy for Shots is a device that has a cold pad placed against the skin and a buzzing bee that vibrates. Buzzy is placed over the site of a needlestick for 30 seconds and then moved and placed proximally during the needlestick. The cold and vibration stimulation interferes with pain

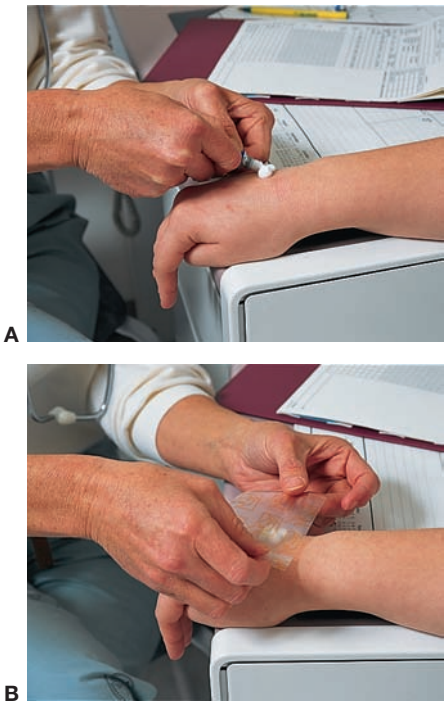

Figure 15–6 **Anesthetizing cream (e.g., L-M-X4 or EMLA) may be prescribed for use prior to a painful needlestick. *A*, Apply a thin layer on selected sites and wait 30 seconds, and then apply a thick layer of cream over intact skin. *B*, Cover the cream with plastic wrap or a transparent adhesive dressing to keep the cream in place and to prevent ingestion. Depending on the cream used, the dermal surface is anesthetized in 30 to 60 minutes.**

transmission, and it also provides distraction for the child (Buzzy, 2014). See Figure 15–7.

- A needle-free powder lidocaine delivery system (J-Tip) produces rapid analgesia (within 1 to 3 minutes) for IV starts and venipuncture. The system has a sterile, single-use, prefilled, and disposable cartridge that is pressed against the skin. Pressurized carbon dioxide gas ruptures the cartridge and forces lidocaine particles to penetrate the skin. Prepare the child for the small pop sound when it is used.
- LET (lidocaine, epinephrine, and tetracaine) is a topical anesthetic for laceration repair. The LET liquid is applied to a cotton ball and the skin, or LET gel is applied to the skin and covered with an occlusive dressing. The anesthetic works in 30 minutes (Barnes, 2014).

A local anesthetic such as lidocaine buffered by sodium bicarbonate or bupivacaine is often injected subcutaneously to provide analgesia for emergent invasive procedures.

Assemble a pain management kit to promote distraction, imagery, and relaxation in children. Include items such as magic wands, pinwheels, bubble liquid, a Slinky spring toy, a foam ball, party noisemakers, and pop-up books. It may also be helpful to include items for therapeutic play such as syringes, adhesive bandages, alcohol swabs, and other supplies from a medical kit. The pain management kit may be especially helpful for distracting children who are being prepared for medical procedures.

Figure 15–7 **Buzzy for Shots is a device that uses cold and vibration stimulation to interrupt and reduce pain transmission due to immunization and venipuncture needlesticks. The vibration and colorful bee distract the child. Start by attaching the cold pack to Buzzy and placing this on the target area. Turn the buzzer on for 30 seconds. Then move Buzzy to an area proximal to the planned needle site, turn on the buzzer, and keep in place during the needlestick. This child is being prepared for an IV start on his arm.**

Clinical Tip

Teach parents about the use of anesthetic cream (e.g., L-M-X4 or EMLA) or other pain management tool when the child is scheduled for an immunization or venipuncture. Anesthetic cream can be applied to the skin before departing for the healthcare visit. Provide directions regarding the correct placement of the cream on the arm or leg. Have the parents follow the directions from the package regarding the amount to use and how to cover the site with plastic wrap during the trip to the health center.

DISCHARGE PLANNING AND HOME CARE TEACHING

Children are frequently discharged from the hospital with oral analgesics following surgery, injury, or treatment of acute medical conditions. The child usually leaves the hospital or surgical center pain free, and the parents may not anticipate pain. Provide information about the child's need for pain medication around the clock for the first 1 to 2 days to prevent the child from feeling pain, and the benefits of pain management in promoting the child's healing.

Provide guidance to help parents assess their child's pain, and for school-age children and adolescents to assess their own

pain. Teach parents and children about the dosage and frequency of administration and the side effects of the analgesic ordered. Consider providing a calendar or recommended schedule for daily pain medication and other medications for at least a week. Parents can post this on the refrigerator and check off doses as administered. This strategy may improve adherence with recommendations. Review complementary therapies and encourage children and parents to use the techniques that work best for them.

SAFETY ALERT!

Parents may make common dosing errors when using teaspoons or tablespoons to measure medications such as liquid acetaminophen or ibuprofen for their children, especially if abbreviations (tsp or tbs) are used on the label instructions. For example, use of a tablespoon rather than the recommended teaspoon dose leads to 3 times the appropriate dose. Additionally, the size of tableware spoons varies, which can also affect dose accuracy. Use of dosing devices measured in millimeters (mL) (e.g., oral syringe, dosing spoon, or measuring cup) is an effective way to reduce medication errors that can lead to adverse effects associated with medications prescribed for pain. Educate parents about the correct milliliter dose when labels specify medication volume by teaspoon or tablespoon. The American Academy of Pediatrics (AAP) now recommends that all oral liquid medications be prescribed using metric units or milliliters (AAP Committee on Drugs, 2015).

Remember that many common health problems (otitis media, pharyngitis, and urinary tract infection) have pain as one of the presenting symptoms. Often the only medication prescribed is an antibiotic to clear the infection. The child may be in pain for 48 to 72 hours until the antibiotic controls the infection. Give parents recommendations for pain control and comfort measures during this period. Review the dose, dosing device, and formulation of acetaminophen or ibuprofen used by parents to identify any risk for overdose. Avoid using any leftover pain medications prescribed for other conditions. See Chapter 16.

SAFETY ALERT!

Warn parents who are sent home with a prescription for an opioid for their child about the need to dispose of the remaining medication or to lock it up after it is no longer needed. Adolescents may share unprotected tablets with friends leading to and supporting substance abuse. The rate of poisoning death due to prescription drug misuse has increased dramatically in recent years (see the *Healthy People 2020* objective). Check with local law enforcement or the pharmacy about the availability of medication disposal sites or options.

Healthy People 2020

(SA-19) Reduce the past-year nonmedical use of prescription drugs

Evaluation

Expected outcomes of nursing care include the following:

- The child's pain level is assessed frequently and pain management is effective in improving the child's comfort.
- The child successfully uses a PCA pump to control acute pain.
- Age-appropriate complementary therapies enhance the comfort provided by medications.
- Parents maintain the child's pain management after discharge.

Chronic Pain

Some children have medical conditions that cause chronic pain or recurrent episodes of acute pain, sometimes in more than one body system. Medical conditions such as juvenile idiopathic arthritis, sickle cell disease, cancer, headaches, recurrent abdominal pain, and HIV infection all cause chronic and recurrent pain. Approximately 20% to 35% of children and adolescents are estimated to have chronic pain (APS, 2012). These children and adolescents often have functional limitations related to school, social activities and relationships, physical activity, and family responsibilities. Chronic pain has social and emotional consequences for the child and family.

Clinical Manifestations

Behavioral indicators of chronic pain may include fatigue, inactivity, posturing, difficulty concentrating and sleeping, withdrawal from activities, and mood disturbances. Persistent or continuous chronic pain permits physiologic adaptation so the elevated heart rate, respiratory rate, and blood pressure levels associated with the initial response to acute pain are rarely seen (Huether, 2014). However, the child with intermittent acute painful episodes may have initial vital sign changes. Varying levels of disability may also exist.

Clinical Therapy

An interdisciplinary team that collaborates on addressing the factors that stimulate and contribute to the child's pain in an individualized treatment plan should focus on improving function and comfort. Cognitive behavioral therapies are used to address the connection between thoughts, feelings, and behaviors; reduce stress; and promote coping. Physical and occupational therapy may help restore function. Treatment for sleep disturbances and strategies for school functioning are addressed. Complementary therapies such as relaxation strategies, ice, or heat should be used when appropriate (APS, 2012). Analgesics rarely include opioids except for acute painful episodes. NSAIDs or acetaminophen may be prescribed. Complete pain relief may not be possible. A tricyclic antidepressant may be prescribed for its analgesic properties and because depression may be a coexisting condition.

Health Promotion

Children with chronic pain should learn a cognitive behavioral therapy (e.g., hypnosis, guided imagery) that helps the child to reduce stress, cope with pain, and enhance pain management. Use of relaxation techniques with guided imagery that includes positive suggestions for comfort has helped many children with a chronic painful condition reduce their pain. Improved quality of life scores have been noted (Gottsegen, 2011).

Nursing Management

When assessing chronic pain in the child, approach pain as if it were the primary problem for attention. Consider the physical, behavioral, and psychologic signs and symptoms together. Focus on the following topics to assess and evaluate chronic pain in children (APS, 2012):

- Obtain the history of pain onset, its development over time, intensity, duration, variability, location, and what worsens or relieves it. Ask what the family and child believe causes the pain. Identify past pain problems in the family.
- Learn about the impact of the pain on the child's daily life (sleep, appetite, school, activity, and social interactions). Identify how much distress the child and family experience with pain.
- Identify the child's methods for coping with pain. How does the pain impact the child's emotional function?
- Ask about the current treatment methods, including complementary therapies.
- Observe the child's appearance, posture, gait, and emotional and cognitive state. Perform a complete neurologic examination. Assess muscle spasms, trigger points, and areas sensitive to light touch.

Encourage older school-age children and adolescents with chronic pain or recurrent episodes of acute pain to keep a pain diary to describe the pain intensity, characteristics, timing, activities, and potential triggers of their pain, as well as their response to pain treatment measures. A pain assessment scale should be used to rate the pain intensity before and after medications and other pain-control measures are used. This record can help improve pain management when shared with healthcare providers.

Monitor pain intensity at each office visit and frequently during hospitalizations. Believe the child who reports chronic pain or recurrent episodes of pain, and use pharmacologic and nonpharmacologic methods to reduce or relieve the child's pain. Remember the child may have increased pain sensitivity in anticipation of and during needlesticks and other procedures.

Work with the pain management team to individualize the pain management plan to meet the child's needs, family's beliefs and values, and their cultural preferences for care. Develop a care plan for acute painful episodes associated with the condition. Assist the child and family in identifying age-appropriate and acceptable complementary therapies to help cope with discomfort. Encourage daily exercise to promote function.

Sedation and Analgesia for Medical Procedures

Children undergo a wide variety of painful diagnostic and treatment procedures in the hospital and in outpatient settings. Procedures such as chest tube insertion, arterial puncture, lumbar puncture, bone marrow aspiration, fracture reduction, laceration repair, insertion of a central or peripheral intravenous line, and burn debridement cause significant pain in children. The anticipation of these procedures causes anxiety and emotional distress that can lead to greater pain intensity. For example, children with prior painful cancer treatment procedures may express greater pain during later procedures, even when provided with adequate analgesia (Rosen & Dower, 2011).

Sedation is a medically controlled state of depressed consciousness (light to deep) used for painful diagnostic and therapeutic procedures. **Moderate sedation** (formerly called *conscious sedation*) occurs with lower doses of sedatives and enables the child to maintain protective reflexes independently, continuously maintain a patent airway, and respond to tactile and verbal stimuli. **Deep sedation** is a controlled state of depressed consciousness or unconsciousness in which protective airway reflexes are lost. See Table 15–7 for characteristics of different sedation levels.

Drugs used for sedation include the following:

- Benzodiazepines: midazolam (Versed), diazepam (Valium), and lorazepam (Ativan); antagonist agent is flumazenil
- Hypnotics or barbiturates: methohexital
- Ketamine
- Propofol (Diprivan) or Etomidate
- Chloral hydrate
- Analgesics: fentanyl, alfentanil; antagonist agents are naloxone and nalmefene

Every healthcare facility should have guidelines for the use of sedation to ensure safe healthcare practices. Healthcare providers monitoring the child should have specific qualifications, such as training in pediatric advanced life support. Potential complications of sedation include respiratory depression, a compromised airway, delayed awakening, agitation, nausea and vomiting, and tachycardia or bradycardia (Krauss & Green, 2013).

TABLE 15–7 Clinical Manifestations of Light, Moderate, and Deep Sedation

ASSESSMENT FACTORS	LIGHT SEDATION	MODERATE SEDATION	DEEP SEDATION
Airway	Maintains airway independently and continuously	Maintains airway independently and continuously	Airway may not be maintained, may need ventilation assistance
Cough and gag reflexes	Reflexes intact	Reflexes intact	Partial or complete loss of reflexes
Level of consciousness	Responds normally to verbal stimuli	Purposeful response to verbal or gentle tactile stimuli	Difficult to arouse, purposeful response after repeated or painful stimuli

Source: Data from Jest, A. D., & Tonge, A. (2011). Using a learning needs assessment to identify knowledge deficits regarding procedural sedation for pediatric patients. *AORN Journal, 94*(6), 567–574; Barnes, S. (2014). Analgesia and sedation. In B. Engorn, & J. Flerlage (Eds.), *The Harriet Lane handbook* (20th ed.). Philadelphia, PA: Elsevier Mosby; Krauss, B., & Green, S. M. (2014). Systemic analgesia and sedation for procedures. In J. R. Roberts, & C. B. Custalow (Eds.), *Roberts and Hedges' clinical procedures in emergency medicine* (6th ed.,pp. 586–610). Philadelphia, PA: Elsevier Saunders.

SAFETY ALERT!
Sedation is a continuum, and the child may move from one level of sedation to another. The child must be carefully monitored for respiratory depression and signs of deep sedation, so the airway can be protected and ventilatory support can be provided if needed. A pediatric code cart, resuscitation bag-valve-mask and drugs, oxygen, and suction must be available, along with antagonist agents (naloxone and flumazenil) for opioids and benzodiazepines, when the effects of sedation and respiratory depression must be reversed.

Nursing Management

When the child receives sedation, continuously assess the child's status to include visual confirmation of respiratory effort, chest wall movement, color, vital signs, level of consciousness, and oxygen saturation. Document vital signs every 5 minutes (Jest & Tonge, 2011). A cardiorespiratory monitor, pulse oximeter, and expiratory CO_2 monitor should be used, but the equipment must not replace visual assessment. Be prepared to suction emesis or excessive salivation that could obstruct the airway. After the procedure, check vital signs every 15 minutes until the child regains full consciousness and level of functioning, usually within 30 minutes.

Criteria for discharging the child after sedation include the following (Krauss & Green, 2013):

- Stable vital signs, airway patency, and intact protective reflexes are evident.
- The child sits up without assistance; the infant holds head up.
- Discharge status is the same as admission status.
- Fluid intake is not essential as some sedation medications stimulate vomiting in children.

Inform parents that the child may have mild adverse effects from sedation, such as crying, lethargy, and vomiting. Avoid food and fluids for 2 hours if the child has nausea. For the next 12 hours, do not permit activities such as bicycle riding or gymnastics that require coordination, and do not leave the child unattended in the bathtub or pool.

Chapter Highlights

- Pain is an unpleasant sensation that is either acute or chronic. It is perceived in response to tissue damage that increases the stress in children of all ages. Neuropathic pain is one form of chronic pain.
- Unrelieved pain causes many undesirable physiologic consequences on body systems, such as inadequate lung expansion and coughing, increased metabolic rate, increased sympathetic nervous system activity, decreased gastric acids and intestinal motility, depressed inflammatory responses, and increased pain sensitivity.
- A child's responses to and understanding of pain depend on age, stage of development, culture, and prior painful experiences.
- Assessment of acute and chronic pain should include physical, behavioral, and emotional factors to obtain the most accurate information about the location and intensity of the child's pain and how the child responds to it.
- Pain assessment should include the use of a valid and reliable pain assessment tool that is appropriate for the child's age, cognitive development, and condition.
- Every infant, child, and adolescent has the right to adequate pain control.
- Pharmacologic interventions for pain control include opioids, nonsteroidal anti-inflammatory drugs (NSAIDs), and acetaminophen.
- Analgesia for continuous or severe pain should be given around the clock to maintain pain control.
- Complementary therapies for pain management include the following: parental presence, distraction, cutaneous stimulation, sucrose solution, electroanalgesia, guided imagery, breathing techniques, progressive muscle relaxation techniques, hypnosis, application of heat and cold, biofeedback, and acupuncture.
- Methods to reduce pain associated with needlesticks include vapocoolant spray, LMX-4 cream, Synera patch, Buzzy for Shots, and needle-free lidocaine delivery system.
- Epidural and regional nerve blocks are pain-control methods used more frequently for postsurgical pain management because they have fewer side effects than systemic medications.
- Parents need education and preparation to provide pain management for children who are discharged home following surgery and injuries.
- Children with recurrent and chronic painful conditions need an individualized pain management plan that includes cognitive behavioral therapies, physical and occupational therapy, and other measures to improve function, quality of life, and comfort.
- The child receiving sedation should be continuously and visually monitored for respiratory effort, vital signs, color, level of responsiveness, vomiting, and excessive salivation.

Clinical Reasoning in Action

A 12-year-old boy, Kevin, is recovering at a local children's hospital from a four-wheeler all-terrain vehicle (ATV) crash. He was riding the ATV unsupervised and without permission while his parents were at work. He suffered three broken bones, several lacerations, and an abdominal injury that required surgery. His parents are very worried about his injuries and at the same time angry with him for not following the rules. Kevin appears expressionless in his hospital bed, but cries and grimaces at any slight movement. When asked on a scale of 1 to 10 (10 being the most pain) how much pain he is feeling, he says a 10. His parents are reluctant to let him have any pain medications because they fear he may become dependent on the medication. His father states that Kevin should be a man and tolerate the pain, and he thinks enduring the pain will teach him a lesson about responsibility. The nurse explains that pain management is necessary to improve Kevin's healing, help him mobilize sooner, and potentially shorten his hospital stay. She explains the physiologic consequences of ineffective pain management and discusses how the medication will help him sleep and rest. She explains that some of the pain medications can be addicting, but the chances of Kevin becoming addicted to pain medications for this injury are extremely rare. She also reviews the nonpharmacologic methods of relieving pain. The parents are still reluctant to allow the medications, but agree to conform to the healthcare provider's orders.

1. What are some of the potential physiologic consequences of letting Kevin suffer pain?
2. What are some examples of opioid analgesics appropriate for Kevin?
3. What are some examples of NSAIDs available to Kevin?
4. What are the signs of tolerance to the prescribed opioid?

Chapter 16
Immunizations and Communicable Diseases

Peter Hendrie/Getty Images

We came in today because Chang has a fever. I know Lian and Chang need immunizations. Lian will be going to kindergarten in the fall, so it's very important for her to get all of the immunizations she needs now.

—Mother of Lian, 5 years old, and Chang, 2 years old

Learning Outcomes

16.1 Compare the vulnerability of young children and adults to communicable diseases.

16.2 Propose strategies to control the spread of infection in healthcare and community settings and the home.

16.3 Examine the role that vaccines play in reducing and eliminating communicable diseases.

16.4 Select the appropriate vaccines to administer to an infant, a toddler, a child entering kindergarten, an older school-age child, and an adolescent.

16.5 Plan the nursing care for children of all ages needing immunizations.

16.6 Outline a plan to maintain the potency of vaccines.

16.7 Create a parent education session that focuses on the care of infants and children with a fever.

16.8 Recognize common infectious and communicable diseases.

16.9 Develop a nursing care plan for the child with a common communicable disease.

A **communicable disease** is an infection often caused by **direct transmission** (from one person or animal to another by body fluid contact), via **indirect transmission** (to a person by contact with contaminated objects), or by *vectors* (ticks, mosquitoes, other insects). An **infectious disease** is any communicable disease caused by microorganisms transmitted from one person to another or from an animal to a person. Children can develop complications or secondary infections that require health care and can sometimes result in death.

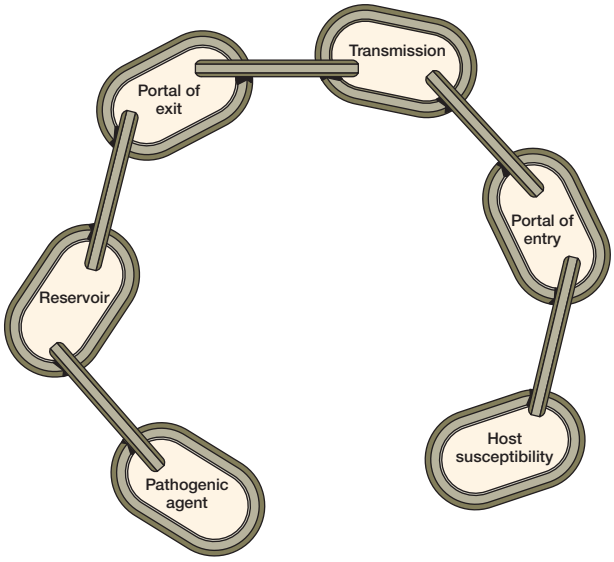
For a communicable disease to occur three factors need to be in place:

1. An infectious agent or pathogen
2. An effective means of transmission
3. Presence of susceptible host (See *Pathophysiology Illustrated: The Chain of Infection Transmission*.)

Special Vulnerability of Infants and Children

Infants and young children are often susceptible hosts. Newborns are more susceptible because the immune system is not fully mature at birth and disease protection from vaccines

Pathophysiology Illustrated: **The Chain of Infection Transmission**



An effective chain of infection transmission requires a suitable habitat or reservoir for the pathogen. To prevent or control the spread of infection, one of the links in the chain must be broken, such as eliminating one or more of the habitats or reservoirs (e.g., insecticide spraying to kill mosquitoes that carry malaria). Isolating an infected individual interferes with disease transmission, and killing the pathogen eliminates the causal agent.

is incomplete. Maternal **antibodies** (proteins capable of responding to specific infectious agents) transferred through the placenta and breast milk provide **passive immunity** to the newborn. Passive immunity may also be provided with immune globulin. These antibodies provide limited protection for some infections, and this protection decreases over several months after birth. Immunodeficiency and poor health may also increase a child's risk for a communicable disease.

Infants and children develop **active immunity**, antibody development for specific infections through immunization or exposure to the natural disease. Exposure to infectious agents leads children to naturally develop antibodies that prevent or reduce the response to future exposure to the same infectious agent (Figure 16–1). (Refer to the section titled *Anatomy and Physiology of Pediatric Differences* in Chapter 22.)

The poor hygiene behaviors of young children promote transmission of communicable diseases in environments where children are in close contact. The fecal–oral and respiratory routes are the most common sources of transmission in children. Children do not wash their hands after toileting unless closely supervised. They then put their hands in their mouth and rub their nose and eyes. Diapers may leak stool and provide the fecal exposure to organisms. In some cases, the child may be contagious before disease symptoms occur (e.g., varicella and parvovirus B-19) and before the child can be isolated. See Table 16–5 later in this chapter for more information about these and other communicable diseases.

Figure 16–1 Infectious diseases are easily transmitted in settings such as childcare centers where multiple children handle common objects that have been sneezed, coughed, or drooled upon.

Public Health and Communicable Diseases

Reducing the number of preventable childhood illnesses is a national goal of *Healthy People 2020*. Approximately 300 children in the United States die each year from vaccine-preventable diseases. Routine immunization, with all recommended vaccines administered to children beginning at birth, is estimated to save 33,000 lives, prevent 14 million cases of disease, and reduce direct healthcare costs by $9.9 billion (U.S. Department of Health and Human Services, 2015).

Healthy People 2020

(IID-1) Reduce, eliminate, or maintain elimination of cases of vaccine-preventable diseases

(IID-3) Reduce meningococcal disease

(IID-4) Reduce invasive pneumococcal infections

Nurses have an important health promotion role in reducing the transmission of infectious diseases by immunization and in educating families to interrupt the transmission of infection. Preventing the spread of infectious diseases involves several strategies that must be well coordinated. Nurses have a significant

Families Want to Know

Reducing the Transmission of Infection

Teach families how to reduce the spread of infection among family members with the following practices:

- Wash hands thoroughly with soap and water or cleansing gels after all contact with the child's diaper, used tissues, runny nose, and mucous membranes.
- Use disposable tissues and discard immediately after use.
- Teach children to cough or sneeze into their elbow rather than their hands.
- Teach children to wash their hands with soap and water after toileting and before eating.
- Do not allow children to share dishes and utensils.
- Wash hands before preparing food and again several times during food preparation. Follow guidelines for safe food preparation and storage. Use warm soapy water to wash dishes and cutting boards.
- Wipe counters and surfaces that are used for diaper changes or that the child touches with a disinfectant such as bleach solution, Lysol, or isopropyl alcohol. Make sure the diaper-changing area is well away from food preparation areas.
- Dispose of diapers in closed containers.

role in this process and are responsible for implementing several infection-control strategies:

- Use proper hand hygiene. Wash hands with soap and water when visibly dirty, when contaminated by blood or other body fluids, when in contact with a contaminated surface, and after using the toilet (Centers for Disease Control, 2014a). Use alcohol-based hand sanitizer to clean the hands in all other routine clinical situations.
- Use standard and transmission-based precautions (see the *Clinical Skills Manual* SKILLS for more information).
- Promote and provide immunizations.
- Separate and quarantine ill children from well children. Separate children at high risk for infection from those with infections in all clinical settings.
- Eliminate the habitat or reservoir of the host (e.g., eliminate standing water where mosquitoes breed).
- Kill the pathogen (e.g., sanitize toys and surfaces exposed to organisms).
- Educate parents and caregivers to reduce the transmission of infectious diseases. (See *Families Want to Know: Reducing the Transmission of Infection*.)

Professionalism in Practice Infection Control in Schools

School nurses have an important leadership role in targeting communicable diseases because of their professional knowledge and public health perspective (National Association of School Nurses, 2011). School nurses document the student immunization records and encourage families to have their children fully immunized. Students with communicable diseases are identified so they can be sent home for care, reducing exposure to other students. It is important for school nurses to stay informed about communicable disease outbreaks in the community and then to be vigilant about monitoring illness patterns among students and faculty. When a communicable disease outbreak occurs in the school setting, the school nurse reports the outbreak to local health officials so that communitywide infection-control information can be shared. They also develop programs and teach students how to reduce the spread of infection.

Immunization

The development and wide use of vaccines is one of the great achievements of modern medicine. A vaccine introduces an **antigen** (a foreign substance that triggers an immune system response) into the body, and the vaccinated person produces antibodies that provide active immunity to a disease without having the clinical disease.

When a child needs antibodies faster than the body can develop them, passive immunity may be provided by giving the child antibodies produced by another human or animal host (e.g., immune globulin). This approach is used with children at risk for a disease to prevent the disease from occurring or to reduce its severity after an exposure. For example, if an unimmunized toddler receiving chemotherapy for cancer is exposed to chickenpox, the child needs immediate protection (passive immunity). Varicella immune globulin is given to reduce the child's risk for developing chickenpox, a potentially fatal infection for this child. Passive immunity does not last long, so the child needs to receive the varicella vaccine at a later time in order to develop active immunity.

Since the first vaccines were developed in the late 1800s, the incidence of many diseases has decreased dramatically. The average infant born in 2016 receives vaccines for 14 childhood diseases by age 6 years. Vaccines have also been developed for older children, adolescents, and adults to protect against pertussis, meningococcus, human papillomavirus, pneumococcus, and herpes zoster. Vaccines improve the health of children and reduce the parents' burden of caring for ill children.

The following lists the types of vaccines against childhood illnesses used in the United States:

- **Killed virus vaccine.** A microorganism has been killed but is still capable of causing the human body to produce antibodies. Example: inactivated poliovirus.
- **Toxoid.** A toxin has been treated (by heat or chemical) to weaken its toxic effects but retain effective antigens. Example: tetanus toxoid.
- **Live virus vaccine.** A microorganism is in a live but attenuated, or weakened, form. Example: measles and varicella vaccines.
- **Recombinant forms.** A genetically altered organism is used in vaccines. Examples: hepatitis B and **acellular pertussis vaccine** (a vaccine that uses pertussis proteins rather than the whole cell to stimulate active immunity).

- **Conjugated forms.** An altered organism is joined with another substance to increase the immune response. Examples: The *Haemophilus influenzae* type b (Hib) vaccine is conjugated with a protein-carrier like tetanus toxoid. No immunity to tetanus develops with this vaccine.

Today's vaccines are often produced synthetically with recombinant DNA technology or genetic engineering to improve vaccine safety and efficacy and to reduce their side effects. See Table 16–1 for recommended pediatric vaccines.

TABLE 16–1 Pediatric Vaccines

VACCINE TYPE	SIDE EFFECTS	CONTRAINDICATIONS	NURSING CONSIDERATIONS
Diphtheria, Pertussis (Whooping Cough), and Tetanus Toxoid (DTaP, Tdap)			
Type: Inactivated ***Dosage:*** 0.5 mL, IM ***Age(s) given:*** 2, 4, 6, 15–18 months; 4–6 years (5 doses); 11–12 years (Tdap) ***Caution:*** For a prior serious reaction to the pertussis component of DTaP vaccine, use DT (children less than 7 years) and Td (children 7 years and older) vaccines. ***Storage:*** Refrigerate, do not freeze. Tripedia and Infanrix vial stopper contains latex.	***Common:*** Redness, pain, swelling, nodule at injection site; fever up to 38.3°C (101.0°F); drowsiness, irritability, fussiness; anorexia within 2 days of injection Increase in frequency and magnitude of local reactions with fourth and fifth doses (e.g., entire limb swelling) ***Serious:*** Allergic reaction, anaphylaxis; shock or collapse (an episode with sudden loss of muscle tone, pallor, fever, and unresponsiveness), fever above 40.5°C (104.8°F); febrile seizure; persistent inconsolable crying	Gelatin allergy (do not use Tripedia) Serious side effects after a prior dose: e.g., anaphylaxis, encephalopathy within 7 days of vaccine dosage ***Precautions and temporary deferral for DTaP and Tdap administration:*** • Infants under age 1 year with evolving neurologic disorder • Guillain-Barré syndrome less than 6 weeks after previous dose • Moderate to severe febrile illness • Older children with a progressive neurologic condition	• Use same brand for all doses if possible. • Ask about previous vaccine reactions. • Shake vaccine before withdrawing. Solution will be cloudy. Do not use if it contains clumps that do not resuspend. • If a child has a history of seizures with or without fever, give acetaminophen at the time of vaccine and then every 4 hr for 24 hr. • Inform parents about an increased potential reaction to the fourth and fifth doses. • A tetanus booster may be given for a contaminated wound or burn, if 5 or more years since the last dose (AAP, 2015, p. 775).
***Haemophilus influenzae* Type B (Hib)**			
Type: Inactivated ***Dosage:*** 0.5 mL, IM ***Age(s) given:*** 2, 4, 6, 12–15 months; (4 doses for PRP-T [ActHIB]) *or* 2, 4, 12–15 months (3 doses for PRP-OMP [PedvaxHIB]) ***Storage:*** Refrigerate, loss of potency if frozen. Vial stopper with Pentacel and MenHibRix contains no latex.	***Common:*** Pain, redness, or swelling at site ***Serious:*** Anaphylaxis (extremely rare); fever	Prior anaphylactic reaction Comvax is contraindicated if yeast allergy exists. ***Precautions:*** Moderate or severe acute illness with or without fever Ask if child is immunosuppressed. Some children benefit from additional doses (AAP, 2015, p. 373).	• Solution is clear and colorless. • Since different product preparations (e.g., single and combination vaccines) affect the immunization schedule, read package inserts carefully. • Follow directions for reconstituting, refrigerating, and discarding unused reconstituted vaccine.
Hepatitis A (HepA)			
Type: Inactivated ***Dosage:*** 0.5 mL (1.0 mL over age 19 years), IM ***Age(s) given:*** 12–23 months; second dose 6–12 months after first dose ***Storage:*** Refrigerate, loss of potency if frozen.	***Common:*** Pain and induration at injection site; fever ***Serious:*** Anaphylaxis reactions are rare.	Known hypersensitivity to any component of vaccine, including neomycin Anaphylactic reaction to prior vaccine dose ***Precautions:*** Pregnancy	• Shake well, slightly opaque white suspension. No reconstitution is needed. • Some Havrix and all Vaqta vials have a latex stopper. • Can be given for postexposure prophylaxis against hepatitis A (AAP, 2015, p. 398). • Immune globulin and vaccine can be given at the same time in different sites.

VACCINE TYPE	SIDE EFFECTS	CONTRAINDICATIONS	NURSING CONSIDERATIONS
Hepatitis B (HB)			
Type: Inactivated ***Dosage:*** 0.5 mL (1.0 mL at 20 years), IM ***Age(s) given:*** Birth, 1–2 months, 6–18 months; 3 doses; a 3-dose series can be started at any age. ***Storage:*** Refrigerate, do not freeze. Vaccine brands can be interchanged for 3-dose series. Use the monovalent (single vaccine) preparation for newborns up to 6 weeks of age.	***Common:*** Pain or redness at injection site ***Serious:*** Anaphylaxis is uncommon.	Anaphylaxis reaction to prior dose Serious hypersensitivity reaction to prior dose related to vaccine component (e.g., yeast) ***Precautions:*** Newborn weighing less than 2000 g (4.4 lb) may receive dose at birth, but receive 3 additional doses starting at 1 month of age Moderate or severe acute illness with or without fever	• Check status of mother's hepatitis B test. If mother has HBsAg+ or unknown status, give vaccine to newborn within 12 hr of birth along with hepatitis B immune globulin in another site. • Shake vaccine before withdrawing. Solution will appear cloudy. • Formulations (pediatric, adult, dialysis) and combination vaccines are available. Read package insert carefully and follow directions for the product used. • Check the anti-HBs and HBsAg levels in infants of HBsAg+ mothers at age 9–18 months, after series completion (AAP, 2015, p. 421).
Human Papillomavirus (HPV4 or HPV2)			
Type: Recombinant ***Dosage:*** 0.5 mL, IM ***Age(s) given:*** 11–12 years, second dose 2 months later, third dose 6 months after the first dose. May be administered to males and females between 9 and 26 years of age. HPV2 is not licensed for males (Markowitz et al., 2014). ***Storage:*** Refrigerate, do not freeze. Light exposure reduces vaccine potency.	***Common:*** Pain, swelling, erythema at the injection site, headache, nausea, pruritus, and fever ***Potential serious reactions:*** Guillain-Barré syndrome, blood clot, bronchospasm, asthma, arthritis	Severe allergic reaction to prior dose or hypersensitivity to a vaccine component (e.g., yeast) Pregnancy ***Precautions and deferral:*** Moderate to severe acute illness with or without fever. Can be given when mild acute illness is present.	• Use same brand for each dose if possible. • Shake well before use. Solution is a white cloudy liquid. No dilution or reconstitution. • Observe adolescent for 15 min when seated because of risk of fainting and syncope. • Administer vaccine before onset of sexual activity. • Educate adolescents that this vaccine prevents only one sexually transmitted infection.
Influenza (IIV or LAIV)			
Type: Inactivated (IIV), or live attenuated (LAIV) for intranasal (IN) use ***Route:*** IM (all ages), IN (2 years and older) ***Dosage:*** 0.25 mL in infants 6–35 months, 0.5 mL starting at 3 years for IIV; 0.2 mL for LAIV ***Age(s) given:*** Annually in the fall, beginning at 6 months of age; then annually. Children under age 9 years receiving IIV or LAIV for the first time should receive a second dose 4 weeks later (AAP, 2015, p. 483). ***Storage:*** ***IIV:*** Refrigerate, do not use if frozen. ***LAIV:*** Keep frozen. May thaw and refrigerate for 24 hr before use.	***Common after IIV:*** Soreness at injection site, fever, aches ***Common after LAIV:*** Runny nose or nasal congestion, decreased appetite, irritability, sore throat, fever	***IIV and LAIV:*** Severe allergic reaction to eggs or prior vaccine dose, such as anaphylaxis ***LAIV:*** Contraindicated in children less than 2 years old with immunosuppression, asthma or wheezing episode in prior 12 months, or receiving an aspirin-containing product. ***Precautions:*** ***LAIV:*** Postpone vaccine when child has nasal congestion. ***IIV:*** May be given with minor illness, with or without fever. Give IIV if close contact with a severely immunocompromised person.	• Thawed LAIV is pale yellow, clear to slightly cloudy. • Split LAIV dose with a dose divider clip. Administer while child is sitting upright. Insert the tip of the sprayer inside each nostril and depress the plunger. • Reimmunize with 1 dose each year as immunity wanes, and vaccines are modified to include the new season's viruses. • If the child has received at least 2 doses of IIV since July 2010, only 1 annual dose is needed (Grohskopf et al., 2014).

(*continued*)

TABLE 16–1 Pediatric Vaccines (*continued*)

VACCINE TYPE	SIDE EFFECTS	CONTRAINDICATIONS	NURSING CONSIDERATIONS
Measles, Mumps, Rubella (MMR)			
Type: Live attenuated ***Dosage:*** 0.5 mL, subcutaneously (SQ) ***Age(s) given:*** 12–15 months; 4–6 years (2 doses) Give MMR and varicella vaccines on the same day or at least 4 weeks apart. ***Storage:*** Freeze or refrigerate vaccine before reconstitution. When reconstituted, keep refrigerated and away from light; discard if unused within 8 hr. Diluent is stored at room temperature or in a refrigerator; do not freeze.	***Common:*** Fever 6–12 days after immunization; redness or pain at injection site; noncontagious rash; joint pain ***Serious:*** Allergic reaction or anaphylaxis; febrile seizure; meningitis (usually mild); encephalopathy; thrombocytopenia purpura; and rare cases of coma and permanent brain damage Children, ages 12–23 months, receiving the combined MMR and varicella vaccine have an increased risk of febrile seizures compared to children receiving MMR as separate vaccines (CDC, 2014g).	Prior anaphylactic reaction to neomycin Severe allergic reaction to prior vaccine dose or vaccine component Pregnancy Severe immunodeficiency due to malignancy, congenital immunodeficiency disease, long-term immunosuppressive therapy, or child with HIV infection ***Precautions and deferral:*** Receipt of immune globulin or blood product in last 3–11 months. History of thrombocytopenia or thrombocytopenic purpura Moderate or severe acute illness with or without fever Personal or family history of seizures may increase risk of febrile seizures after immunization (McLean, Fiebelkorn, Temte, et al., 2013).	• Ask about immune suppression. • Reconstituted vaccine is a clear, yellow solution. • Give entire contents of reconstituted vial even if more than 0.5 mL. • May give to a child with an egg allergy (AAP, 2015, p. 541). • Give to children with HIV unless severely immunocompromised. • Give tuberculosis (TB) test at same time as MMR or 4–6 weeks later. • Educate adolescent girls to avoid pregnancy for 28 days after immunization.
Meningococcal Tetravalent Conjugate (MenACWY-D, MenACWY-CRM)			
Type: Conjugate ***Dosage:*** 0.5 mL, IM ***Age(s) given:*** 11–12 years, and booster dose 16–18 years MenACWY-CRM may be given to high-risk children (2 months and older). Infants under 7 months get 4 doses (2, 4, 6, and 12 months); older children get 2 doses, with second dose 3 months later or after 12 months of age (MacNeil et al., 2014). ***Storage:*** Refrigerate until used, do not freeze.	***Common:*** Swelling and pain at injection site, irritability, headache, fatigue, anorexia, and diarrhea	Severe allergic reaction (e.g., anaphylaxis) after prior dose or to a vaccine component (e.g., diphtheria toxoid) ***Precautions:*** Previous history of Guillain-Barré syndrome, unless at high risk for meningococcal disease	• Protect vaccine from light. • Verify that correct vaccine licensed for infants and children less than 24 months of age is used. • Give a booster dose to children 2–6 years old with immunosuppression 3 years after first dose for children 2–6 years and then every 5 years. • Give a booster dose to children 7 years and older with immunosuppression 5 years after first dose and then every 5 years (AAP, 2015, p. 555).
Pneumococcal Conjugate (PCV13)			
Type: Conjugate ***Dosage:*** 0.5 mL, IM ***Age(s) given:*** 2, 4, 6, 12–15 months ***Storage:*** Refrigerate, do not freeze.	***Common:*** Pain, redness, swelling, induration at injection site; fever; irritability, decreased appetite, increased or decreased sleep ***Severe:*** Allergic reaction or anaphylaxis	Severe allergic reaction (e.g., anaphylaxis) after a prior dose of PCV7, PCV13, or vaccine containing diphtheria toxoid, or a component of one of the listed vaccines ***Precautions and deferral:*** Moderate or severe acute illness with or without fever	• Clear, colorless, or slightly opalescent liquid. • Give a supplemental dose using PCV13 if a child 6–18 years is at risk for invasive pneumococcal disease who also received PPSV23 (AAP, 2015, p. 635).

VACCINE TYPE	SIDE EFFECTS	CONTRAINDICATIONS	NURSING CONSIDERATIONS
Poliovirus Vaccine (IPV)			
Type: Inactivated ***Dosage:*** 0.5 mL, subcutaneously or IM, follow guidance for brand used ***Age(s) given:*** 2, 4, 12–18 months; 4–6 years (4 doses) ***Storage:*** Refrigerate, do not freeze.	***Common:*** Swelling and tenderness, irritability, tiredness ***Serious:*** Allergic reaction or anaphylaxis	Severe allergic reaction, e.g., anaphylaxis, after prior dose or to vaccine components (neomycin, streptomycin, polymyxin B) ***Precautions and deferral:*** Pregnancy Moderate or severe acute illness with or without fever	• Ask about an allergy to the antibiotic contained in the specific IPV product available. • Clear, colorless suspension. Do not use if it contains particulate matter, becomes cloudy, or changes color.
Rotavirus Vaccine (RV1, RV5)			
Type: Live ***Dosage:*** 1 mL or 2 mL, oral ***Age(s) given:*** RV1 at 2 and 4 months (2 doses); RV5 at 2, 4, and 6 months (3 doses); all 3 doses of vaccine should be completed by 8 months of age. Complete the series with the same vaccine. ***Storage:*** Refrigerate, do not freeze.	***Common:*** Irritability, cough, runny nose, loss of appetite, vomiting ***Severe:*** Potential increased risk for intussusception	Severe allergic reaction to a previous dose or to a vaccine component Severe combined immunodeficiency disease Uncorrected gastrointestinal malformation that puts infant at risk for intussusception History of intussusception ***Precautions and deferral:*** Altered immunosuppression Moderate or severe acute illness with or without fever, including diarrhea and vomiting Preexisting chronic gastrointestinal disease Spina bifida or bladder exstrophy	• Pale yellow clear liquid. Protect vaccine from light. • Ask about contacts that might have immunodeficiency; viral shedding is known to occur. • Squeeze the liquid into the infant's mouth toward the inner cheek until the dosing tube is empty. • RV1 applicator has latex; RV5 applicator is latex-free. • Do not repeat the dose if the infant spits out, vomits, or regurgitates during or after the dose. • There are no food or liquid restrictions before or after vaccine.
Varicella Virus Vaccine			
Type: Live attenuated ***Dosage:*** 0.5 mL, subcutaneously ***Age(s) given:*** 12–18 months, 4–6 years May be given in combined vaccine with MMR. ***Storage:*** Keep frozen at 5°F (–15°C) or colder. May be stored for up to 72 hr in refrigerator prior to reconstitution. Diluents kept at room temperature. Once reconstituted, use vaccine within 30 min or discard.	***Common:*** Pain or redness at injection site; fever; a vaccine-related rash (2–5 maculopapular or vesicular lesions may occur 5–26 days after injection). ***Severe:*** Allergic reaction or anaphylaxis; rare cases of encephalitis, pneumonia, erythema multiforme, Stevens-Johnson syndrome, thrombocytopenia, seizure, and Guillain-Barré syndrome	Severe allergic reaction (e.g., anaphylaxis) after a prior dose or to a vaccine component (e.g., neomycin or gelatin). Known severe immunodeficiency due to malignancy, chemotherapy, congenital immunodeficiency disorder, long-term immunosuppressive therapy, or clients with HIV infection who are severely immunocompromised Pregnancy Active untreated tuberculosis ***Precautions and deferral:*** Receipt of blood products or immune globulin within past 3–11 months Moderate or severe acute illness with or without fever	• Ask if child is immunodeficient or has an allergy to a vaccine component. • Clear, colorless to pale yellow liquid when reconstituted. • Give the entire contents of the vial even if more than 0.5 mL. • Instruct adolescent girls of childbearing age to avoid pregnancy for 3 months after immunization. • Antiviral agents should not be used 1 day before or for 21 days after vaccine. • Avoid exposure to immunodeficient persons for 6 weeks after vaccinated.

Clinical Manifestations

Children have a variety of reactions to the antigens in different vaccines, and those reactions occur because of the child's immune system response. Common local reactions at the injection site include erythema, swelling, pain, and induration. Systemic reactions such as fever, fussiness or irritability, malaise, and anorexia may occur. A rash or arthralgia may occur with some vaccines. Highly anxious adolescents may have syncope or a vasovagal reaction within 15 minutes of immunization, leading to fall-related injuries (American Academy of Pediatrics [AAP] Committee on Infectious Disease, 2015, p. 26–27).

Allergic reactions to vaccines occur occasionally, such as a wheal and urticaria, within minutes to hours after the injection. A severe local allergic reaction is manifested by warmth, erythema, edema, petechiae, or ulceration occurring 2 to 8 hours after vaccination. A non–life-threatening systemic allergic reaction, such as generalized urticaria or transient petechiae, may occur within minutes. Anaphylaxis, a life-threatening reaction manifested by hypotension, generalized urticaria, angioedema, and laryngeal edema, rarely occurs with any vaccine. Allergic reactions are most often associated with vaccine components such as eggs, gelatin, yeast, and neomycin (AAP, 2015, pp. 54–56). See Table 16–1 for potential vaccine allergies.

Collaborative Care

Vaccines are recommended for administration at specific ages and intervals. Timing for first immunizations is determined by the age at which **transplacental immunity** (passive immunity transferred from mother to infant) decreases or disappears, and the infant or child develops the ability to make antibodies in response to the vaccine. Scientists continue to study the duration of protection from vaccines. Many vaccines are repeated at a later age to boost immunity.

Clinical Tip

Make every effort to stay current on immunization guidelines and information about vaccines, safe administration, adverse effects, and so on. Major resources provide more extensive information about immunization schedules and specific vaccines, as well as infectious and communicable diseases. The American Academy of Pediatrics' *Red Book: Report of the Committee on Infectious Diseases* is updated about every 3 years. Another resource is *Epidemiology and Prevention of Vaccine-Preventable Diseases*, commonly called the *Pink Book*, published by the Public Health Foundation, which has comprehensive information on communicable diseases and vaccines. The revised immunization schedule is published each January in several pediatric medical and nursing journals. The Centers for Disease Control and Prevention (CDC) maintains a website with detailed information about immunizations, the recommended vaccine schedule, and infectious and communicable diseases.

IMMUNIZATION SCHEDULES

The recommended immunization schedule is updated at least annually to reflect new vaccine information. The Advisory Committee on Immunization Practices (ACIP) of the Centers for Disease Control and Prevention (CDC), the American Academy of Pediatrics (AAP), and the American Academy of Family Practitioners (AAFP) collaborate to provide a uniform recommended schedule. See Figure 16–2 for the 2016 recommendations for vaccines that all children should receive. Schedules and recommendations vary for children who begin immunizations later in childhood or need catch-up doses.

Children with **asplenia** (loss of the spleen due to surgery or nonfunctioning due to sickle cell disease) are at higher risk for invasive pneumococcal and meningococcal infections. After completion of the PCV13 series, these children should receive pneumococcal polysaccharide vaccine (PPSV23) beginning at age 24 months. A second dose is given 5 years later. Some children who are American Indians or Alaska Natives living in areas of increased incidence of invasive pneumococcal disease may also be given PPSV23 (AAP, 2015, p. 92). See Table 16–1 for MCV4 guidelines.

Healthy People 2020

(IID-7) Achieve and maintain effective vaccination coverage levels for universally recommended vaccines among young children

(IID-10) Maintain vaccination coverage levels for children in kindergarten

(IID-11) Increase routine vaccination coverage levels for adolescents

IMPROVING IMMUNIZATION RATES

The effort to increase the numbers of children protected from vaccine-preventable diseases and to monitor immunization status is a national public health initiative.

For children between 19 and 35 months of age in 2014, the *Healthy People 2020* goal of 90% of children in this age group immunized with these vaccines—three IPV, one MMR, three HepB, and one varicella—was achieved. The goal was not achieved for full immunization of DTap, Hib, PCV, rotavirus, and HepA. Less than 1% of children received no vaccines. Variations were found by racial and ethnic groups and family income level (Hill, Elam-Evans, Yankey, et al., 2015). In 2014, adolescents between 13 and 17 years of age were found to have the following rates of immunization for recommended vaccines: one Tdap (87.9%), one MCV4 (79.3%), second MMR (90.7%), three HB (91.4%), second varicella or disease (85.0%), and three HPV (in females, 39.7%, and in males, 21.6%) (Reagan-Steiner, Yankey, Jeyarajah, et al., 2015). Increasing the immunization rate of adolescents has many challenges.

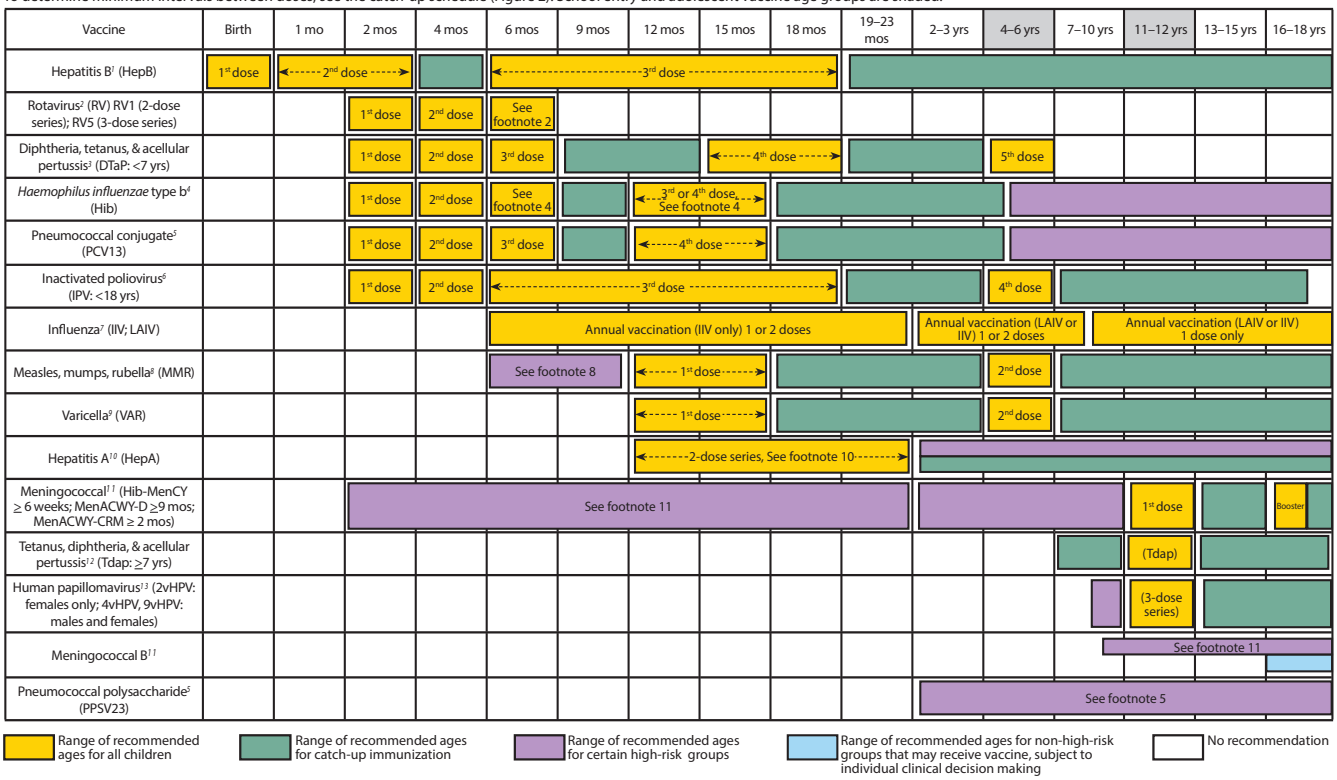
Lower immunization rates are often associated with economic factors, limited access to health care, lack of primary care at hours convenient for working parents, inadequate education about the importance of immunization, and cultural or religious prohibitions. The federal Vaccines for Children program provides free vaccines for qualified children and adolescents less than 19 years of age and has resolved some of the economic factors associated with vaccine coverage. However, the cost of vaccines, approximately $2575 for all approved vaccines for fully immunizing a child through the adolescent years in 2015, may be a barrier for children with private health insurance whose parents must co-pay (CDC, 2015a).

An increasing number of parents are choosing not to immunize their children for philosophical, religious, or other reasons, such as (Hendrix et al., 2014):

- Belief that vaccine-preventable diseases are not dangerous, and they occur rarely today
- Concerns that the frequency and number of vaccines to be administered cause pain and may overwhelm an infant's immune system

A. Recommended immunization schedule for persons aged 0 through 18 years – United States, 2016.
(FOR THOSE WHO FALL BEHIND OR START LATE, SEE THE CATCH-UP SCHEDULE [FIGURE 2]).

These recommendations must be read with the footnotes that follow. For those who fall behind or start late, provide catch-up vaccination at the earliest opportunity as indicated by the green bars in Figure 1. To determine minimum intervals between doses, see the catch-up schedule (Figure 2). School entry and adolescent vaccine age groups are shaded.



This schedule includes recommendations in effect as of January 1, 2016. Any dose not administered at the recommended age should be administered at a subsequent visit, when indicated and feasible. The use of a combination vaccine generally is preferred over separate injections of its equivalent component vaccines. Vaccination providers should consult the relevant Advisory Committee on Immunization Practices (ACIP) statement for detailed recommendations, available online at http://www.cdc.gov/vaccines/hcp/acip-recs/index.html. Clinically significant adverse events that follow vaccination should be reported to the Vaccine Adverse Event Reporting System (VAERS) online (http://www.vaers.hhs.gov) or by telephone (800-822-7967). Suspected cases of vaccine-preventable diseases should be reported to the state or local health department. Additional information, including precautions and contraindications for vaccination, is available from CDC online (http://www.cdc.gov/vaccines/recs/vac-admin/contraindications.htm) or by telephone (800-CDC-INFO [800-232-4636]).

This schedule is approved by the Advisory Committee on Immunization Practices (http//www.cdc.gov/vaccines/acip), the American Academy of Pediatrics (http://www.aap.org), the American Academy of Family Physicians (http://www.aafp.org), and the American College of Obstetricians and Gynecologists (http://www.acog.org).

NOTE: The above recommendations must be read along with the footnotes of this schedule. See http://www.cdc.gov/vaccines/schedules/index.html.

Figure 16–2 ***A,*** **Recommended immunization schedule for children 0 to 18 years, United States, 2016. For further guidance on the vaccines listed see http://www.cdc.gov/vaccines/hcp/acip-recs/index.html.**

- A vaccine's potential harm to the child because of the amount of its chemical and biologic content and its side effects
- Concerns that vaccines are related to autism
- Mistrust in healthcare provider recommendations

Other parents are selecting an alternate immunization schedule to delay or space out vaccines, such as the Sears Alternative Vaccine Schedule. However, this approach is not supported by evidence or public health officials.

See Table 16–2 for common misconceptions some parents have about vaccines and vaccine safety information. Increasing immunization rates of children whose parents are hesitant is a challenge. See *Evidence-Based Practice: Immunization Challenges*.

VACCINE INJURY COMPENSATION

Vaccines are tested for safety before being licensed by the U.S. Food and Drug Administration; however, serious vaccine reactions occur in rare instances. When a link between a child's immunization and a serious adverse reaction is identified, the National Vaccine Injury Compensation Program provides compensation for the family. The Vaccine Adverse Event Reporting System (VAERS) was established in 1988 to track serious vaccine reactions. See Table 16–3 for the serious reactions specific to each vaccine that are eligible for compensation.

Nursing Management

For the Child Receiving Immunizations

Nursing Assessment and Diagnosis

Nurses are responsible for reviewing a child's health record to determine whether the child needs vaccines. Identify any potential contraindications to vaccines by asking the following:

- Has the child had a serious reaction to any vaccine? Has the child had any vaccines in the last 4 weeks?
- Are there allergies to any vaccine components (e.g., eggs, neomycin, gelatin, or yeast) or latex?
- Does the child have a serious medical condition (seizures, cancer, HIV infection, immune diseases, blood disorder, asthma) or wheezing in the past 12 months?
- Has the child received any blood products, immune globulin, or any antiviral drugs in the past year?

B. Catch-up immunization schedule for persons aged 4 months through 18 years who start late or who are more than 1 month behind — United States, 2016.
The figure below provides catch-up schedules and minimum intervals between doses for children whose vaccinations have been delayed. A vaccine series does not need to be restarted, regardless of the time that has elapsed between doses. Use the section appropriate for the child's age. Always use this table in conjunction with Figure 1 and the footnotes that follow.

Vaccine	Minimum Age for Dose 1	Minimum Interval Between Doses			
		Dose 1 to Dose 2	Dose 2 to Dose 3	Dose 3 to Dose 4	Dose 4 to Dose 5
Children age 4 months through 6 years					
Hepatitis B[1]	Birth	4 weeks	8 weeks *and* at least 16 weeks after first dose. Minimum age for the final dose is 24 weeks.		
Rotavirus[2]	6 weeks	4 weeks	4 weeks[2]		
Diphtheria, tetanus, and acellular pertussis[3]	6 weeks	4 weeks	4 weeks	6 months	6 months[3]
Haemophilus influenzae type b[4]	6 weeks	4 weeks if first dose was administered before the 1st birthday. 8 weeks (as final dose) if first dose was administered at age 12 through 14 months. No further doses needed if first dose was administered at age 15 months or older.	4 weeks[4] if current age is younger than 12 months **and** first dose was administered at younger than age 7 months, **and** at least 1 previous dose was PRP-T (ActHib, Pentacel) or unknown. 8 weeks *and* age 12 through 59 months (as final dose)[4] • if current age is younger than 12 months **and** first dose was administered at age 7 through 11 months (wait until at least 12 months old); OR • if current age is 12 through 59 months **and** first dose was administered before the 1st birthday, **and** second dose administered at younger than 15 months; OR • if both doses were PRP-OMP (PedvaxHIB; Comvax) **and** were administered before the 1st birthday (wait until at least 12 months old). No further doses needed if previous dose was administered at age 15 months or older.	8 weeks (as final dose) This dose only necessary for children age 12 through 59 months who received 3 doses before the 1st birthday.	
Pneumococcal[5]	6 weeks	4 weeks if first dose administered before the 1st birthday. 8 weeks (as final dose for healthy children) if first dose was administered at the 1st birthday or after. No further doses needed for healthy children if first dose administered at age 24 months or older.	4 weeks if current age is younger than 12 months and previous dose given at <7months old. 8 weeks (as final dose for healthy children) if previous dose given between 7-11 months (wait until at least 12 months old); OR if current age is 12 months or older and at least 1 dose was given before age 12 months. No further doses needed for healthy children if previous dose administered at age 24 months or older.	8 weeks (as final dose) This dose only necessary for children aged 12 through 59 months who received 3 doses before age 12 months or for children at high risk who received 3 doses at any age.	
Inactivated poliovirus[6]	6 weeks	4 weeks[6]	4 weeks[6]	6 months[6] (minimum age 4 years for final dose).	
Measles, mumps, rubella[8]	12 months	4 weeks			
Varicella[9]	12 months	3 months			
Hepatitis A[10]	12 months	6 months			
Meningococcal[11] (Hib-MenCY ≥ 6 weeks; MenACWY-D ≥9 mos; MenACWY-CRM ≥ 2 mos)	6 weeks	8 weeks[11]	See footnote 11	See footnote 11	
Children and adolescents age 7 through 18 years					
Meningococcal[11] (Hib-MenCY ≥ 6 weeks; MenACWY-D ≥9 mos; MenACWY-CRM ≥ 2 mos)	Not Applicable (N/A)	8 weeks[11]			
Tetanus, diphtheria; tetanus, diphtheria, and acellular pertussis[12]	7 years[12]	4 weeks	4 weeks if first dose of DTaP/DT was administered before the 1st birthday. 6 months (as final dose) if first dose of DTaP/DT or Tdap/Td was administered at or after the 1st birthday.	6 months if first dose of DTaP/DT was administered before the 1st birthday.	
Human papillomavirus[13]	9 years	Routine dosing intervals are recommended.[13]			
Hepatitis A[10]	N/A	6 months			
Hepatitis B[1]	N/A	4 weeks	8 weeks **and** at least 16 weeks after first dose.		
Inactivated poliovirus[6]	N/A	4 weeks	4 weeks[6]	6 months[6]	
Measles, mumps, rubella[8]	N/A	4 weeks			
Varicella[9]	N/A	3 months if younger than age 13 years. 4 weeks if age 13 years or older.			

NOTE: The above recommendations must be read along with the footnotes of this schedule. See http://www.cdc.gov/vaccines/schedules/index.html.

Figure 16–2 (*Continued*) ***B*, Catch-up immunization schedule for children 4 months to 18 years, United States, 2016. For further guidance on the vaccines listed see http://www.cdc.gov/vaccines/hcp/acip-recs/index.html**

SOURCE: Centers for Disease Control (CDC).

- Has the child taken cortisone, prednisone, other steroids, or anticancer drugs or had radiation treatments in the past 3 months?
- Is the female adolescent possibly pregnant now, or will she be in the next month?

Healthcare providers miss many opportunities to immunize children. Assess the immunization status of children (and siblings present) during all healthcare visits and hospitalizations and in schools. Use the most current immunization schedule to identify needed vaccines. When a child needs immunizations, determine the best combination of vaccines to give at this visit to better protect the child. However, make sure the appropriate interval has occurred between vaccine dosages, using the catch-up vaccine schedule. Ways to reduce the number of missed opportunities for full immunization of children include the following:

- Place a reminder in the child's health record to alert health professionals about the child's need for immunizations. Establish a system to send parents a reminder when the child's immunizations are due or overdue.

SAFETY ALERT!

Immune globulin, blood products, and immunosuppressive agents inhibit the child's response to live virus vaccines (MMR, varicella), so ask parents about any recent administration of these products. When possible, administer inactivated vaccines 2 or more weeks before and live virus vaccines 4 or more weeks before immunosuppressive therapy is begun (Rubin et al., 2013). Refer to the most current guidelines from the Centers for Disease Control and Prevention's Advisory Committee on Immunization Practices (ACIP) to identify the correct interval (3 to 11 months) between the administration of the blood product, immune globulin, or completion of immunosuppression therapy and administration of a live virus vaccine (Kroger, Sumaya, Pickering, et al., 2011.

If immune globulin or blood products were given 14 days before or up to several months following a vaccine, readminister the vaccine after the period specified by the CDC, unless serologic testing determines that the child developed adequate serum antibodies (AAP, 2015, pp. 38–39).

Text continues on page 345

TABLE 16–2 Common Misconceptions About Vaccines and Correct Information

COMMON MISCONCEPTIONS	CORRECT VACCINE INFORMATION
Vaccine-preventable diseases have been eliminated.	The incidence of vaccine-preventable diseases is low in the United States, but these diseases occur elsewhere in the world. Unvaccinated travelers have reintroduced diseases from a country or a U.S. community where the disease exists. Recent outbreaks of measles have been linked to unimmunized travelers who became infected in one of 18 countries (Gastañaduy et al., 2014). Children with lowered immune status (e.g., treatment for cancer) are at higher risk for exposure to infection because of lowered herd immunity. **Herd immunity** is the protection provided by a large group of persons who have immunity to a disease and indirectly protect others without immunity by reducing the risk for exposure and infection.
Immunization weakens the immune system. Multiple vaccines overload the immune system and cause harmful effects.	Vaccines use the body's immune system to prevent a future infection. Infants are capable of developing protective immune responses to multiple vaccines simultaneously. The number of antigens in these vaccines is substantially fewer than the immune challenges associated with daily environmental exposures (DeStefano, Price, & Weintraub, 2013).
Thimerosal use in vaccines may cause mercury poisoning.	Thimerosal, a bacteriostatic agent that contains ethyl mercury, previously was used to sterilize vaccines in multidose vials. Because of concerns about mercury poisoning and related nerve and brain damage, thimerosal has been eliminated from all but the influenza vaccine. A thimerosal-free influenza vaccine is available for children (AAP, 2015, p. 18).
It would be better to let the child get the disease than get immunized.	Most parents have never seen these diseases and do not understand how dangerous they may be, sometimes leading to hospitalization, disability, and even death. Infected children can spread the infection to pregnant women, exposing the fetus, and to infants and children with serious medical conditions.
Vaccines do not work; children still get the disease.	No vaccine is 100% effective, and immunity does wane over time, leading to the need for a booster dose.

EVIDENCE-BASED PRACTICE | Immunization Challenges

Clinical Question

What strategies are needed to increase acceptance of vaccines in hesitant parents?

The Evidence

A randomized trial study using web-based interactions with 1759 parents investigated the effectiveness of public health messages about the safety of the MMR vaccine or the danger of measles, mumps, and rubella diseases. The four messages integrated CDC vaccine language and included (1) corrected misinformation that vaccines cause autism, (2) presented information on disease risks, (3) a story about a child hospitalized with measles, and (4) photographs of infected children to emphasize the disease risks. The outcome measure was parent intention to give the MMR vaccine to a future child. None of the messages increased parents' intent to immunize a future child with the MMR vaccine. Provaccine messages were least effective in parents with negative attitudes about vaccines. In some cases, messages increased beliefs about MMR side effects (Nyhan, Reifler, Richey, et al., 2014).

A randomized trial survey of 802 parents of infants less than 12 months of age were presented four vaccine messages to identify which one increased a parent's intent to immunize their child with the MMR vaccine. The Vaccine Information Sheet (VIS) was the control message. The other three messages included the VIS plus (1) the benefits of the vaccine to the child, (2) the benefits of immunizing the child to society, and (3) the benefits of the vaccine to the child plus society. Parents had a significantly higher intent to immunize their infant when the benefits of the vaccine to the child or the benefits to the child plus society messages were used when compared to the control message (Hendrix et al., 2014).

A study using data from the National Immunization Survey for Teens focused on reasons parents gave for adolescents who were not up-to-date on Tdap/Td, MCV4, and HPV as not receiving the vaccines. The reasons given for Tdap/Td and MCV4 were the same: not recommended by a healthcare provider, not needed, lack of knowledge, or don't know. The HPV vaccine was not accepted more commonly for these reasons: not sexually active, not needed or not necessary, and vaccine safety concerns (Darden et al., 2013).

Best Practice

With the increased trend in undervaccination of children, efforts have shifted to finding messages that will increase a parent's acceptance of vaccines. One study identified that a higher acceptance occurred when the discussion with the parent about a vaccine focused on the benefit for their child rather than societal benefits. Exposure to viruses and bacteria causing vaccine-preventable diseases is unpredictable, so vaccines are given before an exposure. For adolescents, it is important to emphasize the reduced risk of cervical cancer that may occur 20 to 40 years after exposure to HPV. Since the virus is acquired during sexual activity, it is important for adolescents to receive the vaccine before sexual activity begins.

Clinical Reasoning

Think about some specific benefits to a child for each of the vaccines administered (e.g., no discomfort due to the disease, fewer days of school missed, fewer days the parents have to miss work because of a sick child). When in a clinical setting, identify and include the specific benefits for the child for each vaccine in the education provided to parents when seeking consent for vaccine administration.

TABLE 16–3 National Vaccine Injury Act—Vaccine Injury Table

VACCINE	ILLNESS, DISABILITY, INJURY, OR CONDITION COVERED	TIME PERIOD FOR FIRST SYMPTOM OR MANIFESTATION OF ONSET OR OF SIGNIFICANT AGGRAVATION AFTER VACCINE ADMINISTRATION
Vaccines containing tetanus toxoid (e.g., DTaP, Tdap, DTP-Hib, DT, Td, or TT)	Anaphylaxis or anaphylactic shock	4 hr
	Bacterial neuritis	2–28 days
	Any acute complication or sequela (including death) of above events occurring in the specified time period	Not applicable
Vaccines containing whole cell pertussis bacteria, extracted or partial cell pertussis bacteria, or specific pertussis antigen(s) (e.g., DTaP, Tdap, DTP, P, DTP-Hib)	Anaphylaxis or anaphylactic shock	4 hr
	Encephalopathy (or encephalitis)	72 hr
	Any acute complication or sequela (including death) of above events occurring within the specified time period	Not applicable
Measles, mumps, rubella vaccine or any of its components (e.g., MMR, MR, M, R)	Anaphylaxis or anaphylactic shock	4 hr
	Encephalopathy (or encephalitis)	5–15 days
	Any acute complication or sequela (including death) of above events occurring within the specified time period	Not applicable
Vaccines containing rubella virus (e.g., MMR, MR, R)	Chronic arthritis	7–42 days
	Any acute complication or sequela (including death) of above events occurring within the specified time period	Not applicable
Vaccines containing measles virus (e.g., MMR, MR, M)	Thrombocytopenic purpura	7–30 days
	Vaccine strain measles viral infection in an immunodeficient recipient	6 months
	Any acute complication or sequela (including death) of above events occurring within the specified time period	Not applicable
Vaccines containing polio live virus (OPV)	Paralytic polio	
	• in a nonimmunodeficient recipient	30 days
	• in an immunodeficient recipient	6 months
	• in a vaccine-associated community case	Not applicable
	Vaccine-strain polio viral infection	
	• in a nonimmunodeficient recipient	30 days
	• in an immunodeficient recipient	6 months
	• in a vaccine-associated community case	Not applicable
	Any acute complication or sequela (including death) of above events	Not applicable
Vaccines containing polio inactivated virus (IPV)	Anaphylaxis or anaphylactic shock	4 hr
	Any acute complication or sequela (including death) of above events occurring within the specified time period	Not applicable
Hepatitis B vaccines	Anaphylaxis or anaphylactic shock	4 hr
	Any acute complication or sequela (including death) of above events occurring within the specified time period	No limit
Haemophilus influenzae type b polysaccharide conjugate vaccines	No condition specified	Not applicable
Hepatitis A vaccines	No condition specified	Not applicable
Varicella vaccine	No condition specified	Not applicable
Rotavirus vaccine	No condition specified	Not applicable
Pneumococcal conjugate vaccines	No condition specified	Not applicable
Meningococcal vaccines	No condition specified	Not applicable
Trivalent influenza vaccines	No condition specified	Not applicable
Human papillomavirus (HPV) vaccines	No condition specified	Not applicable
Any new vaccine recommended by the CDC for routine administration to children after publication by the Secretary of the Department of Health and Human Services of notice of coverage	No condition specified	Not applicable

Effective date: November 12, 2013. For guidance in further interpretation of this table, visit the website below.

Source: From Health Resources and Services Administration. (2013). *Vaccine injury table.* Retrieved from http://www.hrsa.gov/vaccinecompensation/vaccineinjurytable.pdf

- Give vaccines when the child has a minor illness, even with a low-grade fever and antibiotic treatment, or has a recent exposure to an infectious disease.
- Use combination vaccines (e.g., DTaP-HepB-IPV) to reduce the number of injections from 20 to 13 in the first 2 years (see Table 16–4).
- Give multiple vaccines at the same time, using separate syringes and injecting in separate sites. If using the same extremity, separate injection sites by an inch (AAP, 2015, p. 36).
- Give medically stable low–birth-weight infants all vaccines appropriate for chronologic age as full-term infants. Use the full dose (AAP, 2015, pp. 68–69).
- Give the vaccine even when a prior dose caused a local reaction or a family member had an adverse response.

The accompanying *Nursing Care Plan* explores two potential nursing diagnoses that apply to the child needing immunizations. Additional nursing diagnoses may include the following (NANDA-I © 2014):

- ***Skin Integrity, Risk for Impaired,*** related to vaccine response
- ***Health Maintenance, Ineffective,*** related to philosophical beliefs regarding routine immunization
- ***Anxiety*** related to fear of needles

Planning and Implementation

Nursing management focuses on protecting the potency of vaccines, being a strong advocate for immunization, educating parents about immunizations and possible side effects, addressing their fears about possible reactions, obtaining consent, and reporting adverse reactions.

PROTECT VACCINE POTENCY

Take special care to ensure vaccine potency, so all children develop adequate immune response (CDC, 2014b).

- Store vaccines properly in the refrigerator or freezer (i.e., separate doors for refrigerator and freezer, storage conditions should be adequate: Refrigeration: 35°F to 46°F [2°C to 8°C]; Freezer: 5°F [–15°C] or lower as stated in vaccine package inserts).
- Keep jugs of water in the refrigerator and trays of ice in the freezer to help maintain a consistent temperature.
- Store the vaccines on the middle shelves of the units, 2 to 3 in. away from the walls, with space for air to circulate between boxes; place older vaccines in the front.
- Check the refrigerator and freezer temperatures twice daily and record the temperatures on a log or use an automatic temperature measurement system.
- Make an emergency plan for safe storage of vaccines in case of a power outage or natural disaster.

TABLE 16–4 Combination Vaccines

VACCINE NAME	VACCINE COMPONENTS	AGES USED
Comvax	Hib and HepB	2, 4, and 12–15 months of age, 3 doses
TriHIBit	DTaP and Hib	15–18 months, fourth dose of Hib and DTaP series
Twinrix	HepA and HepB	18 years and older
Pediarix	DTaP, HepB, and IPV	2, 4, and 6 months of age, 3 doses
ProQuad	MMR and Varicella	12–15 months of age, and 4–6 years of age
Kinrix	DTaP and IPV	4–6 years, fifth dose of DTaP and fourth dose of IPV
Pentacel	DTaP, IPV, and Hib	2, 4, 6, and 15–18 months of age, 4 doses
MenHibrix	Hib, Meningococcal CY serotypes	2, 4, 6, and 12–15 months of age

Source: Adapted from Kroger, A. T., Sumaya, C. V., Pickering, L. K., & Atkinson, W. L. (2011). General recommendations on immunization: Recommendations of the Advisory Committee on Immunization Practices (ACIP). *Morbidity and Mortality Weekly Report*, *60*(2), 37; MacNeil, J. R., Rubin, L., McNamara, L., Briere, E. C., Clark, T. A., & Cohn, A. C. (2014). Use of MenACWY-CRM vaccine in children aged 2 through 23 months at increased risk for meningococcal disease: Recommendations of the Advisory Committee on Immunization Practices, 2013. *Morbidity and Mortality Weekly Report*, 63(24), 527–530.

OBTAIN CONSENT

Federal legislation requires written consent before administering a vaccine. The nurse often has the responsibility to inform the child's parents or legal guardian, and supply the most current Vaccine Information Statement (VIS) for each vaccine to be given, a requirement of the National Vaccine Injury Act.

Explain the risks and benefits of each vaccine and common local reactions. Answer all the parents' questions. Parents may have heard sensational stories about vaccines, and correct information is needed to help them make informed decisions.

Developing Cultural Competence **Vaccine Information Statements (VIS)**

Consider literacy and reading level when giving a VIS to a parent. The VIS is written at a sixth-grade level, but parents may have poor literacy. The VIS has been translated into 40 languages, and these are available through the CDC website. Ask rather than assume the parent can read the preferred spoken language. It is acceptable to read the VIS to parents and make sure that they understand the information.

Nursing Care Plan: The Child Needing Immunizations

1. Nursing Diagnosis: *Infection, Risk for,* related to incomplete immunizations for age (NANDA-I © 2014)

GOAL: The child will become adequately protected from disease-preventable illnesses.

INTERVENTION	RATIONALE
• Review the child's immunization record for needed vaccines at each healthcare visit.	• Children who need vaccines can be identified.
• Identify all due vaccines that can be provided simultaneously.	• Multiple vaccines given at the same visit more adequately protect the child.
• Identify potential contraindications to needed vaccines. Review past reactions to vaccines.	• Identifying contraindications and past reactions reduces the risk for adverse reactions to vaccines.

EXPECTED OUTCOME: Child will be adequately protected for age from vaccine-preventable illnesses.

2. Nursing Diagnosis: *Health Management, Readiness for Enhanced* (NANDA-I © 2014)

GOAL: Parents will sign consent for vaccines to be given.

INTERVENTION	RATIONALE
• Educate the parents and adolescents about the need for specific vaccines and the risk if not given. Obtain signed consent before giving vaccines.	• Informed consent is required for all treatments.

EXPECTED OUTCOME: Parent(s) will complete the consent forms, which are placed in the child's file.

GOAL: Parents and adolescents will state the side effects of vaccines given.

INTERVENTION	RATIONALE
• Review past reactions to vaccines and describe common potential reactions and why they occur.	• Parents should expect common reactions and know they indicate the child's body is building protection to the illness.
• Describe serious side effects that should be reported to the healthcare provider.	• Parents need to be prepared for potential serious side effects so they can obtain care if needed.

EXPECTED OUTCOME: Parents will report all serious side effects to the healthcare provider.

GOAL: Parents will manage common side effects of vaccines.

INTERVENTION	RATIONALE

• Teach parents general comfort measures for common side effects, for example:
  • Cool pack to tender leg
  • Acetaminophen or ibuprofen for fever and discomfort
  • Rocking and holding the infant
  • Gentle movement of affected extremity
	• Parents will know how to make the child more comfortable during the 24–48 hr after the vaccine is given.

EXPECTED OUTCOME: Child will be given comfort measures after vaccine administration.

Families Want to Know

Care of the Child After Immunizations

When a child receives an immunization, educate parents to observe for any reactions that might occur and call the child's healthcare provider if there is concern about any of the symptoms listed.

- Local pain, redness, and swelling are common. Use ice on the injection site to help reduce swelling and pain. Acetaminophen or ibuprofen may be given to reduce a fever and pain. The symptoms should disappear in a day or two.
- The child may have a fever, joint pain, muscle aches, or fatigue within hours to days after the vaccine is given. Give acetaminophen or ibuprofen for pain.
- With a mild allergic reaction to the vaccine, a few hives may be noted around the injection site.
- A severe allergic reaction is indicated by a flushed face; swelling of the face, mouth, or throat; wheezing or other difficulty breathing; shock (confusion, lack of movement or response, or unconsciousness); and abdominal cramping. Call 9-1-1 for emergency treatment. Have the child lie down with the legs raised higher than the level of the heart until the ambulance arrives to promote blood return to the vital organs.

When a parent refuses to accept a particular vaccine, have the parent sign an informed refusal document. If a disease outbreak occurs, the unimmunized child must be kept out of school or child care. See the section on fever, later in this chapter, for guidance on home care of the child with an infectious disease.

For each vaccine administered, the nurse is required to record the (1) month, day, and year of administration, (2) vaccine given, (3) manufacturer, (4) lot number and expiration date of the immunization given, (5) site and route of administration, and (6) name, title, and address of the person who administers the vaccine. Provide parents with a record of the child's immunizations, and enter the information on vaccines administered into the healthcare agency's official records.

Provide guidance for managing expected mild reactions at home (see *Families Want to Know: Care of the Child After Immunizations*). Provide information about the proper dose of acetaminophen or ibuprofen to give the child.

ADMINISTER VACCINES

Check the expiration of vaccines before use. Follow the manufacturer's directions for reconstituting vaccines and use the solution provided. Write the date and time on the bottle if it is a multidose vial. Reconstitute vaccines immediately before use as some have a short shelf life.

Use 1-in. needles rather than 5/8 in. (25 mm rather than 16 mm) for infants for IM injections to give the vaccine deep in the muscle mass. Stretch the skin to decrease the amount of subcutaneous tissue the needle must go through. Follow facility needle length guidelines for children of other ages. For vaccines given subcutaneously, select a 5/8-in. 23- to 25-gauge needle. Use the upper thigh in infants less than 12 months of age, and the upper outer triceps region for older children (Kroger et al., 2011).

SAFETY ALERT!

Adolescents who are extremely fearful of getting an injection are at a greater risk for fainting, syncope, or vasovagal response after a vaccine injection. Provide the injection when the adolescent is sitting or lying down. Observe the adolescent while sitting or lying down for 15 minutes to prevent secondary injury in case of syncope.

REDUCE PAIN AND ANXIETY

Make an effort to reduce the pain associated with vaccine injections, especially since infants and children must return for more injections. Give the appropriate immunizations to the child as efficiently as possible, while providing support to the child (Figure 16–3). Suggestions for pain management include the following techniques:

Figure 16–3 Give immunizations quickly and efficiently. Do not prolong the wait and let fear grow. The child will be anxious, especially if more than one injection must be given.

- Coach the parent to hold and talk with the child during the injections. Funny faces, a toy, or age-appropriate distraction might also help. Encourage parents to give comfort measures after the injection.
- Give infants up to 4 months of age 24% sucrose water to drink (e.g., Sweetease or mix 1 packet of table sugar with 10 mL of tap water) prior to the injection (see Chapter 15). Then allow the infant to suck on a pacifier or breastfeed during the injections.
- Apply pressure at the site for 10 seconds before the injection.
- Provide information about obtaining L-M-X4 (a topical anesthetic available without a prescription) prior to the next visit. Instruct parents how to apply L-M-X4 cream to one or more sites prior to the child's appointment. See Chapter 15 for information regarding use of L-M-X4.
- Spray the planned injection site with vapocoolant spray immediately before the injection, or spray it on a cotton ball and hold that against the skin.
- Have two providers each give an injection simultaneously in different extremities.

- Do not prolong the process of giving immunizations. Give the child honest answers that the needles will cause some pain.
- Let the child select the arm or leg for the injection and forms of distraction to promote coping.

PREPARE FOR EMERGENCIES

Be prepared for potential vaccine anaphylaxis even though it is a rare event. Keep epinephrine and resuscitation equipment immediately available. The dose for epinephrine (aqueous 1:1000) is 0.01 mL/kg per dose (maximum dose is 0.5 mL) intramuscularly. The dose can be repeated every 5 to 15 minutes in order to control symptoms and maintain blood pressure. When the child is stable, oral antihistamines and corticosteroids may be prescribed for an additional 24 to 48 hours (AAP, 2015, pp. 66–68).

Remember to report anaphylaxis and other severe reactions following immunization to the Vaccine Compensation Injury Program. See Table 16–3.

Evaluation

Expected outcomes of nursing care include the following:

- Parents are fully informed and give consent for immunizations.
- All vaccines appropriate for the child's age are given at each health visit.
- The parents are prepared to identify serious vaccine reactions and manage mild reactions at home.

Clinical Reasoning Immunizations

A 5-year-old girl, Lian, has accompanied her mother and 2-year-old brother Chang to the pediatric clinic. Lian's mother is concerned because Chang has had a fever of 38.3°C (101.0°F) for the past 3 days. Although Chang has visited this clinic several times in the past few months for health care, this is the first time Lian has come along.

When asked, Lian's mother says Lian had a healthcare visit about 2 years ago, but she does not know if she had all of her shots. In checking Lian's health records, the nurse notes that she needs DTaP, IPV, PCV13, MMR, varicella, and HepA vaccines. Chang needs MMR, varicella, HepA, and PCV13 vaccines.

Should Lian receive any of these vaccines today, even though her brother is ill? Which vaccines could be given during one visit? Should Chang receive any vaccines today?

Communicable Diseases in Children

Communicable diseases cause acute illnesses resulting from bacterial, viral, protozoan, or fungal organisms. Infants and children are more susceptible and develop communicable diseases more frequently than adults do. Active immunity to microorganisms does not occur until there is natural exposure or immunization that leads to antibody production.

The epidemiology, clinical manifestations, treatment, prevention, and nursing care of selected communicable diseases of childhood are described in Table 16–5. Infectious diseases transmitted by animal vectors are detailed in Table 16–6. See Chapter 26 for information on sexually transmitted infections, Chapter 19 for information about conjunctivitis, Chapter 20 for information on tuberculosis, and Chapter 25 for information on hepatitis and parasites.

Clinical Manifestations

The child with an infectious or communicable disease has a cluster of symptoms specific to the disease that appear at the end of the **incubation period**, the time interval between exposure and development of symptoms. Some diseases have a **prodrome**, the phase of early manifestations of the infection until the development of the overt clinical syndrome. Fever is the most common sign of communicable disease in infants and children. Other nonspecific signs are related to the specific disease and may include fatigue, malaise, weakness, decreased responsiveness or inability to concentrate, skin rash, poor appetite, vomiting, diarrhea, and body aches.

Developing Cultural Competence Disease Causation

In some cultures, infectious diseases are seen as punishment or the result of curses or evil spirits. For example, American Indians (e.g., Navajo) traditionally view illnesses as the result of disharmony or displeasing the spirits. They may not believe in the germ theory of disease causation (Purnell, 2014).

FEVER

Fever is an increased body temperature of 38.0°C (100.4°F) or higher taken by rectal or tympanic route, and 37.8°C (100.0°F) or higher by the oral or temporal route. The hypothalamus is the body's thermostat or control center for the regulation of body temperature (see *Pathophysiology Illustrated: Fever*). As blood circulates through the hypothalamus, the body is directed to conserve or release heat, depending on the temperature of the blood.

FEVER MANAGEMENT

A fever can be a beneficial physiologic response to infection, helping to slow the growth and reproduction of organisms that thrive at lower body temperatures. A fever decreases the serum levels of zinc, iron, and copper needed by bacteria for reproduction. It also encourages the body to shift to a metabolism that burns fat and proteins rather than glucose, which deprives bacteria of a food source (Huether, 2014). Fever is not inherently harmful until it reaches 41.0°C (105.9°F). Medical management may include postponing treatment of low-grade fevers (under 38.9°C [102.0°F]) to promote the body's natural defenses against an infection.

Fevers are often treated if they cause discomfort with acetaminophen or ibuprofen. Aspirin is no longer recommended for children because of its association with Reye syndrome (see Chapter 27). Antipyretics inhibit prostaglandin synthesis, which results in lowering of the body's temperature set point and reducing the fever.

Developing Cultural Competence Hot and Cold Therapy

Many Latino and Asian cultures subscribe to the hot and cold theory of disease causation. Fever, a hot condition, is treated by giving the ill person cold substances (either foods or medicines). Cold foods include dairy products, fresh vegetables, fruits, chicken, goat meat, and fish. Cold medicines include orange flower water, linden, and sage (Purnell, 2013). See Table 2–2, *Hot and Cold Conditions and Foods*.

Text continues on page 361

TABLE 16–5 Selected Infectious and Communicable Diseases in Children

DISEASE	CLINICAL MANIFESTATIONS	CLINICAL THERAPY	NURSING MANAGEMENT
CHICKENPOX (VARICELLA)[a,b]			
Causal agent: Varicella-zoster, human herpesvirus 3. ***Epidemiology:*** Humans are the source of infection. Peak occurrence is in the late fall, winter, and spring. Maternal antibodies disappear 2–3 months after birth. ***Transmission:*** Direct contact of the virus to the mucous membranes or conjunctiva primarily through airborne secretions and sometimes with lesion contact. ***Incubation period:*** 14–21 days. ***Period of communicability:*** Most contagious 1–2 days before the rash to shortly after onset of rash. Contagious until all lesions are crusted over. Contagious state may be prolonged after passive immunization or in immunodeficient children. Kasiap/Shutterstock	Acute onset of mild fever, malaise, anorexia, headache, mild abdominal pain, and irritability occurs before and with eruption. Begins as a macular rash that progresses to a papule, then clear fluid-filled vesicle before crusting. Rash erupts for 1–5 days, and up to 250–500 lesions of all stages may be present at any one time. Crusts may remain for 1–3 weeks. Lesions begin on the trunk, scalp, and face, and spread to the rest of the body. Mucous membranes may have ulcerative lesions. Mouth lesions may lead to decreased fluid intake. ***Complications:*** Complications are rare but can include secondary infection (cellulitis, local abscesses, sepsis, meningitis, encephalitis, pneumonia), thrombocytopenia, and Reye syndrome. Chickenpox can be fatal in newborns of infected mothers and immunocompromised children. Carefully monitor children undergoing chemotherapy, steroid treatment, or transplant therapy after exposure to the disease.	***Diagnostic testing:*** Polymerase chain reaction or direct fluorescent antibody testing of fluid from vesicle or scab. ***Medical management:*** Supportive care. IV acyclovir is used for immunocompromised clients and those on high-dose corticosteroids (AAP, 2015, p. 851). Give varicella-zoster immune globulin as soon as possible (within 10 days) to newborns of infected mothers, hospitalized premature neonates, and immunocompromised, unimmunized children (Marin, Bialek, & Seward, 2013). ***Prognosis:*** Most children recover fully. Children who are immunocompromised must be treated aggressively. ***Prevention:*** Varicella is vaccine preventable (see Table 16–1). The vaccine may be given within 72 hr after exposure to prevent or to significantly modify the disease. Wild virus (varicella strain not covered in the vaccine) cases occur in vaccinated children.	• Use airborne and contact precautions. • Isolate all hospitalized children with a recent exposure to varicella to protect newborns and immunocompromised clients. Nurses caring for the child should have documented immunity. • At home, isolate the child from susceptible individuals (medically fragile and immunocompromised children or adults, and women early in pregnancy). Notify the school or childcare facility of the child's illness. • Secondary cases are often more severe than the primary case. The child with atopic eczema or sunburn may have a more severe rash. • Give acetaminophen or ibuprofen to control fever. • Control itching with oral antihistamines, soothing oatmeal and Aveeno baths, or Caladryl lotion. • Keep the child's fingernails trimmed and clean. Place soft cotton mittens over the hands of young children when itching cannot be controlled. • Change bed linens frequently. • Reassure the child that the lesions are temporary and will go away. • Monitor for signs of complications (e.g., drowsiness, meningeal signs, respiratory distress, and dehydration). Disorientation and restlessness may indicate viral encephalitis. • Monitor for acyclovir side effects. Monitor renal function if the child has renal insufficiency.

(*continued*)

TABLE 16–5 Selected Infectious and Communicable Diseases in Children (*continued*)

DISEASE	CLINICAL MANIFESTATIONS	CLINICAL THERAPY	NURSING MANAGEMENT
DIPHTHERIA[a,b]			
Causal agent: *Corynebacterium diphtheriae.* ***Epidemiology:*** Occurs mostly in colder months in unimmunized and inadequately immunized children. Cases of cutaneous and wound diphtheria occur sporadically in the tropics. The disease is endemic in parts of Africa, Latin America, Asia, the Middle East, and states of the former Soviet Union. ***Transmission:*** Contact with respiratory droplets, nasal or eye discharge, or skin lesion; less commonly by indirect contact with contaminated items; or unpasteurized milk. ***Incubation period:*** 2–7 days or longer. ***Period of communicability:*** Usually 2–4 weeks or until 4 days after antibiotics are started.	The characteristic lesion is an adherent grayish pharyngeal membrane that in severe cases may extend into the trachea or cause airway obstruction. Attempts to remove the membrane result in bleeding. Symptoms can be mild or severe with a gradual onset over 1–2 days. A sore throat and enlarged tender cervical lymph nodes are present. The child may have a swollen neck. ***Complications:*** The organism produces an endotoxin that causes myocarditis and peripheral neuropathy (diplopia, slurred speech, difficulty swallowing, or paralysis of the palate) or ascending paralysis that may be confused with Guillain-Barré syndrome.	***Diagnostic testing:*** Culture from any mucosal or cutaneous lesion. ***Medical management:*** IV equine antitoxin (for respiratory diphtheria) is given after the child is tested for sensitivity. Antibiotic therapy is prescribed for 14 days with IV or IM penicillin G, changing to oral erythromycin when the child can swallow. ***Prognosis:*** Respiratory diphtheria may be complicated by life-threatening airway obstruction. ***Prevention:*** Diphtheria is a vaccine-preventable disease (see Table 16–1). This is a reportable disease.	• Use transmission-based precautions and isolate the child. • Monitor closely for signs of increasing respiratory distress, as well as cardiac and neurologic complications. • Have emergency airway equipment available. Provide humidified oxygen as necessary. • Administer antitoxin and antibiotics as prescribed. Give no medications containing caffeine or other stimulants. • Use oral suction gently as necessary. • Allow children to use mouthwash if desired. Gargling is not permitted because it can irritate the pharyngeal surfaces. • Encourage liquids as tolerated. Intravenous fluids may be necessary. • Provide emotional support to the family. • Initiate the search for client contacts to give antibiotics and immunization boosters.
ENTEROVIRUSES			
Causal agent: Group A and B coxsackieviruses, human enteroviruses. ***Epidemiology:*** Occurs worldwide, most commonly in summer and early fall. More common in settings with poor hygiene and overcrowding. Immunity to specific virus probably occurs after infection, but duration is unknown. ***Transmission:*** Fecal–oral and respiratory routes. ***Incubation period:*** 3–6 days. ***Period of communicability:*** Viral shedding may occur for weeks or months after infection.	Irritability, fever, anorexia, malaise, rash, and a sore throat. Each virus causes additional manifestations. ***Herpangina:*** Small, grayish papulovesicular ulcerative pharyngeal lesions that gradually increase in size. ***Hand, foot, and mouth disease:*** Diffuse lesions on the mucous membranes of the mouth; papulovesicular lesions on the hands and feet last for 7–10 days. ***Enterovirus D-68:*** Severe respiratory illness in children with history of asthma or wheezing (Midgley et al., 2014). ***Complications:*** Children with immune deficiency may have more severe manifestations.	***Diagnostic testing:*** Polymerase chain reaction or culture of stool, throat, or other primary site may be obtained. ***Medical management:*** Supportive care. IV immune globulin may be used in life-threatening neonatal infections and in immunodeficient children with chronic meningoencephalitis (AAP, 2015, p. 336). ***Prognosis:*** Recovery is generally good with supportive care. ***Prevention:*** Avoid contact with infected persons early in the disease.	• Use standard and contact precautions if the child is hospitalized. • Use good hand hygiene. • Apply topical lotions and give systemic medications as ordered to lessen the pain and relieve the irritation. • Offer cool drinks and soft, bland foods (no citrus, salty, or spicy foods). Swallowing may be painful. Observe for dehydration. • Offer warm saline mouth rinses. • Provide reassurance and support to parents. • Give acetaminophen or ibuprofen for fever. • Keep the child out of school or child care while febrile.

[a]Indicates that a vaccine or antitoxin is available for use in high-risk or as-needed situations.

[b]Indicates that the disease has a safe and effective vaccine.

DISEASE	CLINICAL MANIFESTATIONS	CLINICAL THERAPY	NURSING MANAGEMENT
ERYTHEMA INFECTIOSUM (FIFTH DISEASE)			
Causal agent: Human parvovirus B19. ***Epidemiology:*** Occurs worldwide, most often in winter and spring. Also occurs in epidemics, with peak activity every 3–4 years (CDC, 2012). The incidence is highest in children between the ages of 5 and 14 years. ***Transmission:*** Respiratory secretions and blood. ***Incubation period:*** 4–20 days. ***Period of communicability:*** No longer contagious once rash appears. 	***Stage 1:*** Begins as a mild illness (fever, headache, chills, malaise, nausea, body ache) lasting 2–3 days, followed by a symptom-free period of 1–7 days. ***Stage 2:*** Fiery-red rash on the cheeks giving a "slapped face" appearance (see figure); circumoral pallor. In 1–4 days a lacelike symmetric, erythematous, maculopapular rash appears on the trunk and spreads to the extremities; spares the palms and soles. The rash may last 7–10 days or longer. ***Stage 3:*** Over 1–3 weeks the rash fades, but can reappear if the skin is irritated or exposed to sunlight. ***Complications:*** Children with hemolytic conditions may have transient aplastic crisis. Polyarthropathy is rare in children.	***Diagnostic testing:*** Diagnosis by physical signs or positive serum immunoglobulin (Ig) M parvovirus B19-specific antibody (important when exposure to a pregnant woman is likely). ***Medical management:*** Supportive care usually leads to spontaneous recovery. Children with hemolytic conditions may need blood transfusions if an aplastic crisis occurs. Administer IV immune globulin to immunodeficient clients who develop a chronic infection (AAP, 2015, p. 595). ***Prognosis:*** Fetal infection may occur resulting in fetal hydrops, anemia, or spontaneous abortion. ***Prevention:*** Avoid contact with infected persons. Exposed pregnant women should seek prompt medical attention.	• Use standard and droplet precautions. Isolation is needed only for children hospitalized with aplastic crisis or when immunosuppressed. • Give acetaminophen or ibuprofen to control fever. • Use soothing oatmeal or Aveeno baths if the rash is pruritic. Antipruritics may also help to relieve itching. • Encourage rest and offer frequent fluids. • Keep children out of direct sunlight if possible. Provide protective, light, loose clothing if exposure to sunlight cannot be avoided. • Provide quiet diversionary activity. • Allow the child to return to school or child care once the rash appears (AAP, 2015, p. 596). • Explain the three stages of rash development to parents.
***HAEMOPHILUS INFLUENZAE*, TYPE B[b]**			
Causal agent: Coccobacilli *H. influenzae* bacteria (several serotypes, encapsulated or nonencapsulated). ***Epidemiology:*** Occurs most often in the spring and summer. Unimmunized and inadequately immunized infants and young children are most commonly affected. Neonates may acquire the organism by aspirating amniotic fluid or contact with vaginal secretions. ***Transmission:*** Direct contact or respiratory droplet inhalation. Asymptomatic colonization in the nose and throat is common. ***Incubation period:*** Unknown, but may be a few days. ***Period of communicability:*** 3 days from onset of symptoms.	Begins with a viral upper respiratory infection. The organism passes through the mucosal barrier to directly invade the bloodstream. It can cause severe invasive illnesses, including meningitis, epiglottitis, pneumonia, infectious arthritis, and cellulitis. It may cause sepsis in infants. Other illnesses caused by the organism include sinusitis, otitis media, bronchitis, and pericarditis. Each disease has specific clinical manifestations. Invasive disease has decreased 99% since introduction of the vaccine (AAP, 2015, p. 369). ***Complications:*** Responds to antibiotic therapy. If untreated, severe sequelae and death can occur from conditions such as meningitis, epiglottitis, sinusitis, pneumonitis, and cellulitis, especially in young infants.	***Diagnostic testing:*** Culture of blood, cerebrospinal fluid, or middle ear aspirate may be obtained. ***Medical management:*** Treatment for invasive disease is IV antibiotics for 10 days. Dexamethasone may be given to reduce the neurologic sequelae of meningitis. Infections such as otitis media can be managed with oral antibiotics. Rifampin may be given to unprotected household contacts if another child 4 years or younger has not had the vaccine series. ***Prognosis:*** With rapid diagnosis and treatment, recovery is good. When treatment is delayed, disability may occur. ***Prevention:*** *H. influenzae* type b is a vaccine-preventable disease (see Table 16–1).	• Use droplet precautions until 24 hr after the initiation of antibiotics. • Identify potential contacts and review their immunization status. Determine the need for rifampin. Inform parents to seek health care rapidly if the exposed child becomes ill. • Administer acetaminophen or ibuprofen to increase the child's comfort. • Closely monitor IV sites for patency and infiltration. • Perform nursing care measures specific to the illness. • Inform family members that rifampin turns urine and other body fluids orange, and it will cause stains.

(*continued*)

TABLE 16–5 Selected Infectious and Communicable Diseases in Children (*continued*)

DISEASE	CLINICAL MANIFESTATIONS	CLINICAL THERAPY	NURSING MANAGEMENT
INFLUENZA[b]			
Causal agent: Orthomyxoviruses, types A, B, and C. Type A can be subtyped based on surface proteins: hemagglutinin (H) and neuraminidase (N). ***Epidemiology:*** Prevalent in the United States from October to March, but the virus is active in other parts of the world year-round. The influenza A virus mutates each season. The number of infections peak in about 3 weeks from the initial case and continue for about 3 months. Incidence of infection is often greater in young children who have fewer prior influenza infections and antibodies. ***Transmission:*** Spreads by aerosolized particles and direct contact with respiratory secretions. ***Incubation period:*** 1–4 days. ***Period of communicability:*** 1 day before symptoms to 5–7 days after symptom onset.	Abrupt onset of fever 100.4–104.0°F (38–40°C), chills, cough, runny nose, sore throat, malaise, aches, headache, and anorexia. Children may have nausea and vomiting, diarrhea, and abdominal pain. Recovery usually occurs in 3–5 days. ***Complications:*** Pneumonia, otitis media, asthma exacerbations, tracheitis, myocarditis, myositis, febrile seizures, sinusitis, and neurologic conditions such as meningitis, encephalitis, encephalopathy, or Guillain-Barré syndrome. Children with chronic pulmonary, hematologic, metabolic, and cardiovascular conditions are at greater risk for severe infection. In the 2013–2014 influenza season, 924 children aged 0–17 years were hospitalized, and 50 children died due to influenza (Arriola et al., 2014).	***Diagnostic testing:*** Rapid antigen testing from throat swabs, nasopharyngeal washings, and sputum detects antigens of influenza A and B. Viral cultures, direct fluorescent antibody, or indirect immunofluorescent antibody staining. ***Medical management:*** Treatment is supportive. Antiviral therapy may be used to treat symptomatic children or for prevention. Oseltamivir (Tamiflu), amantadine (Symmetrel), zanamivir (Relenza), and rimantadine (Flumadine) are approved for children with specific age guidelines. Antiviral therapy should be started within 48 hr of symptoms for best results (AAP, 2015, p. 481). ***Prognosis:*** Most children recover. ***Prevention:*** Annual influenza immunization beginning at age 6 months (see Table 16–1).	• Use droplet and contact precautions for hospitalized infants and children. • For home care, encourage parents to wash hands frequently and to isolate the child from other family members. • Provide fluids to keep nasal secretions moist and to prevent dehydration. • Provide acetaminophen or ibuprofen for fever management and mild pain. • If antiviral medications are given, be alert for nausea and vomiting. Zanamivir can exacerbate asthma. • Provide rest and quiet diversional activities. • Children should be kept home until 24 hr after fever is gone. • Teach parents to be alert to signs of complications from the viral infection. • Become familiar with community pandemic infection plans.
MEASLES (RUBEOLA)[a,b]			
Causal agent: Morbillivirus, a member of the paramyxovirus group. ***Epidemiology:*** Occurrence peaks in the late winter and early spring. In 2014, 592 cases and 18 outbreaks occurred in the United States, mostly in unimmunized children. Most outbreaks were linked to cases imported from other countries (CDC, 2014c). ***Transmission:*** Direct contact with respiratory droplets and airborne spread. ***Incubation period:*** About 8–12 days. ***Period of communicability:*** From 4 days before the rash until 4 days after its appearance. Barbara Rice/Centers for Disease Control and Prevention	***Prodromal stage:*** High fever (up to 105.0°F [40.5°C]), malaise, cough, coryza, conjunctivitis. Koplik spots (1–3 mm gray or blue-gray spots on an erythematous base) appear opposite the second molars on the buccal mucosa. They slough before or during the onset of the rash. This stage lasts 1–3 days. ***Stage 2:*** Maculopapular rash (dark red to purple), reaching a peak in 2–4 days when it becomes confluent. The mildly pruritic rash begins on the face and spreads to the trunk and extremities. Other symptoms include fatigue, photophobia, and generalized lymphadenopathy. ***Complications:*** About 30% of cases develop pneumonia, otitis media, diarrhea, or encephalitis (CDC, 2014c). Complications and death occur most often in children who are malnourished or immunocompromised.	***Diagnostic testing:*** Serologic test for immunoglobulin (Ig) M measles antibody. ***Medical management:*** Supportive care. No antiviral therapy is available. Antibiotics are used for secondary bacterial infections. MMR vaccine within 72 hr of exposure or immune globulin within 6 days of exposure may help prevent or reduce disease severity. ***Prognosis:*** Increased risk of death in children under age 5 years and immunocompromised persons (AAP, 2015, p. 535). ***Prevention:*** Measles is a vaccine-preventable disease (see Table 16–1). This is a reportable disease.	• Maintain airborne precautions when the child is hospitalized. • Use a cool-mist vaporizer to help clear respiratory passages. Suction nose and oral cavity gently if needed. • Give nonaspirin antipyretics for fever and antipruritics for itching. Cough medication may be prescribed. • Teach parents to observe for complications and to seek care as needed. • Keep lights dim, and cover windows if the child has photophobia. • Keep skin clean and dry. Avoid using soap. • Offer cool liquids frequently in small amounts. Blended, pureed, and mashed foods are most easily tolerated. • Maintain bed rest. Visitors should be immune to measles. Provide diversional activities.

[a]Indicates that a vaccine or antitoxin is available for use in high-risk or as-needed situations.

[b]Indicates that the disease has a safe and effective vaccine.

DISEASE	CLINICAL MANIFESTATIONS	CLINICAL THERAPY	NURSING MANAGEMENT
MENINGOCOCCUS ***Causal agent:*** *Neisseria meningitidis,* a gram-negative diplococcus. ***Epidemiology:*** Often occurs in winter or early spring. Serogroups B, C, and Y cause the most disease in the United States. Highest rates occur in infants under 1 year of age and adolescents 16–21 years. Outbreaks have occurred in childcare centers, college dormitories, and military recruit camps. There are fewer than 1000 cases annually in the United States (CDC, 2014e). ***Transmission:*** Spread by direct contact with respiratory secretions from human carriers. ***Incubation period:*** 3–7 days. ***Period of communicability:*** Until 24 hr of treatment with an effective antibiotic.  Medical-on-Line/Alamy	***Meningitis:*** Most common invasive disease. Abrupt onset of flulike symptoms of fever, malaise, stiff neck, nausea, vomiting, decreased mental status, seizures, and coma. ***Meningococcemia*** (sepsis caused by meningococcus): Fatigue; vomiting; cold hands and feet; chills; severe aches and pains in muscles, joints, chest, and abdomen; rapid breathing; diarrhea. An urticarial, maculopapular or petechial rash appears that may progress to purpura (see figure) and severe septic shock. ***Complications:*** Approximately 11%–19% of survivors have serious sequelae (CDC, 2014d). Survivors of meningitis may develop hearing loss or neurologic disability. Survivors of meningococcemia may have permanent disabilities from digit or limb amputations, and scarring from skin grafts.	***Diagnostic testing:*** Cultures of the blood and cerebrospinal fluid, and a Gram stain of petechial skin scrapings. ***Medical management:*** IV antibiotics with penicillin G, cefotaxime, ceftriaxone, or ampicillin; chloramphenicol for children allergic to penicillin. The child is treated in the ICU for shock with IV fluids and vasopressors, and with respiratory support. Blood products are used to treat disseminated intravascular coagulation. Several surgeries may be needed for removal of necrotic tissue. ***Prognosis:*** Even with antibiotic treatment about 10%–15% of clients die (CDC, 2013e). ***Prevention:*** Several serotypes are vaccine preventable (see Table 16–1). Close contacts receive an antibiotic. Community contacts should also receive the meningococcal vaccine to prevent an outbreak (AAP, 2015, p. 557). This is a reportable disease.	• Use standard and droplet precautions until an effective antibiotic has been administered for 24 hr. • Be alert for development of shock and respiratory compromise as the disease progresses quickly. Have emergency equipment available. • Avoid overloading the child with IV fluids and blood products. Administer medications as prescribed. • Monitor the child with meningitis for signs of increased intracranial pressure. • Help the family mobilize its support system, and keep the family informed of the child's status and treatment as the disease progresses. • Help identify contacts who should receive prophylactic antibiotics. Educate them about the expected side effects (i.e., orange urine with rifampin). • Teach contacts to be observant for signs of illness and to seek health care promptly if they occur. • The surviving child will often need rehabilitation for limb amputations or hearing loss. Work with the social worker to transition the child to long-term care.
MONONUCLEOSIS ***Causal agent:*** Epstein-Barr virus (EBV), human herpesvirus type 4. ***Epidemiology:*** The virus infects the oral mucosa and salivary glands. Occurs worldwide in no seasonal pattern. Infection is common in adolescents and young adults in the United States. ***Transmission:*** Direct contact with saliva or exposure to body fluids (e.g., blood or semen). ***Incubation period:*** Estimated to be 4–6 weeks.	Young children may have a mild infection with no distinguishing clinical signs. Symptoms include fever, malaise, headache, anorexia, abdominal pain, a painful sore throat (exudative pharyngotonsillitis), and enlarged cervical lymph nodes. An enlarged spleen and liver may occur. The syndrome typically lasts 2–4 weeks, but fatigue may continue for weeks. ***Complications:*** Peritonsillar abscess, sinusitis, mastoiditis.	***Diagnostic testing:*** A heterophil antibody response test. Greater than 10% atypical lymphocytes and a positive heterophil antibody response test are diagnostic (AAP, 2015, pp. 337–338). ***Medical management:*** Supportive care. Corticosteroids may be used for tonsillar swelling and impending airway obstruction, massive splenomegaly, myocarditis, or hemolytic anemia. Antibiotics (ampicillin and amoxicillin) are not used because a nonallergic rash often develops (AAP, 2015, p. 339).	• Use standard precautions if the child is hospitalized. • Give antipyretics and analgesics for fever and sore throat. Offer warm salt water for gargling. Offer soft foods and encourage fluids. • Maintain bed rest during acute phase. • Educate the teen to avoid intimate contact and not to share food and beverages until recovered.

(*continued*)

TABLE 16–5 Selected Infectious and Communicable Diseases in Children (*continued*)

DISEASE	CLINICAL MANIFESTATIONS	CLINICAL THERAPY	NURSING MANAGEMENT
MONONUCLEOSIS (*continued*)			
Period of communicability: May be weeks before symptoms occur, and becomes latent after infection. Contagious if reactivation occurs (CDC, 2014e).	Rare conditions include neurologic disorders (e.g., meningitis, encephalitis, and Guillain-Barré syndrome), hematologic disorders (lymphocytosis), and immune disorders. Those with immune disorders have more severe disease.	***Prognosis:*** Rarely fatal. After recovery, the virus becomes latent in the lymphoid system and can reactivate during periods of immunosuppression. ***Prevention:*** No known prevention.	• Return to contact sports and strenuous activity (e.g., weight lifting) is approved by the healthcare provider when the liver and spleen are normal size, usually in about 4 weeks. • If splenomegaly is present, alcohol should be avoided for 3 months after liver function test results return to normal.
MUMPS (PAROTITIS) [b]			
Causal agent: *Rubulavirus* in the Paramyxoviridae family. ***Epidemiology:*** Occurs worldwide in unvaccinated children, most often in winter and spring. Infection and vaccination induce lifelong immunity. ***Transmission:*** Inhalation of respiratory secretion droplets. ***Incubation period:*** 12–25 days. ***Period of communicability:*** Up to 5 days before and after parotid swelling onset.  Centers for Disease Control and Prevention	Acute onset of malaise, fever, muscle aches, and swelling of one or more salivary glands (parotid, sublingual, or submaxillary) are the classic signs. Other signs include earache, headache, pain with chewing, and decreased appetite and activity. May be asymptomatic in some children. ***Complications:*** **Orchitis** (inflammation of the testicles) that rarely leads to fertility problems, encephalitis, oophoritis (inflammation of ovaries), temporary or permanent deafness. Viral meningitis occurs in less than 10% of cases (AAP, 2015, p. 564).	***Diagnostic testing:*** Viral culture from a throat washing, urine, or cerebrospinal fluid. A serologic test for mumps-specific IgM antibodies may be performed. ***Medical management:*** Supportive care focused on symptom relief. ***Prognosis:*** Mumps is usually self-limiting. ***Prevention:*** Mumps is a vaccine-preventable disease. See Table 16–1. This is a reportable disease.	• Use standard and droplet precautions for hospitalized children while contagious. • Children are cared for at home. They may be uncomfortable but rarely very ill. Provide diversion. • Avoid exposure to immunocompromised or susceptible individuals. • Give acetaminophen or ibuprofen to control fever and pain. • Encourage fluid intake. Offer soft and blended foods as chewing and swallowing may be painful. Avoid foods and beverages that increase salivary flow and cause pain (e.g., citrus, spices, and candies). • Be alert for signs of complications. • Keep children out of school or child care until 5 days after parotid swelling occurs.
PERTUSSIS (WHOOPING COUGH)[b]			
Causal agent: *Bordetella pertussis.* ***Epidemiology:*** Occurs worldwide and year-round. Rates have increased because of waning immunity with 28,639 cases in 2013 (CDC, 2013a). Children with waning immunity can spread the disease to unimmunized young infants at greatest risk for death from the infection. ***Transmission:*** Inhalation or direct contact with respiratory droplets. ***Incubation period:*** 5–10 days.	***Catarrhal stage:*** The onset is insidious with cold symptoms, a runny nose, mild cough, and fever, lasting about 1–2 weeks. ***Paroxysmal stage:*** A series of rapid coughs followed by a forceful inspiration through a narrowed glottis causes stridor, or the "whoop." The child has cyanosis, vomiting, and exhaustion associated with coughing paroxysms. Infants under 6 months of age may have gagging, gasping, or apnea rather than whooping. Sucking on a bottle may trigger coughing, leading to poor oral intake and dehydration. The "whoop" may be absent in immunized children.	***Diagnostic testing:*** Nasopharyngeal culture, polymerase chain reaction (PCR) testing, and serology. ***Medical management:*** Supportive care. Macrolide antibiotics (erythromycin, clarithromycin, azithromycin, and trimethroprim-sulfamethoxazole). Symptoms are reduced only if initiated in the catarrhal stage (CDC, 2013a). ***Prognosis:*** The disease is most severe in infants younger than 6 months, of which 1.6% will die (CDC, 2013a).	• Use droplet precautions until 5 days after effective antibiotic is initiated. • Monitor respirations and oxygen saturation with a cardiac monitor and pulse oximetry. The smaller the infant, the greater the risk for apnea. • Meet infant needs promptly to reduce crying, which can precipitate coughing. Remain with the child during coughing spells, when hypoxic and apneic episodes are most likely. Give oxygen if ordered. Have emergency equipment available.

[a]Indicates that a vaccine or antitoxin is available for use in high-risk or as-needed situations.

[b]Indicates that the disease has a safe and effective vaccine.

DISEASE	CLINICAL MANIFESTATIONS	CLINICAL THERAPY	NURSING MANAGEMENT
Period of communicability: Most contagious prior to the paroxysmal cough stage and for 2 weeks after cough onset if untreated. Communicable for 5 days after beginning effective antibiotic.	***Convalescent stage:*** Up to 6–10 weeks later paroxysms gradually subside. ***Complications:*** Among infants: pneumonia, seizures, apnea, encephalopathy, and death. In adolescents: sleep disturbance, incontinence, syncope, rib fractures, and pneumonia (CDC, 2013a).	***Prevention:*** Pertussis is a vaccine-preventable disease (see Table 16–1). The vaccine protection wanes over time. All adults should receive a Tdap booster every 10 years. Pregnant women should be immunized to protect their newborns from pertussis during the third trimester. The father and family members who will have close contact with the newborn should receive a Tdap booster prior to the newborn's birth (CDC, 2015b). Close contacts should receive macrolide antibiotic prophylaxis.	• Provide humidification. Gentle suctioning may be necessary. • Give nonaspirin antipyretics as needed for fever. • Encourage frequent rest periods. • Provide small frequent feeding of desired foods. Encourage fluids. The child may need IV hydration if oral intake is not tolerated. • Provide emotional support to parents. • Teach parents to watch for signs of respiratory failure and dehydration if the child is managed at home.
PNEUMOCOCCAL INFECTION[b]			
Causative agent: *Streptococcus pneumoniae,* a gram-positive diplococcus, many serotypes. ***Epidemiology:*** Found in the pharynx of healthy people. Outbreaks occur in winter and spring in temperate climates, and only a few of the 90 serotypes account for most of the invasive pediatric infections. ***Transmission:*** Direct contact with respiratory secretions, and droplets and self-innoculation. ***Incubation period:*** 1–3 days. ***Period of communicability:*** Unknown. Probably within 24 hr after effective antibiotic therapy is initiated.	Causes invasive disease with signs and symptoms are related to the focal area of infection. ***Otitis media*** — upper respiratory infection, fever, ear pain, and decreased appetite. ***Bacteremia*** — unexplained fever, reduced responsiveness, and no localized infection site. ***Pneumonia*** — fever, chills, chest pain, dyspnea, malaise, and a productive cough. ***Meningitis*** — inconsolable crying, increased irritability, lethargy, refusal to eat, nausea, vomiting, diarrhea, myalgia, photophobia, and seizures. The organism also causes sinusitis, pharyngitis, cellulitis, and laryngotracheobronchitis. Children under age 2 years, or having immunodeficiency (e.g., asplenia, malignancy, sickle cell disease, HIV infection, and nephrotic syndrome) and cochlear implants are at higher risk of invasive disease. ***Complications:*** Hearing loss or developmental delay from meningitis, empyema or pericarditis from pneumonia, and death.	***Diagnostic testing:*** Bacterial culture from the site of infection. ***Medical management:*** Symptomatic care. Antibiotic selection is based upon culture sensitivity. Many pneumococcal strains are resistant to penicillin, cefotaxime, and ceftriaxone. Vancomycin may be required. Dexamethasone may be an adjunctive therapy for meningitis. ***Prognosis:*** An estimated 200 children die annually from pneumococcal disease (CDC, 2013b). Pneumococcal meningitis is associated with neurologic sequelae (e.g., hearing loss, motor deficits). ***Prevention:*** Many serotypes are vaccine preventable (see Table 16–1). Pneumococcal vaccine with 23 serotypes (PPSV23) is used for children at high risk of pneumococcal invasive disease.	• Maintain standard precautions. • Provide nonaspirin antipyretics for control of fever and comfort. • Encourage fluids, and monitor intake and output. • Monitor vital signs and level of consciousness to identify signs of worsening condition. • Educate parents about the need for the vaccine. The unimmunized child can become infected repeatedly with different serotypes. • Many children with mild disease will be treated at home. Educate parents about signs indicating a need to seek urgent medical care, medication administration, and comfort measures for the child.

(*continued*)

TABLE 16–5 Selected Infectious and Communicable Diseases in Children (*continued*)

DISEASE	CLINICAL MANIFESTATIONS	CLINICAL THERAPY	NURSING MANAGEMENT
POLIOMYELITIS[b]			
Causal agent: Poliovirus is an enterovirus with three serotypes. ***Epidemiology:*** Global eradication efforts have interrupted the transmission of polio in all but three countries—Afghanistan, Nigeria, and Pakistan (CDC, 2013c). Imported and wild polio is a threat to inadequately immunized children. ***Transmission:*** Direct contact with respiratory secretions and body fluids. ***Incubation period:*** Usually 7–10 days (range 3–36 days). ***Period of communicability:*** Greatest shortly before and with onset of clinical symptoms. The virus is excreted in the feces for 3–6 weeks.	More than 90% of infections are asymptomatic. ***Mild illness:*** A low-grade fever and sore throat. This minor illness may be followed by aseptic meningitis and paresthesias. ***Serious illness:*** Asymmetric flaccid paralysis may occur acutely in up to 1% of cases. Site of paralysis is commonly the legs, but it may affect the respiratory muscles. Residual paralysis may occur in more than half of those affected (AAP, 2015, p. 644). ***Complications:*** Permanent motor paralysis, respiratory arrest, postpolio syndrome, and death.	***Diagnostic testing:*** Cell culture from stool or throat swabs. ***Medical management:*** Supportive therapy. No effective chemotherapeutic agents exist. ***Prognosis:*** Respiratory paralysis may lead to death. Motor paralysis may result in long-term disability. ***Prevention:*** Poliomyelitis is a vaccine-preventable disease (see Table 16–1). The vaccine is believed to confer lifelong immunity. This is a reportable disease.	• Use standard and droplet precautions. • Monitor for respiratory paralysis (ineffective cough, talking with frequent pauses, shallow and rapid respiratory rate). Have emergency equipment at bedside. Assist ventilations as needed until mechanical ventilation is set up. • Use moist hot packs, which may relieve discomfort. • Encourage fluids. • Keep the child on bed rest. Position the child to promote body alignment. • Perform range of motion exercises to prevent contractures after the acute phase. • Provide emotional support. Keep the child and family informed about the illness and therapies. • Help coordinate rehabilitation, such as long-term physical therapy when needed.
ROSEOLA (EXANTHEM SUBITUM, SIXTH DISEASE)			
Causal agent: Human herpesvirus type 6 (HHV-6). ***Epidemiology:*** Occurs worldwide year-round with no seasonal pattern. Occurs primarily in children 6–24 months of age (as maternal antibodies decline). Nearly all children are infected by 3 years of age. Congenital infection is also possible (AAP, 2015, p. 451). ***Transmission:*** Contact with saliva or respiratory secretions. ***Incubation period:*** Appears to be 9–10 days. ***Period of communicability:*** Healthy persons shed the virus (AAP, 2015, p. 450).	***Prodromal stage:*** Sudden fever greater than 103.0°F (39.5°C) for 3–7 days, during which the child has a normal appetite and behavior, no rash or specific disease signs. ***Rash stage:*** A characteristic pale pink, discrete, maculopapular rash starts on the trunk and spreads to the face, neck, and extremities, lasting hours to days. The child may have characteristic postoccipital lymphadenopathy, tympanic membrane redness, and respiratory and gastrointestinal signs. ***Complications:*** Febrile seizures are common; encephalopathy or encephalitis may occur.	***Diagnostic testing:*** Polymerase chain reaction (PCR) testing for HHV-6 in the blood or cerebrospinal fluid. ***Medical management:*** Supportive treatment for this self-limiting condition. ***Prognosis:*** Full recovery is usual. ***Prevention:*** No preventive measures.	• Use standard precautions if the child is hospitalized. • Give nonaspirin antipyretics to control fever. • Observe closely for any seizure activity, especially during the acute febrile periods. • Encourage fluids to maintain hydration. • Reassure parents that the rash will disappear in a few days.
ROTAVIRUS[b]			
Causal agent: RNA viruses of the Reoviridae family. Groups A, B, and C infect humans.	Acute onset of fever and vomiting followed by watery diarrhea 1–2 days later. Up to 10–20 diarrheal stools a day. Symptoms last 3–8 days.	***Diagnostic testing:*** Enzyme immunoassay or latex agglutination assay of a stool specimen.	• Use standard and contact precautions. • Use good hand hygiene with soap and water or gel cleansers.

[a]Indicates that a vaccine or antitoxin is available for use in high-risk or as-needed situations.

[b]Indicates that the disease has a safe and effective vaccine.

DISEASE	CLINICAL MANIFESTATIONS	CLINICAL THERAPY	NURSING MANAGEMENT
Epidemiology: Occurs more often in cool periods, peaking in the spring in the United States. A common cause of severe diarrhea in children less than age 5 years. ***Transmission:*** Fecal–oral route, direct contact with contaminated objects. ***Incubation:*** 1–3 days. ***Period of communicability:*** Virus may persist in stool when child is immunocompromised.	***Complications:*** Dehydration and electrolyte disturbances. Immunocompromised children may develop persistent infection and diarrhea (AAP, 2015, p. 684).	***Medical management:*** Treatment involves adequate amounts of fluid and electrolyte replacement with oral rehydration solution. Antimotility drugs should not be used. If severely dehydrated, IV fluid resuscitation is performed. No antiviral therapy is available. ***Prevention:*** Vaccine prevents several common viral groups (see Table 16–1).	• Clean and disinfect contaminated surfaces. • Assess hydration status frequently. • Breastfeeding is continued during oral rehydration therapy, but wait up to 24 hr before giving formula. • Feed older children complex carbohydrates and lean meats, yogurt, fruits, and vegetables 12–24 hr after starting oral rehydration therapy.
RUBELLA (GERMAN MEASLES)[b]			
Causal agent: An RNA virus, member of the family Togaviridae, genus *Rubivirus.* ***Epidemiology:*** Occurs worldwide. Most prevalent in winter and spring. No longer endemic in the United States (AAP, 2015, p. 689). Most U.S. cases occur among persons from other countries and those underimmunized. Congenital rubella syndrome occurs between 12 weeks of gestation to the end of the second trimester. ***Transmission:*** Droplet spread, direct contact with nasal secretions. ***Incubation period:*** 14–21 days. ***Period of communicability:*** 7 days before until 7 days after rash onset. Infants with congenital rubella may shed the virus for 1 year or longer after birth.	***Prodromal stage:*** Asymptomatic or low-grade fever, malaise, coryza, and sore throat, 1–5 days before the rash. Forschheimer spots (discrete, erythematous pinpoint or larger lesions on the soft palate) are seen. Posterior auricular and suboccipital lymphadenopathy may precede the rash. ***Rash stage:*** 1–5 days later a pink, maculopapular rash appears on the face and neck. The rash spreads to the trunk and legs, and fades in the same sequence. ***Complications:*** Transient arthralgia in adolescents; encephalitis. Pregnant females infected during the first trimester may have a fetus with congenital rubella syndrome birth defects (e.g., cataracts, heart defects, hearing impairment, thrombocytopenia, and purpuric skin lesions that give a "blueberry muffin" appearance) (see figure).	***Diagnostic testing:*** Cell culture from a nasal swab, and detection of IgM or IgG antibodies. ***Medical management:*** Supportive treatment. Rubella is self-limiting in children. ***Prognosis:*** Full recovery is expected. Congenital rubella syndrome may result in death or congenital anomalies. ***Prevention:*** Rubella is a vaccine-preventable disease (see Table 16–1). Centers for Disease Control and Prevention	• Maintain standard and droplet precautions. • Maintain contact precautions for infants with congenital rubella syndrome until 1 year of age unless nasopharyngeal and urine cultures are repeatedly negative after 3 months of age (AAP, 2015, p. 691). • Children are usually treated at home. Provide quiet activities. • Isolate the child from pregnant women. • Give nonaspirin analgesics and antipyretics for any pain and fever. • Encourage the child to consume preferred fluids and food. • Exclude children from child care or school for 7 days after onset of rash. Notify the school or childcare facilities of the child's illness.
STREPTOCOCCUS A			
Causal agent: Group A streptococci (GAS), numerous serotypes. ***Epidemiology:*** Pharyngeal infections tend to occur more in late fall, winter, and spring when closer person-to-person contact occurs. Pyodermal infections more often occur in warmer seasons with minor skin trauma and insect bites. Different serotypes are associated with pharyngeal and pyodermal infections, rheumatic fever, and acute glomerulonephritis (AAP, 2015, p. 733).	***Pharyngeal:*** Abrupt onset with a sore throat, dysphagia, tender cervical lymph nodes, malaise, high fever, chills, headache, abdominal pain, anorexia, and vomiting. The pharynx is beefy red with exudates, and palatal petechiae may be seen. ***GAS respiratory tract infection:*** Children younger than 3 years may have serous rhinitis, moderate fever, irritability, and anorexia rather than pharyngitis.	***Diagnostic testing:*** Rapid strep test or a culture of secretions from the pharynx and tonsils, blood culture for invasive disease. Cultures of skin lesions do not reveal primary organism (AAP, 2015, p. 737). ***Medical management:*** Prompt oral antibiotic therapy with penicillin V or amoxicillin or IM penicillin G benzathine. Clindamycin or oral macrolide may be used if the child is allergic to penicillin.	• Use standard and droplet precautions for pharyngeal infections and contact precautions for skin infections. • Promote bed rest during the febrile stage. • Give nonaspirin antipyretics to control fever. Teach parents important signs of a worsening condition. • For pharyngeal infections, offer warm salt water for gargling and nonacidic beverages. Encourage cool, clear liquids and a soft diet. Swallowing may be difficult.

(*continued*)

TABLE 16–5 Selected Infectious and Communicable Diseases in Children (*continued*)

DISEASE	CLINICAL MANIFESTATIONS	CLINICAL THERAPY	NURSING MANAGEMENT
STREPTOCOCCUS A (*continued*)			
Transmission: Contact with respiratory secretions for pharyngitis or skin lesions for pyoderma. ***Incubation period:*** Pharyngeal: usually 2–5 days. Pyodermal: usually 7–10 days. ***Period of communicability:*** For weeks in untreated pharyngeal infections; not contagious within 24 hr of starting antibiotics. Bubbles Photolibrary/Alamy	***Scarlet fever:*** A characteristic erythematous, confluent, sandpaper rash, starting on the neck and spreading to the trunk and extremities. The rash blanches with pressure, concentrates in flexor skin creases, and spares the circumoral area. In 3–4 days, the rash begins to fade and the tips of the toes and fingers peel. The classic strawberry tongue is seen on days 4–5. Most often occurs after pharyngeal symptoms. ***Pyodermal:*** Lesions (impetigo) are honey-colored crusts at the site of open lesions (see figure). ***Complications:*** If untreated, acute otitis media, sinusitis, peritonsillar or retropharyngeal abscess, cervical lymphadenitis, acute rheumatic fever, and acute glomerulonephritis. Invasive disease with toxic shock syndrome, bacteremia, necrotizing fasciitis, or myositis can be fatal.	Uncomplicated impetigo is treated with mupirocin or retapamulin ointment. See Chapter 31 for more information about bacterial skin infections and toxic shock syndrome. See Chapter 21 for treatment of acute rheumatic fever. ***Prognosis:*** Recovery is usually good with antibiotic therapy. Children can become long-term carriers of streptococcus A in their pharynx. ***Prevention:*** None.	• Explain to parents the importance of giving the full course of antibiotics. • Encourage other family members with sore throats to have throat cultures taken. • For impetigo, encourage good hand hygiene. Teach the parents to wash the skin, remove crusts, and apply antibiotic ointment. • Replace the child's toothbrush after treatment to prevent reinfection.
TETANUS[a,b]			
Causal agent: *Clostridium tetani,* an anaerobic gram-positive bacillus. ***Epidemiology:*** Bacillus is common and exists as a spore in soil, dust, and manure. The organism produces an endotoxin that affects the central nervous system. ***Transmission:*** Wounds (e.g., superficial, puncture, burns, crush injuries) exposed to contaminated soil or objects. ***Incubation period:*** 3–21 days (average 10 days). ***Period of communicability:*** No direct person-to-person contact.	Fever, diaphoresis, headache, and neck and jaw stiffness with painful facial spasms and difficulty chewing and swallowing, seizures, painful muscle stiffness, hypertension, tachycardia. Facial muscle spasms may produce a grinning expression (risus sardonicus). Eventual rigidity of the abdomen and trunk produce **opisthotonos** (rigid hyperextension of the entire body). Respiratory muscles may be affected and cause airway obstruction and suffocation. Newborns have increasing difficulty with sucking, irritability, and neck stiffness. ***Complications:*** Laryngospasm, respiratory distress, death.	***Diagnostic testing:*** Based on clinical signs; cultures often ineffective. ***Medical management:*** IM human tetanus immune globulin with some injected into the wound site. The wound is cleaned and debrided. Antibiotics and medications to relieve muscle spasms are administered. Intensive care is provided with assisted ventilation, nutrition, and supportive care. Complete recovery may take weeks. ***Prognosis:*** Fatality rates are 10%–20%, depending on quality of supportive care (CDC, 2013d). ***Prevention:*** Tetanus is a vaccine-preventable disease (see Table 16–1). A tetanus booster is needed every 10 years, or, if a contaminated wound occurs, in 5 years.	• Use standard precautions. • Assist with wound debridement. • Monitor the child's condition. Handle as little as possible. Reduce stimulation by placing the child in a quiet, darkened room. • Offer skin and respiratory care. The child may need an endotracheal tube, suctioning, and supplemental oxygen for airway support. • Provide feedings via total parenteral nutrition or feeding tube. • Maintain hydration with IV fluids and electrolytes. • Try to reduce the child's anxiety, as mental status may be unaffected by disease process. • Prepare the family for a possible poor prognosis.

[a]Indicates that a vaccine or antitoxin is available for use in high-risk or as-needed situations.

[b]Indicates that the disease has a safe and effective vaccine.

TABLE 16–6 Selected Infectious Diseases Transmitted by Insect or Animal Hosts (Zoonosis)

DISEASE	CLINICAL MANIFESTATIONS	CLINICAL THERAPY	NURSING MANAGEMENT
LYME DISEASE			
Causal agent: *Borrelia burgdorferi,* a spirochete transmitted by ixodid ticks. ***Epidemiology:*** It occurs in most U.S. states, with greatest number of cases in the Northeastern, Mid-Atlantic, and North Central states. Exposure occurs in any outdoor setting where ticks are endemic. Most cases occur between May and November, with the highest rate in the summer. Among children, the highest incidence in the United States is in 5- to 9-year-olds (AAP, 2015, p. 518). ***Transmission:*** The tick is attached for 36–48 hr before the infection is transmitted (CDC, 2014f). Lyme disease is the most common vectorborne illness in North America. ***Incubation period:*** 1–32 days after an infected tick bite. ***Period of communicability:*** The infection is not communicable from person to person. Kevin Shields/Alamy	***Localized disease (LD):*** Erythema migrans, a painless annular red rash that expands over days or weeks to 5–30 cm (2–12 in.) in diameter (see figure). It may have partial central clearing (bull's eye) or look like a bruise in clients with dark skin. It occurs in about 70%–80% of cases, an average of 7 days after the tick bite (CDC, 2014f). The client may only have fever, chills, fatigue, body aches, malaise, and swollen lymph nodes. Some clients have both the rash and illness. ***Early disseminated disease (EDD):*** In 3–10 weeks after the tick bite, multiple smaller erythema migrans lesions, generalized lymphadenopathy, and fatigue. Meningitis, facial nerve palsy, carditis, and migratory muscle and joint pain may occur. ***Late disseminated disease (LDD):*** In 2–12 months, Lyme arthritis develops, commonly in the large joints such as the knee. Joint swelling, pain, and tenderness are seen. ***Complications:*** Left untreated, Lyme disease progresses to LDD with cranial nerve palsies, carditis, encephalitis, or meningitis.	***Diagnostic testing:*** Enzyme-linked immunosorbent assay (ELISA) plus the Western blot test. ***Medical management:*** Oral amoxicillin, cefuroxime axetil, or doxycycline for 14–21 days for LD, 21–28 days for EDD, and up to 28 days for LDD. Intravenous antibiotics may be administered for up to 28 days for persistent arthritis, carditis, meningitis, or encephalitis. ***Prognosis:*** Treatment during LD or EDD rarely progresses to LDD. May result in significant morbidity when chronic Lyme disease develops. ***Prevention:*** No vaccine is available. There is no acquired immunity, so reinfection may occur. Avoid areas that are heavily tick infested, and wear protective clothing. Check for ticks (especially hidden in hair) after every outing. Check pets that may carry home ticks that can transfer to the child. Remove ticks as soon as possible.	• Use standard precautions if the child is hospitalized. • Educate parents about the importance of giving the full course of antibiotics. • Have the child avoid sun exposure when taking doxycycline. • Provide nonaspirin analgesics and antipyretics for relief of fever, headache, and muscle or joint aches. • Children with Lyme disease may tire easily. Promote rest and avoid vigorous activities. • Teach parents to safely remove ticks. Grasp the tick gently but firmly with fine-point tweezers where the mouthparts are attached. Pull gently until the tick releases. Clean the area with soap and water.
MALARIA			
Causal agent: *Plasmodium*, four species (*P. falciparum, P. vivax, P. ovale, P. malariae*) ***Epidemiology:*** Occurs in tropical and subtropical regions on four continents (Africa, Americas, Asia, and Oceana). Children have the highest mortality. The disease is acquired during travel to an endemic area, most often among immigrants visiting their home country who did not take preventive measures. *P. falciparum* causes the most serious disease. In 2011, 1947 cases were reported in the United States; 15% of all reported cases occurred in children 18 years old and younger (Cullen & Arguin, 2013).	Malaria begins with nonspecific signs such as high fever alternating with chills, profuse diaphoresis, and fatigue. Periods of symptomatic improvement may be seen between cycles lasting 48 or 72 hr depending upon type of infection. Children may also have fever, anorexia, vomiting, jaundice, splenomegaly, and anemia. Additional symptoms include nausea, vomiting, diarrhea, cough, tachypnea, arthralgia, and body aches. Attacks may recur over the course of the year after infection, but the parasites die out gradually if no reinfection.	***Diagnostic testing:*** Blood smears for parasites, or a PCR assay. A rapid malaria test is available. Blood tests may show anemia and thrombocytopenia. ***Medical management:*** The child is hospitalized for fluid replacement, anemia management, and antipyretics. The blood is regularly monitored for parasite density. IV or oral antimalarial medication (e.g., chloroquine, quinine sulfate, doxycycline, mefloquine, and atovaquone-proguanil) is selected based on region visited and resistance of species to the medication. Hypoglycemia may result from quinine treatment or because parasites consume large quantities of glucose.	• Use standard precautions. • Maintain fluid intake. Monitor intake and output. • Monitor the hematocrit and hemoglobin, as well as the blood glucose level. • Observe for signs of increasing illness severity such as confusion, seizures, and shock. Be prepared to protect the child from injury and provide emergency support with airways and oxygen until the child can be transferred to the ICU. • Administer antipyretics to control the fever and promote comfort.

(*continued*)

TABLE 16–6 Selected Infectious Diseases Transmitted by Insect or Animal Hosts (Zoonosis) (*continued*)

DISEASE	CLINICAL MANIFESTATIONS	CLINICAL THERAPY	NURSING MANAGEMENT
MALARIA (*continued*)			
Transmission: An infected female mosquito introduces the parasite through a bite. The parasite infects hepatic cells and reproduces leading to hepatic cell rupture. Parasites are released and infect the red blood cells. Transmission can occur by blood transfusion or transplacentally ***Incubation period:*** Varies by type, generally 8–25 days after a mosquito bite, but may be up to 1 year. ***Period of communicability:*** Communicable by blood, blood product transfusion, or organ transplant from an infected person.	Children who live in endemic areas and survive the first 5 years of life develop immunity to the severe effects of the disease as long as they have frequent reexposure to the infection. ***Complications:*** Severe anemia and cerebral malaria in young children. Pulmonary edema, respiratory failure, renal failure, spontaneous bleeding, and shock in older children and adolescents. Children with asplenia are at high risk for death.	Children may need blood transfusions. Primaquine may be prescribed to prevent relapse. ***Prognosis:*** Certain species have dormant liver-stage parasites, which can reactivate several months or years after initial infection. ***Prevention:*** While traveling in endemic areas, use DEET insect repellent, screened rooms, DEET-treated mosquito netting, and cover the body with light-colored clothing. Antimalarial chemoprophylaxis may be prescribed when traveling in an endemic region. A vaccine is being tested in children. This is a reportable disease.	• Educate families traveling to endemic areas about the need for and correct administration of antimalarial drugs, despite the nausea and vomiting side effects. • Discuss protecting children during mosquitoes' nocturnal feeding times with protective clothing, mosquito repellent, and mosquito netting around the bed.
RABIES (HYDROPHOBIA)			
Causal agent: *Lyssavirus* in the Rhabdoviridae family, two types (urban, in dogs; wild, in wildlife). ***Epidemiology:*** Occurs worldwide. Urban rabies is generally controlled by vaccination of dogs and cats. The most common carriers of rabies are raccoons, bats, skunks, and foxes (CDC, 2013e). ***Transmission:*** Infected saliva from the bite of a rabid animal introduces the virus into the wound. The virus travels along the nerves to the brain where it multiplies and migrates along the efferent nerves to the salivary glands. Rare cases of human-to-human transmission through exposure to mucous membranes, aerosol droplets, and organ transplant. ***Incubation period:*** Highly variable but usually 1–3 months.	No signs during the long incubation period. ***Prodromal stage:*** Over 2–10 days the child has fever, headache, malaise, apprehension, and paresthesia at the site of the bite. ***Neurologic stage:*** Cerebral signs of agitation, anxiety, confusion followed by abnormal behavior, delirium, hallucinations, and insomnia. The child progresses to coma and respiratory failure. ***Complications:*** Usually results in death.	***Diagnostic testing:*** Confirmed by direct fluorescent antibody staining of the dead animal's brain tissue or detection of the virus in the client's saliva or cerebrospinal fluid. ***Medical management:*** Immediately wash animal bites thoroughly with soap and water and irrigate well with a virucidal agent such as povidone-iodine. Antibiotics and wound suturing are determined for individual cases. Postexposure prophylaxis—1 dose of human rabies immune globulin (HRIG) and human diploid cell rabies vaccine (HDCV) is given IM the day of the bite when the animal may be rabid. HRIG is infiltrated locally around the bite with remaining volume given IM at a site distant from the vaccine. HDCV is repeated on days 3, 7, and 14 after the bite (4 doses) (CDC, 2013e). The vaccine is of no value once rabies symptoms are present. ***Prognosis:*** Usually fatal. ***Prevention:*** Immunize all domestic animals against rabies.	• Alert the local animal control to find and quarantine the unimmunized animal for observation. • Administer human rabies immunoglobulin (HRIG) and human diploid cell vaccine (HDCV) as ordered. Inject vaccine into the muscle to prevent vaccine failure. • Support the family while reinforcing the urgency for the vaccine and series of injections. • Educate parents about the vaccine side effects—irritation and itching at the injection site, headache, muscle aches, nausea, and dizziness. • If the child acquires rabies, the child will be hospitalized. Use standard and contact precautions. • Make the child as comfortable as possible. • Keep liquids out of sight of the hydrophobic child. • Provide emotional support to the family of the dying child. • Teach children to avoid contact with all unknown animals, dead or alive. • Participate in local education about rabies and safe interactions with dogs. See Chapter 31.

DISEASE	CLINICAL MANIFESTATIONS	CLINICAL THERAPY	NURSING MANAGEMENT
ROCKY MOUNTAIN SPOTTED FEVER (TICKBORNE TYPHUS FEVER, SAO PAULO TYPHUS)			
Causal agent: *Rickettsia rickettsii,* a gram-negative coccobacillus. ***Epidemiology:*** Occurs throughout the United States, southern Canada, and Central and South America. In the United States, 60% of cases occur in North Carolina, Oklahoma, Arkansas, Tennessee, and Missouri (CDC, 2013f). Most infections generally occur between April and September. ***Transmission:*** Transmitted by bites of ticks, principally dog and wood ticks. ***Incubation period:*** 2–14 days (most commonly 7 days) after bite of an infected tick. ***Period of communicability:*** There is no evidence of person-to-person transmission. Science Source	Onset may be gradual or rapid with vague signs that mimic other diseases. Early symptoms are fever, malaise, headache, muscle aches, anorexia, nausea, vomiting, and diarrhea. The red maculopapular rash that blanches generally occurs 2–5 days after the fever. It appears first on the wrist, forearms, and ankles and then spreads to trunk and sometimes the palms and soles (see figure). The rash may be difficult to see on children with dark skin. A petechial rash appearing about day 6 is a sign of progression to severe disease. ***Complications:*** Vasculitis resulting in bleeding, disseminated intravascular coagulation (DIC), reduced circulation resulting in gangrene of digits or extremities, and neurologic deficits.	***Diagnostic testing:*** Immunofluorescent antibody testing; direct immunofluorescence or immune-peroxidase tests may be performed on skin biopsies. Blood test may reveal thrombocytopenia. ***Medical management:*** Doxycycline regardless of client's age for 7–14 days (at least 3 days after fever subsides). The client with severe disease needs IV antibiotics. ***Prognosis:*** Delay in treatment can cause severe disease. A mortality rate of 1% is associated with delayed treatment (CDC, 2013f). ***Prevention:*** Avoid areas that are heavily tick infested, and wear protective clothing. Check children for ticks and remove promptly if found.	• Use standard precautions. • The child may require care in the ICU. Have hemodynamic monitoring equipment and emergency supplies readily available. • Administer antibiotics as ordered. • Observe for any purpura development or abnormal bleeding. • Make the child as comfortable as possible. • Provide quiet diversion activities. • Provide emotional support, and keep parents informed about the child's condition. • Educate parents about prevention and the appropriate technique for tick removal.

ANTIBIOTIC USE

Antibiotics are often prescribed to treat bacterial infectious diseases; however, strains of bacteria have developed resistance to many antibiotics. Examples are community-acquired methicillin-resistant *Staphylococcus aureus* and drug-resistant strains of tuberculosis. Children with chronic conditions may be more susceptible to infection by drug-resistant pathogens. Many specialty organizations and medical centers have developed best practice guidelines for the use of antibiotics in treating common infections, such as acute otitis media.

Antiviral medications may be prescribed for viral infections, such as chickenpox and influenza. When the child is immunocompromised, antiviral medication should be started early to minimize the potential life-threatening consequences of the infection.

Cases of many communicable diseases must be reported to the state health department, using standardized state forms or on a designated website.

Nursing Management

For the Child With a Communicable Disease

Nursing Assessment and Diagnosis

Assess the child's hydration status and fluid intake, vital signs, comfort level, and appetite. Observe for seizures and for a **toxic appearance** (lethargy, poor perfusion, hypoventilation or hyperventilation, and cyanosis). The child with a fever may be irritable and restless, sleep fitfully, and have nonspecific muscular pain. Identify febrile children who may be at higher risk for a serious illness, in particular:

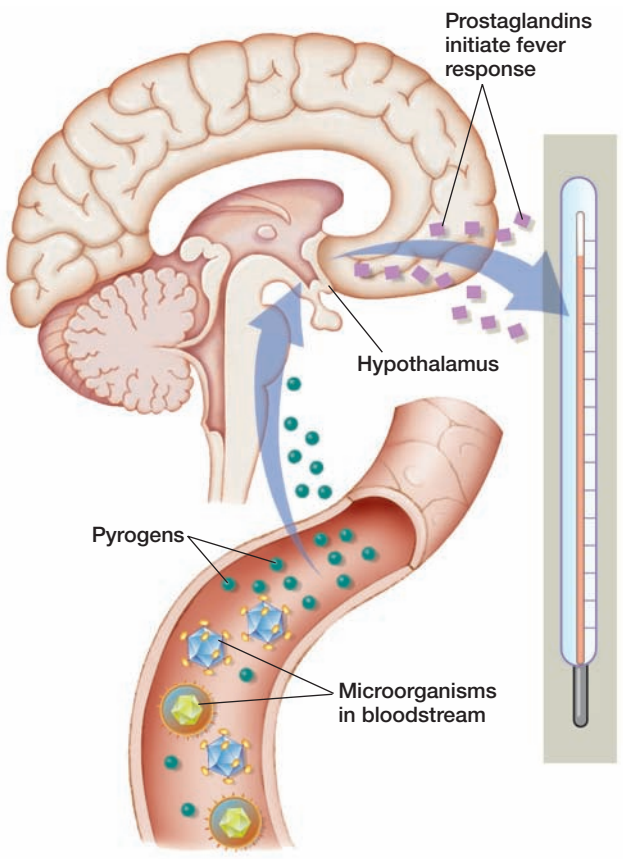
- Infants and children having a toxic appearance.
- Newborns less than 28 days of age with a temperature over 38.0°C (100.4°F).
- Children less than 4 years of age with a temperature over 41.0°C (105.8°F).
- Children with conditions such as a congenital heart disease, ventriculoperitoneal shunt, asplenia, and sickle cell disease.

Observe the child for other signs of infection, such as a rash, nausea and vomiting, or diarrhea, as well as generalized symptoms of a poor appetite, muscle aches, and malaise.

The following nursing diagnoses may be appropriate for children with communicable diseases (NANDA-I © 2014):

- ***Hyperthermia*** related to infectious disease process
- ***Skin Integrity, Impaired,*** related to skin lesions and scratching
- ***Mucous Membrane: Oral, Impaired,*** related to infectious disease process
- ***Fluid Volume: Deficient*** related to repeated episodes of vomiting and diarrhea
- ***Health Management, Family, Ineffective,*** related to complexity of care required by child

Pathophysiology Illustrated: **Fever**



The hypothalamus functions as the body's thermostat, directing the body to conserve or dissipate heat. When microorganisms invade the body, endogenous pyrogens (interleukins, interferons, and tumor necrosis factor) are released by macrophages into the bloodstream. These substances travel to the hypothalamus where they trigger the production and release of prostaglandins, resulting in the fever response. A rise in the hypothalamus's set point leads to heat generation with shivering and chills, vasoconstriction, and decreased peripheral perfusion. Blood is diverted from the extremities to more central vessels to decrease heat loss. Shivering increases both metabolic action and heat production. The hypothalamus then maintains the temperature at the new set point. When the temperature is elevated, the heart rate, respiratory rate, and metabolic rate increase. Vasodilation occurs and the skin flushes, becoming warm to the touch.

Planning and Implementation

Most children with communicable diseases are cared for at home; however, infected children are seen in all healthcare settings. Nursing care includes collecting cultures, providing supportive care, administering antibiotics on schedule, monitoring antibiotic blood levels if indicated to ensure appropriate results, promoting the child's comfort, and educating parents.

PREVENT DISEASE TRANSMISSION

Nursing care of children with communicable diseases in healthcare settings focuses on preventing the spread of infection. Isolate children with suspicious rashes and respiratory infections. Cover draining wounds and dispose of dressings appropriately. All items with which the infected child comes into contact are considered contaminated (e.g., linens, toys, medical equipment). Use standard precautions and good hand hygiene. Recall that the fecal–oral and respiratory routes are the most common routes of transmission in children. Wipe down hard surfaces in the examining room with an antiseptic solution before another child uses the room. If possible, wipe down toys in the waiting room daily with a nontoxic antiseptic solution. Dispose of linens in appropriately marked linen bags. Ensure that all healthcare providers are fully immunized or that unimmunized or pregnant healthcare providers are not exposed to children with certain infections (e.g., pertussis, rubella, or varicella). See *Families Want to Know: Reducing the Transmission of Infection* earlier in this chapter.

Children with severe infections are often admitted to the hospital for treatment. In addition, countless numbers of **nosocomial** (hospital-acquired) **infections** occur each year. Follow the facility's standard and transmission-based precautions to reduce the spread of infectious diseases to staff and other children. Discuss any concerns with the hospital's infection control nurse. (See the *Protective Methods* chapter in the *Clinical Skills Manual* SKILLS for more detailed information.)

FEVER MANAGEMENT

Nursing care for treatment of fever includes removing unnecessary clothing, encouraging increased fluid intake, and administering nonaspirin antipyretics. Identify clear fluids the child prefers to drink to encourage greater intake. Parents often fear a fever, believing it is a disease rather than a symptom of an illness. Provide information and reassurance. Help them to recognize signs that the child's condition is worsening. See *Families Want to Know: Guidelines for Evaluating and Treating Fever in Children*.

EDUCATING THE FAMILY

Teach parents to care for their child at home. This includes how and when to give antipyretics and antibiotics if ordered, when over-the-counter medications may be used, appropriate fluids and foods to provide, and the care of rashes and other symptoms.

Teach parents to give all the antibiotic doses for the full number of days prescribed. Help develop a schedule that matches the family's routines. Make sure family members know whether to give the antibiotic by mouth with or without food or apply topically. Inform them to discard the antibiotic when all doses have been given, and not to share the antibiotic with any other family member. These efforts will help fully treat the infection and reduce the chance that the infectious organism develops resistance to the antibiotic.

Families Want to Know

Guidelines for Evaluating and Treating Fever in Children

Facts about fevers:

- A fever is not a disease; it is the body's response to an infection. It means the child's body is using natural defenses to fight an infection.
- If the child has a fever and does not look sick, it may be better to let the child use natural defenses to fight off the virus or bacteria causing the fever.

Treating the fever:

- Use a thermometer to check the child's temperature every 4 to 6 hours, or more often if the fever returns.
- Use acetaminophen or ibuprofen (do not use aspirin) to lower the temperature. Use the correct dose and preparation for the child's weight, and mark down when the medication is given. Do not exceed the number of doses per day listed on the bottle to prevent an overdose. If the child is taking a cold medication with acetaminophen, call the healthcare provider for advice about acetaminophen dosage.
- Remove all but a light layer of the child's clothing.
- Monitor the child's behavior and response to fever medication. The medication will reduce the child's temperature. The temperature may rise again in 4 to 6 hours after the medicine has worn off. Check the temperature and give another dose of medication. The temperature will return to normal when the child is recovering from the illness.
- Sponging the child is not recommended. The lukewarm water may increase shivering and discomfort. Do not use alcohol for sponge baths.
- Give the child lots of fluids to drink and allow the child to rest.

Contact your healthcare provider immediately if:

- The infant is under 2 months old and has a fever over 38.0°C (100.4°F).
- The child has a fever over 40.1°C (104.2°F) and any of the following symptoms:
  - The child acts or looks very sick.
  - Inconsolable crying or whimpering. The child cries when moved or otherwise touched by the parent or other family members.
  - Difficult to awaken.
  - A stiff neck.
  - Purple spots on the skin.
  - Difficulty breathing that does not improve after the nose is cleared.
  - Unable to swallow and drooling saliva.
  - The child has a seizure.

Call your healthcare provider within 24 hours if:

- The child is 2 to 4 months old (unless fever occurs within 48 hours of a DTaP shot and the infant has no other serious symptoms).
- The child's fever is higher than 40.1°C (104.2°F), especially if the child is younger than age 3 years.
- The child complains of burning or pain with urination.
- The fever has been present more than 24 hours without an obvious cause or location of infection.
- The fever went away for more than 24 hours and then returned, or the fever has been present for more than 72 hours.

SAFETY ALERT!

Acetaminophen and ibuprofen preparations are available as infant drops, liquid syrup, chewable tablets, and adult-strength tablets or capsules. Identify the preparation used in the home to recommend the correct dosage for the child. The dose of acetaminophen is 10–15 mg/kg/dose and of ibuprofen is 4–10 mg/kg/dose. Alert parents that many over-the-counter medications also contain acetaminophen or ibuprofen; they should not be used at the same time as the antipyretic for fever to prevent an overdose.

ACETAMINOPHEN	IBUPROFEN
Infant drops—160 mg/5 mL using package dispenser	Infant drops—50 mg/1.25 mL using package dispenser
Children's liquid—160 mg/5 mL	Children's liquid—100 mg/5 mL
Chewable tablets—80 mg and 160 mg	Chewable and junior tablets—50 mg and 100 mg
Adult tablets or caplets—325 mg and 500 mg	Adult tablets or caplets—200 mg

Educate parents about methods to reduce disease transmission in the home. Encourage parents to limit the exposure of elderly family members, those with impaired immunity, infants, and visitors to the ill child. Make sure that the ill child's dishes and utensils are washed in hot soapy water or sanitized in a dishwasher. Place dressings with drainage in a plastic bag for disposal to prevent contact by other family members.

Encourage children to rest. Provide quiet diversional activities such as board games, computer games, DVDs, and music. Promote fluid intake and provide foods that the child prefers and do not cause discomfort. Reduce itching of rashes with lukewarm baths with Aveeno or oatmeal and topical lotions. Keep the child's hands clean and nails trimmed. Cover the hands with clean socks or mittens if scratching cannot be controlled.

Evaluation

Expected outcomes of nursing care include the following:

- Opportunities for spread of infection between clients and family members are minimized.
- The child's fever is effectively managed with antipyretics.
- The full treatment with antibiotics, if ordered, is completed.

Sepsis and Septic Shock

Sepsis or septicemia is a systemic inflammatory response syndrome (SIRS) in the presence of infection, such as bacteria invading the bloodstream. Infants and children who are at high risk include those with a chronic condition, burns, multiple invasive procedures, invasive catheters, a compromised immune system, or those on long-term antibiotics. Severe sepsis that progresses to septic shock is a significant health problem with an estimated in-hospital mortality rate of up to 10% (Hazinski, Mondozzi, & Baker, 2014).

Sepsis is caused by the effects of the infectious agent and its toxins. At least one of these significant events leads to the development of sepsis: an infectious agent causes severe tissue injuries that result in multiple system organ failure, the child's excessive inflammatory response triggers a secondary response, or counterregulatory mechanisms are ineffective (Roberts & Coffin, 2013). Septic shock results from a disrupted balance between proinflammatory mediators and anti-inflammatory mediators. The disrupted inflammatory mediators lead to greater tissue injury, abnormalities in coagulation and fibrinloysis, disseminated intravascular coagulation (DIC), vasodilation, major organ dysfunction, and increased susceptibility to other infections (see Chapter 23 for more information on DIC). Fibrin deposits in the microcirculation disrupt the blood flow and the delivery of oxygen and nutrients to the tissues. Cellular hypoxia and major multiple organ system dysfunction result.

Early signs of SIRS in children include fever or hypothermia, tachycardia, and tachypnea. Signs of septic shock include fever, tachycardia, tachypnea, and inadequate perfusion (altered responsiveness, prolonged capillary refill time, either diminished or bounding pulses, mottled cool extremities, and decreased urine output). Hypotension may be present despite adequate fluid resuscitation.

Diagnosis is often suspected from clinical signs and symptoms. Cultures of the blood, urine, cerebrospinal fluid, and skin lesions are obtained, as well as a complete blood count with differential. The white blood cell count may be elevated or low for age. Clinical therapy focuses on preserving vital organ function with oxygen, IV fluid resuscitation, vasopressor medications, and antibiotics. The treatment plan focuses on restoring the blood pressure, returning the heart rate and capillary refill rate to more normal levels, maintaining the cardiac output, and increasing oxygen delivery to the tissues and vital organs. Acid–base, glucose, and electrolyte level imbalances are managed. Enteral or parenteral nutritional support may be initiated early. Septic shock may progress to cardiac arrest if interventions are unsuccessful.

Nursing Management

Nursing care of the infant or child with sepsis occurs in the neonatal or pediatric intensive care unit. Nursing care of children with sepsis involves careful assessment and management of the child's vital signs, fluid and electrolyte balance, perfusion, hemodynamic stability, and response to clinical therapy. Families need extensive support for this life-threatening infection. Encourage the parents to participate in the child's care as much as possible. Observe for signs that the condition is worsening or resolving.

Emerging Infection Control Threats

Public health officials are conducting disease surveillance to identify emerging infections, such as **pandemic flu**, a worldwide influenza epidemic, or other epidemics such as Ebola and Zika virus. Some infectious agents have the potential to be weapons of terrorists (anthrax, smallpox, plague, botulism, hemorrhagic fever, or tularemia). Early recognition and reporting of clusters of patients with similar symptoms is essential to initiate public health measures that will reduce disease transmission. Additionally, confirmation of an epidemic triggers the mass casualty response needed to care for large numbers of ill adults and children. See Table 16–5 for influenza information.

Nursing Management

Maintain a high level of suspicion when greater than the expected number of individuals with similar signs and symptoms come to school or seek care in any healthcare facility. Initiating airborne and contact precautions and instituting isolation before a definitive diagnosis is appropriate when the level of suspicion is high. Assess children and provide supportive nursing care for the identified infection.

Chapter Highlights

- Reducing the number of preventable childhood illnesses is a major national public health goal.
- A communicable disease is an illness caused by microorganisms that are commonly transmitted from one host (animal or human) to another.
- Newborns and infants are especially vulnerable to infectious diseases because their immune systems are immature, their passively acquired maternal antibodies provide limited protection, and disease protection through immunization is not yet complete.
- For a child to acquire a communicable disease, an infectious agent or pathogen, an effective means of transmission, and a susceptible host need to be present.
- Infection control measures caregivers can take include the following: good hand hygiene with soap and water or alcohol-based gels, disinfecting hard surfaces touched by the child or the child's body fluids, disinfecting toys, and making sure all children are fully immunized.
- The average infant born in 2016 will receive immunizations for 16 communicable diseases by 18 years of age.

- The Vaccines for Children program provides free immunizations for low-income children to ensure that finances are not a barrier to full immunization of those children.
- When parents resist immunizations for religious or philosophical reasons, the nurse should provide them with accurate information and help them understand how their child may benefit from immunization. If they still resist, inform them that their child may be at a significant risk for an infection and will need to be held out of school if an outbreak occurs.
- The potency of vaccines must be protected with storage in the refrigerator or freezer at the appropriate temperature.
- The National Vaccine Injury Acts of 1986 and 1993 provide compensation if a link between immunization and a serious adverse effect is found. The Vaccine Adverse Event Reporting System has been established to track serious vaccine reactions.
- Immunization information is updated frequently. It is the nurse's responsibility to regularly obtain current information about vaccines, immunization schedule, and important information to share with parents and adolescents.
- Infectious and communicable diseases are caused by bacterial, viral, protozoan, or fungal organisms.
- Fever is often a sign of infectious disease in children. When pathogens invade the body, endogenous pyrogens travel to the hypothalamus, where they trigger the production and release of prostaglandins, which initiate the fever response.
- The child with a toxic or septic appearance has the following signs: lethargy, poor perfusion, tachypnea or bradypnea, and pallor or cyanosis.
- The appropriate use and administration of antibiotics to help reduce the development of antibiotic-resistant bacteria includes the following: Give antibiotic dosages as prescribed for the full number of days ordered, do not share with other family members who might be ill, and discard when all doses have been given.
- Sepsis is a systemic response to infection that has a high mortality rate.
- The public health system conducts disease surveillance to detect the emergence of rare infections, an epidemic, or the presence of infectious disease potentially caused by terrorists.

Clinical Reasoning in Action

Keisha, 7 years old, and Brandon, 6 months old, are brought to the pediatric clinic, needing immunizations. Even though Brandon is sick today, their mother would still like Keisha to have her vaccines, and she would also like both children to have a complete checkup before their vaccines to make sure they are healthy.

You examine Keisha's vital signs as: 80th percentile in height, 40th percentile in weight, temperature 98.9°F, blood pressure 105/62 mmHg, urinalysis with a trace of leukocytes, and she passes her hearing and vision screening. She seems extremely anxious about having to get a needle. There is evidence of eczema and allergic rhinitis.

You examine Brandon as a sick visit while he clings to his mother. His vital signs are: temperature 102°F, respiratory rate of 30 breaths per minute, and heart rate of 90 beats per minute. In Brandon's mouth, grayish, papulovesicular, ulcerative lesions are observed, evidence of an enterovirus. This type of illness does not respond to antibiotics. You advise the mother to avoid exposing Brandon to other persons because it is contagious and to offer cool drinks and bland foods. You also suggest that warm saline mouth rinses may be helpful if Keisha develops the illness. You advise the mother to observe for dehydration, and to give ibuprofen or acetaminophen as needed.

1. Since Brandon has been in to the office several times for various infections, what education can be given to his mother to reduce the chances of future infections?
2. Keisha has eczema and allergic rhinitis. Would this be a contraindication to giving vaccines?
3. What are questions the nurse should ask the mother before administering vaccines to Keisha to make sure there are no contraindications to giving them?
4. What should the mother be told about caring for Keisha after her vaccines?
5. How should the mother be told to manage Brandon's fever?

Chapter 17
Social and Environmental Influences on the Child

Steve Skjold/Alamy

Amy has always been a challenge! She has already left home a couple of times and lived on the streets, which was very hard on us. Lately, she has been more interested in school and is living at home and trying to do well. We want her to succeed and learn the skills she needs in her life. I wish she would not have all of these body piercings, but we don't want to make too big an issue of it as long as she is doing well in school.

—Mother of Amy, 15 years old

Learning Outcomes

17.1 Identify major social and environmental factors that influence the health of children and adolescents.

17.2 Apply the ecologic model and resiliency theory to assessment of the social and environmental factors in children's lives.

17.3 Examine the effects of substance use, physical activity, and other lifestyle patterns on health.

17.4 Plan nursing interventions for children who experience violence.

17.5 Evaluate the environment for hazards to children, such as exposure to harmful substances and potential for poisoning.

17.6 Explore the nursing role in prevention and treatment of child abuse and neglect and other forms of violence.

17.7 Plan nursing interventions for children related to social and environmental situations.

Many of the major causes of mortality and morbidity in children and adolescents are closely linked with social influences in the child's world. The social contexts for young children growing up today are different from those of even a decade ago. Examining the social contexts in which children live and grow can provide insights into behavior, and present opportunities for nursing interventions. All nurses must examine the social influences and apply the knowledge gained to plan health care that will benefit youth as they grow into adulthood.

Children and adolescents are also influenced by their environments. The physical setting, exposure to chemical agents, and other environmental factors are increasingly identified as being instrumental in determining health. Nurses assess the environment for its risk and protective factors, and then use this information to plan nursing care appropriate to enhance the health status of children and adolescents.

What are the settings where nurses might work with youth in the community? What are the challenges of today's society that children must often face at very young ages? How can nurses help children face these challenges and emerge as healthy and contributing members of society? What roles do nurses play in identifying and using the protective factors and in minimizing the risk factors of youth? This chapter will examine and apply these social and environmental concepts in a variety of nursing settings.

Examine again the major causes of death for children from 1 year of age through adolescence that are presented in Chapter 1. Notice that most morbidity is related to preventable causes linked to present-day lifestyles. Car crashes, fires, drowning, and homicides are a few examples of common causes of death in children and adolescents.

Respiratory conditions and injuries are major causes of hospitalization in children. By the teen years, pregnancy and mental disorders are the most common admitting diagnoses to hospitals (Agency for Healthcare Research and Quality, 2013). All of these conditions are related, at least in part, to the social and environmental settings in which children live. These settings and their influences must be examined to understand how best to intervene with children. Consult other chapters for additional information on related topics. For example, Chapter 4 fully discusses growth and development of children, Chapter 9 addresses health promotion topics of adolescents including homosexuality, Chapter 12 discusses chronic conditions, and Chapter 28 details cognitive variations and mental health issues such as suicide.

Basic Concepts

In this chapter, two main theories provide a framework for examining societal influences on children. The ecologic and resiliency theories are discussed in Chapter 4, and should be reviewed now to assist in evaluating the environmental settings that influence children.

The ecologic theory views the child and the environment as interacting forces, with children influencing systems around them, even while they are influenced by these systems (Bronfenbrenner, 2005). The systems with which the child has daily contact are microsystems (e.g., family, child care, school), but other systems such as parental work and political or cultural environments are also important. Understanding these systems, or the forces in which children function, can provide information that guides healthcare providers. For example, if the parents' employers do not provide healthcare insurance, their children may not get needed health care such as immunizations, treatment for diseases, and growth monitoring.

Resiliency theory examines risk and protective factors in the child's environment and their influence on the child's ability to adapt to stressful events. Such factors can be modified to lead to more productive and healthy outcomes. Resilience is the ability to exhibit healthy responses even when faced with significant stress and adversity (see Chapter 4 for a further description of resiliency theory) (Benard, 2014; Henderson, Bernard, & Sharp-Light, 2007). Families may have protective factors that provide strength and assistance in dealing with crises and risk factors that contribute to healthcare challenges. For example, if a young child is hospitalized for treatment of an acute infectious illness, some **protective factors** might include the ability of one parent to stay with the child at all times, the ability of a grandmother to care for siblings at home during this time, and the child's ability to adapt to new situations and communicate readily with staff members. On the other hand, **risk factors** might include lack of comprehensive health insurance to pay for the hospitalization, lack of an identified healthcare "home" (consistent healthcare provider) for the child, and incomplete immunizations. The concepts of resiliency theory can be applied to Amy's family as described in the chapter-opening quotation. She experienced disruption in family stability. The risk and protective factors interacted with her own personality in ways that resulted in her desire to be an independent person, establishing her identity through body art, and, finally, a desire to return to school.

The National Longitudinal Study of Adolescent Health was conducted with over 100,000 adolescents in the United States, and found that parent–family connectedness, school connectedness, a belief in a higher being, and academic success were predictive of youth having lower health risks. Follow-up interviews are currently being carried out with the participants, who are now young adults; the resulting longitudinal data will show what characteristics and influences persist into adult life (Add Health Study, 2014). Nurses can assist adolescents and their families in establishing a sense of attachment to each other. Encourage families to include adolescents in activities, attend their sports and other school events, have meals together regularly, and attend faith-based activities or other community events as a family.

Theoretical frameworks are discussed in Chapter 4 and are useful when examining social and environmental influences on children because they guide us to examine certain factors that can be altered or understood. They suggest the assessment data to collect and pertinent nursing interventions to use. They also foster partnerships with other care providers who use these and similar theories to plan social, psychologic, and other types of care for children and their families.

Social Influences on Child Health

Poverty

An important risk factor that influences the health of children is poverty. Conversely, basic financial stability is a protective factor that contributes to the general health and well-being of children. Twenty percent (14.7 million) of U.S. children are poor and living in a family earning less than $23,624 annually for a family of four (Federal Interagency Forum on Child and Family Statistics, 2015).

Children who are poor are more likely to have unmet health needs, to have difficulty in school, to become teen parents, and to experience multiple health problems, including stunted growth and lead poisoning. Inadequate or unsafe housing, food insecurity, and poor dietary quality are more common (Federal Interagency Forum on Child and Family Statistics, 2015). What is the face of poverty? Some statistics that may prove surprising include the following:

- Children most likely to be living in poor households are those below 5 years of age.
- About 48% of children living in a single-headed household are poor, whereas only 11% in married-couple households are poor.
- Ethnic variations are startling: 13% of White children, 39% of African American children, and 34% of Hispanic children live in poverty.
- Poverty rates are higher in suburban and rural areas than in central cities.
- Nearly 70% of poor children have at least one parent working full time (Federal Interagency Forum on Child and Family Statistics, 2015).

Poverty leads to homelessness for some children. Families with children are the fastest growing group of homeless people; families experiencing homelessness comprise one third of the total homeless population. Each year, 1 in 30, or 2.5 million, children experience homelessness (National Center on Family Homelessness, 2015). The reasons for homelessness are also common risks for a number of the other challenges to health discussed in this chapter, including poor finances, abuse or other violence, and mental instability.

Children who experience homelessness often have multiple physical and mental health problems, and lack health insurance to provide care for these problems. Some of the common problems faced by homeless children and families include trauma, substance use, respiratory and skin infections, tuberculosis and HIV, and nutritional disorders. Children may have developmental delays, learning problems, or growth disruptions (American Academy of Pediatrics Council on Community Pediatrics, 2013; Kerker et al., 2011). Teens who have been homeless are more likely to engage in risky behavior such as unprotected sex, sex with multiple partners, and substance abuse. They are more likely than other teens to need emergency care, to be depressed or have some other mental illness, and to become pregnant (National Center on Family Homelessness, 2015).

Health problems related to homelessness, and other family characteristics, continue even after finding a place to live. Even after families leave homeless shelters, children frequently become separated from their mothers because of parent stress, lack of access to resources, and inability of parent(s) to provide adequate homes for the children. Complex, ongoing care is needed. This may begin in a shelter for the homeless, but should continue while the family obtains a place to live, accesses other community services, gets the children safely enrolled in school, and has financial and mental stability.

Nursing management for families with children that are poor or homeless focuses on identification of poverty, careful assessment of health risks, and linking the family to resources that can assist with stability and health. There is often no way to identify a poor child from appearance, and they may hide their status when they are in school or come to a healthcare facility. Addresses given may not be accurate, or the address of a shelter might be used. Children living at shelters or in cars and on the street usually do not take the school bus but prefer to walk to avoid stigma. Alternatively, they may be picked up by the bus first, and dropped off last, to reduce embarrassment. Be alert for children who have multiple health problems and repeated infectious diseases. They may be hungry and without adequate nutrition either at times or consistently. Degrees of personal hygiene may vary depending on access to laundry and bathing facilities. See Table 17–1 for examples of nursing care needs for homeless children and families. See *Evidence-Based Practice: Developmental and Health Implications of Homelessness*.

Stress

The adverse effect of stress on adults is well documented and the impact of stress on children has also been recognized. Stress can be acute, such as when a child has an argument with a friend, a test in school, or a family crisis. Stress can also become chronic when the family frequently does not have enough food, when fighting or abuse is frequent, or when the child is overscheduled and feels under constant pressure to perform (Elkind, 2007). Children manifest stress in a variety of ways, including regressive behavior, interrupted sleep, hyperactive behavior, gastrointestinal symptoms, crying, and withdrawal from normal events. Common stressful events for children include moving to a new home or school, marital difficulties in the family, abuse, one or both parents deployed in the military (Figure 17–1), and being expected to achieve at an extremely high level in school or sports. The busy pace of today's lifestyles and the media's encouragement of early development in children may put undue stress on some children and preteens (Elkind, 2007). Adolescents may be stressed by fulfilling many roles, such as student, part-time worker, and active member of a family. They may be in school all day, be in sport or music practice for 2 to 3 hours after school, and then have a job for several additional hours. Lack of adequate sleep is common and adds further to stress, in addition to putting the teen at risk for car crashes and poor school performance. For poor families, commonly reported stressors are related to food, shelter, transportation, medical care, and personal-time needs.

EVIDENCE-BASED PRACTICE | Developmental and Health Implications of Homelessness

Clinical Question

Children are the age group showing the fastest growth in homelessness. Because of their ages, children are vulnerable to developmental delays, mental health problems, poor school achievement, and effects of violence. Mothers are the main support for young children, but when they are homeless, they may not be able to provide the care children need for healthy growth and development. Most nurses have not been homeless and do not understand the experience of homelessness for children. What is the experience of homelessness like for children?

The Evidence

A 15-week nutrition education and physical activity program in a homeless shelter had 162 child participants. The researchers found that the children's past experiences of hunger and food insecurity influenced their present food choices. Their life experiences must be understood to influence changes in nutrition (Rodriguez, Appelbaum, Stephenson-Hunter, et al., 2013). Children from 11 to 14 years in a homeless shelter reported 13 times less suicide ideation following family strengthening approaches to care (Lynn et al., 2014). A report of an undergraduate nursing student experience in a service-learning research project in homeless shelters resulted in many changes in students. These included increased understanding of the needs of homeless people, recognition of mental health disorders, identification of vulnerable populations, and increased advocacy in social justice (August-Brady & Adamshick, 2013).

Best Practice

Youth and families in homeless shelters have multiple healthcare, educational, and social needs. Understanding the backgrounds and offering programs that are most needed can benefit families and children. Developmental screening, identification of health issues, and provision of educational programs are needed.

Clinical Reasoning

Find at least two agencies that provide health care for persons who are homeless in your community. What are some of the common health problems treated? How are youth engaged in care? What explanations are provided? Are mothers of young children offered parenting classes and stress-reduction interventions? What links are available to other community resources? What is the nursing role in the community agencies you located?

TABLE 17–1 Common Health Problems and Nursing Management of Children Who Are Poor and/or Homeless

COMMON HEALTH PROBLEMS	NURSING MANAGEMENT
Lack of immunizations	Check immunization records. Provide immunizations at schools and in homeless shelters.
Common infectious diseases	Facilitate free clinics in shelters, schools, community settings. Teach hygiene measures. Provide information about resources for bathing and hygiene. Provide resources for disease management. Arrange for medications when needed.
Sleep deficits	Inform parents about respite facilities. Arrange for children to have quiet sleep time in school if possible.
Vision and hearing deficits	Perform screening for deficits. Provide resources for eyeglasses, hearing aids, care for ear infections. (Service organizations such as the Lion's Club are good options.)
Nutritional deficits	Perform height and weight checks and a nutritional assessment. Evaluate the family for food security (see Chapter 14). Be sure the child is registered for school breakfast and lunch programs if available. Ensure that children are linked to summer food programs at the end of the academic year. Link to the Special Supplemental Nutrition Program for Women, Infants and Children (WIC). Inform about resources for meals and field gleaning (collecting unused farm produce) in the community.
Dental care problems	Teach oral hygiene. Provide toothbrushes and toothpaste. Provide bottled water if the child lives in a car or on the street. Perform oral assessment. Refer to dental programs for people with low incomes.
Injuries	Teach basic safety precautions. Visit the living situation if possible to assess for safety hazards. Provide helmets, car seats, or other gear as needed. Teach "street safe" skills. Provide resources for violence prevention and intervention.
Adolescent pregnancy and sexually transmitted infections	Provide sexuality teaching in accordance with state law. Inform about access to family planning services. Assess for child abuse and prostitution.
Mental illness	Assess for depression. Evaluate for suicide potential. Provide links to services. Plan programs to foster self-esteem. Arrange for a Big Brother or Big Sister. Refer to extracurricular activities in the school and community. Arrange for a school bus stop away from a shelter so other students do not stigmatize the homeless child.

The child experiencing stress has more frequent respiratory and gastrointestinal illnesses and is more likely to be the victim of an injury. The negative long-term effects of stress on body organs and systems suggest that children under stress are more likely to develop illnesses such as strokes, hypertension, and heart attacks later in life (Balodis, Wynne-Edwards, & Olmstead, 2010; Slopen, McLaughlin, & Shonkoff, 2014).

Nurses help children manage stress by encouraging good coping strategies (Sapienza & Masten, 2011). Emphasize healthy lifestyles with all children, including good nutrition, exercise, and plenty of sleep. Classes in yoga or martial arts may be stress-reducing for some children. Encourage parents to provide youth with activities that foster self-esteem, and to avoid unrealistic expectations about performance in sports and other activities. Provide resources to help with food acquisition, shelter, transportation, and medical care for families needing them. Adolescents may benefit from various approaches for stress management such as massage, rest, physical activity, and yoga.

Since military deployment can create family stress, partner with military families to assist them as one or both parents are deployed for duty in a remote location. Connect parents with resources for child care, mental health services, and arrangements that need to be made to prepare for the absence. If the

Figure 17–1 Stress from military deployment. The special relationship between a father about to be deployed in the military and his young daughter is clear. This father has two other children and is spending time with each of them, as well as with the family together, before leaving. The cycle of leaving and returning home can be stressful for families. Nurses can assist military families in making plans for health care, finances, and communication while gone and providing resources for emotional support for the entire family.

Clinical Reasoning Demographics and Nursing Care

Nurses should understand the demographics in the areas where they work. What is the poverty rate in your community? What ethnic groups are overrepresented among the poor? Locate needed resources such as food services, health care for the underserved, and enhanced school programs in order to refer poor families. Recognize that health promotion services may not be a high priority when a family does not have adequate housing or food. When children are seen in any setting, such as in school or in an emergency department or hospital for acute care, perform needed assessments and intervention. Measure growth, assess vision and hearing, evaluate dietary intake, and check immunization status. Find out the stresses the family experiences and what resources they need to meet basic necessities. Construct a nursing care plan for a family living in poverty with two young children.

family has had frequent moves, they may not be strongly connected to resources in the community. During deployment the remaining parent may return to the home of origin; some family support may then be present. Help families explain to children why and where the parents are going, and how they will keep in touch during their absence. Children need to know who they will stay with, whether they will attend the same school, and how food and other needs will be provided. Parents need family, mental health, and financial support whether they are being deployed or remaining at home (Allen, Rhoades, Stanley, et al., 2011; Aranda, Middleton, Flake, et al., 2011).

Families

The families into which children are born influence them greatly. Children are supported in different ways and acquire different worldviews depending on such factors as whether one or both parents work, how many siblings are present, and whether an extended family is close by. Examine the family structure such as two parents present, single parent, adolescent parent, same-sex parents, extended family, grandparents raising grandchildren, and stepparents. Financial challenges influence work requirements and lifestyle stability. Resources in the community interact with family structures and can provide support and foster resilience in the face of challenges. All of these factors influence the physical and mental health of children, and can determine their needs for nursing interventions.

One common occurrence in the lives of many children is divorce of parents. The divorce rate in the United States is estimated to be around 50% of all marriages. Each year, an additional 1 million children are affected by divorce (Children and Divorce, 2013). Children are inevitably affected by the parents' divorce, even if the divorce was preceded by many periods of stress and tension in the home.

Many children believe they are at fault for the separation and divorce, that they said or did something to make the parent leave. When one parent leaves, the children may feel abandoned by that parent and may fear being abandoned by the remaining parent. Also, children may become engaged in the disputes of parents, and experience conflicts of loyalty when parents fight for their affection.

In divorces involving conflict and hostility, the children may have increased problems with adjustment. When children must make a series of changes in their lives in addition to the parents' separation (new home, different school), their adjustment is made more difficult as their sense of order is upset. Predictable routines have changed, and children may test limits to see if they still apply; academic and behavior problems may manifest.

The age of the child also influences understanding of and reactions to the divorce. For 3- to 5-year-olds, anxiety, temper tantrums, and other behavioral changes may occur; children ages 6 to 8 years are frequently worried and blame themselves for the divorce; 9- to 10-year-old children are predominantly angry; 11- to 13-year-olds feel lonely and deny the permanence of divorce; 14- to 17-year-olds are angry at parents and may act out frustration by abusing substances or challenging parents (Dunn & Craig, 2013).

A family's risk factors (e.g., recent separation, parental stress, and limited healthcare coverage) and its strengths (e.g., loving relationships, influential grandparents or other extended family members, and general good health) should be identified and used in planning care. Parents who are divorced can be assisted to plan strategies to ensure that the child does not feel responsible for the divorce and is able to form strong relationships with both parents. Encourage the family to ensure that the child has a relationship with both parents, using phone, Internet, and other methods to remain in close contact. See Chapter 2 for a thorough discussion of family factors as they relate to family-centered care and a description of strategies for assessment and intervention with families.

School and Child Care

Once a child is 5 or 6 years of age, several hours daily are spent in a school setting. Children develop physical skills through participation in education and sports. Psychosocial stages are met as the child interacts with children and adults and achieves social interaction patterns and pride in accomplishments. The presentation of concepts that challenge thought processes enhances cognitive development.

Although the primary role of schools is educational, they also perform several health-related functions. School health screening programs identify children with problems such as hearing loss, visual impairment, and scoliosis. Nurses provide assessment, teaching, and clinical management related to some health problems. Some schools have clinics that examine and provide even more complete health care for children. Many schools teach good nutrition, healthful living, safe sexual practices, and other health-related subjects. A school nurse may be present, at least part time, to plan these classes or to work with teachers. Nurses assist school districts in providing plans for emergency health care when needed. With the increase in mainstreaming, school staff now have the responsibility for administering medications, maintaining urinary catheters, and providing respiratory care and other treatments to ensure children's proper growth and development. See Chapter 10 for further discussion of school nurse activities.

Some children spend part or nearly all of their days in childcare settings (Figure 17–2). Over 60% of children under 6 years receive some type of child care regularly. Children spend an average of 33 hours/week in childcare settings (Laughlin, 2013). The closeness of the parent–child relationship, the quality of care, and the length of the childcare day are important in determining childcare effects on children. The mother's sensitivity to her child is the best indicator of child behavior regardless of childcare arrangements (ChildStats, 2011).

Nursing management involves helping parents explore types of daycare options available and to evaluate programs in their communities (Table 17–2). Care options for young school-age children, either before or after school, can also be shared with parents. When available, recommend early intervention programs with at-risk children, such as the Zero to Three Project and Head Start, which contribute to children's health and welfare. Nurses frequently manage the health programs in early intervention, providing screening, doing health evaluations, and establishing early intervention education plans. Nurses assist families in evaluation of childcare centers and share information about accreditation. The National Association for the Education of Young Children (2010) has established childcare criteria.

Figure 17–2 **Most children will spend time in childcare settings. It is important to explore options and find the best fit for the child's needs.**

Community

The community in which a child lives may support the child's development or, conversely, expose the child to hazards. Social programs such as Head Start preschools, sports activities, after-school programs, and child abuse treatment centers offer valuable services that improve the experience of growing children. On the other hand, an economically depressed community with scant services and a high homicide rate is unsupportive and hazardous for growing children.

The physical environment is supportive when the child has sidewalks on which to walk to school, open spaces in which to learn and play, and clean air to breathe. Children who must walk to school on unsafe roads, have access to contaminated drinking supplies, or live near polluting manufacturing companies or in crowded housing or old structures are at risk for injuries and health problems such as lead poisoning (see discussion of poisoning later in this chapter).

TABLE 17–2 Types of Child Care

TYPE OF CARE/DESCRIPTION	ADVANTAGES	DISADVANTAGES
In home (caretaker comes to home of the child)	Child can remain at home Little exposure to infectious diseases No need for alternative care when child is ill	Limited contact with other children to encourage development Limited ability to rapidly locate alternate when provider is ill Most costly
Family child care (parent brings child to home of a caretaker)	Limited number of children Family-type atmosphere Some exposure to other children and encouragement of development	Little governmental regulation or examination Care provider may be distracted by activities in the home
Parent brings child to a center where many children receive care	A learning curriculum plan is in place Contact with other children can enhance development Subject to regulation and licensing Care providers are focused solely on the children	Exposure to multiple children increases infectious disease risk Demands of multiple children may distract or tire care providers

Families Want to Know

Evaluation of Child Care

The nurse can help parents evaluate childcare options and make decisions about placement for their children. Parents should always be welcomed to visit an agency or home childcare site—this is essential so they can see the routines in action. Some questions they can ask are suggested as follows:

Administration

- Is the facility licensed?
- Who are the administrators? What is their training and experience?
- How many staff are employed? What is their training?
- Is there a parent board? What part does it play in administering the center?

Physical Environment, Health, and Safety

- What is the neighborhood like? Is transportation to the center convenient?
- What is the condition of the lighting, heat, cooling, and ventilation systems; play spaces (inside and out); and the building's general condition?
- Is playground equipment safe?
- Is there a soft material such as bark, sand, or rubber tiles under climbing equipment?
- Are the children always supervised?
- Are there emergency medical forms and signed forms for field trips?
- Who may pick up children? How are they signed in and out?
- What is the immunization policy and how are records examined and maintained?
- Are criminal background checks of staff done for potential child abuse and other problems?
- What is the policy for children with infectious diseases and other illness?
- How are foods prepared? Are the staff licensed in food handling?
- What is the state of general cleanliness?
- Who changes diapers? Are recommendations for standard precautions to prevent pathogen transfer followed?
- What arrangements and routines are made for naps and quiet times?

Developmental Approaches

- Is the curriculum appropriate for different age groups?
- Are there materials and plans for gross motor, fine motor, language, and social development?
- How much time do children spend in structured time? Free time?
- How is discipline handled?
- Do the children appear occupied and happy?
- What reading materials are available?
- What type and quantity of field trips are planned?
- What is the educational level and longevity of the childcare workers?
- Is there a diversity among the children's backgrounds and experiences?

Source: Adapted from the National Association for the Education of Young Children. (2010). *Introduction to the NAEYC early childhood program standards and accreditation criteria: Program standards*. Retrieved from http://www.naeyc.org/accreditation.

Culture

The child's cultural group may influence the use of traditional and contemporary healthcare practices. If the parents or children are recent immigrants, they may still be learning the English language and finding out about healthcare resources. Children and adolescents of immigrants may feel stress as they combine their family's traditional culture with the new culture in which the family now lives. They may also have a great deal of responsibility to interpret for the family since they often can speak two languages and understand practices in the new culture.

Recent immigrants may experience culture shock, a state of crisis related to the difference in values and lifestyle between the two cultures they have experienced. This can lead to stress-related symptoms, and create a need for healthcare intervention. Children whose parents emigrated from another country may feel different from peers and develop conflict with their parents, particularly during adolescence.

All cultural groups have rules about patterns of social interaction. Schedules of language acquisition are determined by the number of languages spoken and the amount of speech in the home. The particular social roles assumed by men and women in the culture affect school activities and ultimately career choices. Attitudes toward touching and other methods of encouraging developmental skills vary among cultures.

Nurses must become aware of common characteristics of the cultural groups they serve so that they can provide culturally competent nursing care. Arrange for interpreters when needed. Be aware that families often accept and use both traditional and westernized health care, and remain nonjudgmental about traditional healing practices. Provide access to foods for a variety of ethnic backgrounds in healthcare facilities. Evaluate youth

in immigrant families for conflict between family and societal expectations. Incorporate communication with the school nurse, who often has experience with a diversity of ethnic and racial groups and their cultural practices. See Chapter 2 for further exploration of cultural awareness.

Lifestyle Activities and Their Influence on Child Health

Many patterns of daily life play a part in determining the length and quality of one's life. A child's use of tobacco products and controlled substances influences both physical and mental health. Patterns of exercise and use of protective gear protect against early disabilities. The use of decorative patterns to tattoo or scar the skin and can introduce pathogens is an example of a lifestyle pattern that influences mental health, body image, and the body's physical health.

Tobacco Use

Tobacco use is the most preventable cause of adult death in the United States. It leads to 438,000 premature deaths annually, and will be responsible for the premature death of 5 million of today's youth as they reach adult years (U.S. Department of Health & Human Services [USDHHS], 2011). Major health problems linked to tobacco use include cardiovascular disease, cancer, chronic lung disease, increased prevalence of car crashes, low birth weight, and other maternal problems. Cigarette use is most common; however, chewing tobacco, snuff, cigars, hookahs (water pipe for smoking flavored tobacco), and bidis (small, brown, hand-rolled cigarettes) also pose significant health hazards. Even passive smoking (secondhand smoke) or environmental tobacco smoke (ETS) is linked to increased heart disease, blood pressure, respiratory problems, sudden infant death syndrome (SIDS), middle ear infections, and decreased youth academic performance (U.S. Environmental Protection Agency, 2014). "Thirdhand" tobacco exposure refers to the smoking residues that remain on clothing and room/automobile surfaces.

Clinical Tip

Electronic cigarettes, known as e-cigarettes, provide an aerosol that contains nicotine and other substances. Flavorings such as spices or chocolate are frequently added. In just a 1-year period, from 2011 to 2012, e-cigarette use in 6th to 12th graders doubled, from 3.3% to 6.8%. The effects of e-cigarettes and the additives are unknown at this time, but concerns are warranted. Whether they lead to smoking of traditional cigarettes is a question yet unanswered (Centers for Disease Control and Prevention [CDC], 2013a, 2014a). When inquiring about tobacco use, specifically mention new and popular trends such as e-cigarettes and hookah pipes. Ask about frequency, type, and other details of use.

Many nurses view tobacco use as an adult issue, but each day 3200 youths try their first cigarette, and the usual age for trying tobacco is 9 to 14 years (Figure 17–3). Peer pressure is a powerful incentive for trying some form of tobacco. Nicotine is highly addictive, and most people become addicted to the substance in adolescent years. Early initiation of smoking is an extremely risky behavior because 90% of adult smokers began smoking before 18 years of age (CDC, 2011a, 2013b; 2014a). Although sale of tobacco products to children and advertisements aimed at this age group are forbidden by federal law, many youths obtain and use tobacco. About 16% of high school students in the United States have smoked within the past 30 days, and one half of all youth have tried tobacco, making this an important health risk (CDC, 2014a).

Figure 17–3 **Approximately 70% of children have tried smoking by their high school years. Early intervention can begin with discussions about smoking starting at 9 or 10 years of age.**

Developing Cultural Competence Smoking Rates Among Youth

Among youth in the United States, White youth are significantly more likely to smoke than either Hispanic or African American peers. About 19% of White students reported smoking in the previous month, while 14% of Hispanic and 8% of African American students reported this behavior (CDC, 2014a). American Indian and Alaska Natives also have high smoking rates, while Asian Americans have low rates. Youth smoking rates also vary by state, ranging from 4% to 20% among various states (CDC, 2014a; USDHHS, 2011).

Certain characteristics contribute to the likelihood of tobacco use. They include increasing age, male gender, ethnic group, ease of obtaining tobacco products, and smoking among family members. Low socioeconomic group membership, access to tobacco products, low price of products, advertising, and lack of parental involvement in the lives of youth are associated with tobacco use (USDHHS, 2011). Gender differences may exist for youth who are beginning or seeking to quit tobacco use. For example, girls may be more worried about the smell and effect of tobacco on clothing and appearance, while boys more commonly express concern about smoking's effects on sports or activities (Sullivan, Bottorff, & Reid, 2011).

Several programs have been developed to encourage youth to avoid tobacco use. In addition, smoking cessation programs are available to assist youth who are already regular smokers to successfully achieve the goals of cessation or decrease in tobacco use. Use of counseling, tobacco-free environments, and peer cessation programs have been useful. Aids such as patches, gum, lozenges, nasal spray, and medications have not been adequately tested for safety in adolescents (Broberg & Nield, 2013). Once a teen is identified as a tobacco user, a biologic marker such as urine cotinine

(a by-product of tobacco) levels can help to identify the frequency of smoking. This information can be used to make suggestions to the teen about the potential outcomes of the behavior and the cessation program that is most likely to be helpful.

Nursing Management

Tobacco Use

Nursing Assessment and Diagnosis

Nurses are in a unique position to inquire about the incidence of smoking and other tobacco use among youth. Insert questions into all well-child visits, beginning at about 9 to 10 years of age. Inquire about whether family members (especially parents and siblings) smoke or chew, and ask if some of the child's friends have tried smoking. Try to find out the child's knowledge and beliefs about the benefits and risks of tobacco use. As the child gets older, ask more direct and detailed questions. A nonjudgmental and collegial approach will be best to obtain a truthful response. School nurses can make observations about numbers of teens smoking and general attitudes about tobacco use. When children come to hospitals and other health facilities for care, use of tobacco should be part of general admission questions. Include questions about chew and hookah or flavored tobacco exposure.

Some nursing diagnoses that may apply to youth who smoke or show potential for this behavior include the following (NANDA-I © 2014):

- ***Activity Intolerance*** related to lowered oxygen supply
- ***Gas Exchange, Impaired,*** related to ventilation-perfusion imbalance
- ***Self-Esteem, Chronic Low,*** related to negative self-appraisal
- ***Knowledge, Deficient,*** regarding dangers of tobacco use related to developmental focus on present
- ***Nutrition, Imbalanced: Less than Body Requirements,*** related to effects of chemical dependence

Planning and Implementation

The roles of nurses in preventing and intervening in youth smoking are to inform youth, identify smokers, and implement programs (Table 17–3). Provide developmentally appropriate information about the hazards of tobacco use in all settings where youth are present. Addicted teens who share their stories of difficult withdrawal from tobacco and adults who have had cancer of the lungs or larynx may be effective speakers. Offer information on prevention and cessation programs to youths and families in clinics, outpatient surgery centers, community activities, and hospitals. Use opportunities such as adolescent pregnancy and illness to reinforce the hazardous effects of tobacco on the individual and on those around. Adolescent mothers should understand the risks for small-for-gestational age babies when they smoke in pregnancy and the increased risk of sudden infant death syndrome (SIDS) when infants are exposed to secondhand smoke (see Chapter 20). Speak to young athletes about the effects of tobacco on athletic performance. Show youth the ways this product can interfere with meeting life goals. Role-play how to tell other youth "no" when tobacco is offered. Establish programs that increase the sense of self-esteem without tobacco use. Be sure to include parents in the programs so that they see and acknowledge their role in setting an example about tobacco use and in providing guidelines for the child. Provide information on the influence of environmental tobacco smoke (secondhand smoke).

Adopt a nonjudgmental attitude when asking questions about smoking so that youth using tobacco can be identified. Ask questions without parents present and assure youth that the information will not be shared. Encourage youth to cut back and to quit use of tobacco products. Offer assistance to them in these efforts. Encourage positive coping techniques for youth who are engaged in cessation. Such techniques include keeping busy, avoiding smoking situations, using oral stimulation such as a toothpick or gum, exercising, relaxing, and using nicotine replacement approaches (Audrain-McGovern et al., 2011).

Work with the schools and school districts to help establish preventive and cessation programs. There should be clear guidelines about school policies regarding tobacco use on school grounds. Keeping occasional youth tobacco users from becoming regular users should be a goal in order to avoid nicotine addiction. Find out what positive incentives can be offered to youth who are successful in quitting tobacco use. Contract with them to achieve their goals.

Evaluation

Expected outcomes of nursing interventions regarding tobacco use are lowered rates of regular use, delayed initiation of use, and success of cessation programs. *Healthy People 2020* objectives can be used to plan programs.

TABLE 17–3 Nursing Role in Youth Tobacco Use Prevention

INFORM
• Hang posters, provide brochures, and facilitate presentations about tobacco risks in all settings where youth are present. Include contemporary uses such as e-cigarettes and hookahs.
• Target tobacco users with special information about the effects of nicotine on their bodies.
IDENTIFY
• Ask questions about smoking and other tobacco use at every health encounter beginning at about 9 to 10 years of age. Ask if the child's parents, siblings, and/or friends use tobacco.
• For users, ask amount and type of tobacco and nicotine.
• Find resources where youth obtain tobacco in the community and become proactive in stopping sales.
IMPLEMENT
• Encourage youth tobacco users to quit.
• Facilitate referral to cessation programs.
• Arrange positive rewards for youth successful in cessation.

Healthy People 2020

(TU-15.2 and 15.3) Increase smoke-free and tobacco-free environments in schools, including all school facilities, property, vehicles, and school events, to 100%

(TU-18.1–18.4) Reduce exposure to tobacco advertising and promotions that influence adolescents and young adults

(TU-7) Increase smoking cessation attempts by adolescent smokers to 64%

(TU-2.2) Reduce tobacco use by adolescents to 21%

(TU-2.3) Reduce smokeless tobacco use by adolescents to 6.9%

(TU-3.2) Reduce initiation of tobacco use among adolescents to 4.3%

Alcohol Use

Alcohol use by the young is common. An estimated 66.6% have tried alcohol, which is the drug of choice and convenience for youth. By 12th grade, 76.3% of females and 74.9% of males have had alcoholic drinks (CDC, 2014a). Current use is also common with 34% of high school students admitting to drinking within the last month, and 20.8% having engaged in binge drinking, or having five or more drinks within a 2-hour period. Even very young adolescents are affected since 40% of eighth graders have tried alcohol and 11% have had one or more episodes of binge drinking (National Institute on Alcohol Abuse and Alcoholism, n.d.). About 18.6% of high school students report that their first drink was before age 13 (CDC, 2014a).

Many factors influence the child and adolescent who drink alcohol. Patterns in the family, media advertisements, and social environments in high school and college that honor or expect drinking all contribute to the problem. Access to alcohol is easy for most youth because older siblings or classmates often obtain drinks for them. It is a "rite of passage" for many at teen birthday parties or college events. Alcohol is the most common and accepted drug in today's society and, as such, youth are exposed to it. They often experiment with alcohol and experience its effects without understanding or considering the implications of its use. A significant risk factor for initiation of alcohol use is a transition time, such as change from middle to high school, or a major family stress, such as parental separation or divorce.

Drug Use

Substance use occurs in children and adolescents of all socioeconomic levels and is a growing health problem. The use of any drug can pose a serious psychologic and physical risk to children and adolescents.

In addition to alcohol, a variety of other drugs are used by youth. Over 41% of U.S. high school students have used marijuana, and 23% have used it in the last month; 5.5% have used cocaine, with nearly 3% having used it in the last month; 6.6% have used Ecstasy. Inhalant use of glue, paints, or other substances is more common, with nearly 9% reporting use. Approximately 3.2% report methamphetamine use (Figure 17–4), and 2.2% use heroin (CDC, 2014a). Synthetic drugs (commonly referred to as "designer" drugs), such as phencyclidine (PCP), mimic other narcotics, stimulants, and hallucinogens and are also dangerous. "Bath salts" are a contemporary drug that has effects similar to those of amphetamines. These drugs are synthetic versions of cathinone, which occurs naturally in the khat plant (Lehner & Baumann, 2013; McGraw & McGraw, 2012). Common contemporary drugs and street names are listed in Table 17–4. Some youth use these drugs with alcohol, which can lead to deadly consequences.

Figure 17–4 **Methamphetamine is a popular drug because it can be manufactured with items that are available to the lay public. Manufacture of the substance in homes has become a concern of health departments and communities at large. Children can be harmed by the chemicals produced and may experience neglect and abuse. They may suffer even after the home is found and adults are apprehended as they must be placed in foster homes.**

Prescription drugs are sometimes used for nonmedical purposes. For example, methylphenidate (Ritalin) is used for treatment of attention deficit hyperactivity disorder (ADHD) and generally acts as a stimulant. Its unprescribed use among youth has increased dramatically during the past few years. Prescription pain medications are another example of drugs that are easily abused by youth who are treated with them after surgery or other procedures.

Over-the-counter medications are legal, but frequently abused. Easily obtainable at grocery stores and drug stores, these drugs include antihistamines, atropine, bromides, caffeine, ephedrine, pseudoephedrine, phenylpropanolamine, and amphetamine-like substitutes. Volatile inhalants, such as glues, are dangerous substances of abuse, and their use appears to be rising among school-age children and adolescents. Anabolic steroids are the drugs of abuse most commonly used by athletes (see Chapter 14 for further information on enhancing substances).

ETIOLOGY AND PATHOPHYSIOLOGY

In most cases, substance use represents a maladaptive coping response to the stressors of childhood and adolescence. Individual, peer, family, and community risk factors all contribute to increased incidence of use (American Academy of Child and Adolescent Psychiatry [AACAP], 2013). A child may begin using drugs or alcohol to deal with stress because family members or peers do so. Children in families with a history of substance abuse are at higher risk of abusing drugs and alcohol. Other risk factors include rebelliousness, aggressiveness, low self-esteem, dysfunctional parental relationships, lack of

TABLE 17–4 Common Contemporary Club Drugs, Street Names, and Drug Information

DRUG	ACTION	STREET NAMES	ROUTE	TIME OF ACTION
Methylenedioxymethamphetamine (MDMA)	Stimulant; appetite suppressant; increased pulse, BP, temperature; overhydration; hyponatremia; memory loss	Ecstasy, XTC, X, Adam, Clarity, Lover's speed, E	PO (tablets, capsules)	3–6 hr
Cathinone ("bath salts")	Similar to amphetamines: agitation, combative behavior, hallucinations, delusions, hyperthermia, tachycardia, hypertension	Many names such as Bliss, Blue Silk, Charge, Energy-1, Gold Rush, K2, Meph, Mephisto, Ocean Burst, Rave ON, Rush, Special Gold, Spice, Tranquillity, White Knight	PO (capsules), snorted, IV, IM, rectal	2–4 hr but up to 8 hr possible
Gamma-hydroxybutyrate (GHB) (Xyrem)	CNS depressant, euphoria, growth hormone release, hypersalivation, hypotonia	Grievous Bodily Harm, G., Liquid Ecstasy, Georgia Home Boy, date-rape drug	PO (liquid, powder, tablets, capsules)	4 hr
Ketamine	Anesthetic; decreased memory, attention, learning; increased BP; respiratory collapse	Special K, K, Vitamin K, Cat Valiums, Jet	IV, respiratory (injected, snorted, or smoked; liquid or powder)	1–2 hr
Rohypnol (benzodiazepine; flunitrazepam)	Amnesia, sedative; decreased BP, urinary retention; given prior to sexual assault	Roffies, Rophies, Roche, Forget-me Pill	PO, respiratory (snorted; tablets)	8–12 hr
Methamphetamine	Stimulant; highly addictive; memory loss; violence, psychosis; cardiac and neurologic damage	Speed, Ice, Chalk, Meth, Crystal, Crank, Fire, Glass, Tina, Tweak, Yaba (meth and caffeine)	PO, respiratory, IV (smoked, snorted, injected)	Several hours; long-term permanent effects
Lysergic acid diethylamide (LSD)	Hallucinogen; increased pulse, BP, temperature; psychosis, flashbacks	Acid, Boomers, Blotters, Dots, Yellow Sunshines	PO (liquid, tablets, capsules)	1–2 hr; trips last 12 hr; possible flashbacks later

Source: Data from National Institute on Drug Abuse. (2011). *NIDA InfoFacts: Club drugs*. Retrieved from http://www.nida/nih.gov/Infofacts/clubdrugs.html and http://www.drugabuse.gov/drugpages.clubdrugs.html

adequate support systems, academic underachievement, poor judgment, and poor impulse control.

Initial experimentation with alcohol or drugs may be unpleasant. However, with continued use, the adolescent learns to "achieve the high," an illusion of power and well-being. The adolescent wants the high more frequently and actively seeks alcohol or drugs. Tolerance to the substance occurs with continued use, and ever-increasing amounts are required to achieve a pleasurable high. Physical and psychologic dependence ensues as the body's tissues require the substance to function properly. Withdrawal symptoms occur when the child or adolescent is deprived of the substance.

Clinical Tip

Following are common inhalant agents:

AEROSOLS
- Cooking spray
- Whipped cream
- Spray paint
- Cosmetic sprays

SOLVENTS
- Nail polish remover
- Paint thinner or cleaner
- Lighter fluid
- Degreaser

ADHESIVES
- Model glues
- Rubber cements

OTHER
- Gasoline
- Helium

CLINICAL MANIFESTATIONS

Substance abuse in children and adolescents is commonly overlooked and underdiagnosed by healthcare providers, in part because of the wide range of clinical presentations, which vary according to type of drug used, amount, frequency, time of last use, and severity of drug dependence (Table 17–5).

Common physical manifestations include alterations in vital signs, weight loss, chronic fatigue, chronic cough, respiratory congestion, red eyes, and general apathy and malaise. Withdrawal may be shown by anxiety, headache, tremors, nausea and vomiting, malaise, weakness, insomnia, depressed mood or irritability, and hallucinations. The mental status examination (refer to Chapter 5) may reveal alterations in level of consciousness, impaired attention and concentration, impaired thought processes, delusions, and hallucinations. Low self-esteem, feelings of guilt or worthlessness, and suicidal or homicidal thoughts are also common.

Poor school performance and changes in mood, sleep habits, appetite, dress, and social relationships are nonspecific characteristics of the child or adolescent who is using substances.

CLINICAL THERAPY

Multiple psychiatric diagnostic criteria exist for each drug class. Children and adolescents who have other psychosocial disorders commonly use or abuse drugs or alcohol. Treatment should therefore focus not only on the substance use or abuse but also on the issues underlying the problem. Intervention includes the family as well as the substance-abusing child or adolescent.

TABLE 17–5 Clinical Manifestations of Commonly Abused Drugs

DRUG	POTENTIAL FOR DEPENDENCE	CLINICAL MANIFESTATIONS
DEPRESSANTS		
Alcohol, barbiturates (amobarbital, pentobarbital, secobarbital)	Physical and psychologic: high; varies somewhat among drugs	Physical: decreased muscle tone and coordination, tremors Psychologic: impaired speech, memory, and judgment; confusion; decreased attention span; emotional lability
STIMULANTS		
Amphetamines (e.g., Benzedrine), caffeine, cocaine, "bath salts"	Physical: low to moderate Psychologic: high; withdrawal from amphetamines and cocaine can lead to severe depression	Physical: dilated pupils, increased pulse and blood pressure, flushing, nausea, loss of appetite, tremors Psychologic: euphoria; increased alertness, agitation, or irritability; hallucinations; insomnia
OPIATES		
Codeine, heroin, meperidine (Demerol), methadone, morphine, opium, oxycodone (Percodan)	Physical and psychologic: high; varies somewhat among drugs; withdrawal effects are uncomfortable but rarely life threatening	Physical: analgesia, depressed respirations and muscle tone (may lead to coma or death), nausea, constricted pupils Psychologic: changes in mood (usually euphoria), drowsiness, impaired attention or memory, sense of tranquility
HALLUCINOGENS		
Lysergic acid diethylamide (LSD), mescaline, phencyclidine (PCP)	Physical: none Psychologic: unknown	Physical: lack of coordination, dilated pupils, hypertension, elevated temperature; severe PCP intoxication can result in seizures, respiratory depression, coma, and death Psychologic: visual illusions and hallucinations, altered perceptions of time and space, emotional lability, psychosis
VOLATILE INHALANTS		
Glues, typing correction fluid, acrylic paints, spot removers, lighter fluid, gasoline, butane	Physical and psychologic: varies with drug used	Physical: impaired coordination, liver damage (in some cases) Psychologic: impaired judgment, delirium
MARIJUANA		
	Physical: low Psychologic: usually low; occasionally moderate to high	Physical: tachycardia, reddened conjunctiva, dry mouth, increased appetite Psychologic: initial anxiety followed by euphoria; giddiness; impaired attention, judgment, and memory

Families Want to Know

Identifying the Youth Who Is Abusing Substances

Families are often confused about the behavior of adolescents and unsure whether it represents normal development or abuse of substances. Some characteristics of normal development that help to differentiate these occurrences are listed here. When concerned about possible substance use, the parent can confront the child or talk with school nurses or counselors.

- Many youth are periodically distant with parents but remain involved with peers in school sports and other activities. Withdrawal from all activities and friends may indicate substance abuse.
- Adolescents often complain about school, but when teachers report the student meets expectations and is consistently performing in the classroom, this is normal behavior.
- Teens may be weepy on occasion when having a difficult time with friends or not performing as desired. Continued, consistent weepiness is likely to indicate depression or substance abuse.
- Teens like to stay up late and are frequently tired in the morning, whereas abusing teens may "nod off" frequently during the day.
- Many adolescents like to achieve a disheveled look in clothing, but the teen who frequently neglects basic hygiene or does not seem to have the energy to wash and dress may be depressed or be abusing substances.
- All teens get some infections, but teens who are abusing substances may have reddened eyes, oral sores, and constant respiratory discomfort from "snorting" substances.

The primary goal of treatment is to teach the child and other family members to develop and sustain positive coping patterns, and to support them during this process. Most treatment programs offer inpatient and outpatient services, as well as after-care programs. These programs usually consist of peer support that focuses on developing a drug- and alcohol-free lifestyle, healthy family relationships, and positive coping skills. Family involvement is strongly encouraged. Hospitalization is required if the physical dependence is significant and withdrawal places the child at risk for complications such as seizures, depression, or suicidal behavior.

Nursing Management

Alcohol and Drug Use

Nursing Assessment and Diagnosis

Mental health assessment of all older children and adolescents requires screening for alcohol and other substances, including screening for over-the-counter and prescription medication use (American Academy of Pediatrics Committee on Practice and Ambulatory Medicine, 2014; Havens, Young, & Havens, 2011). Maintaining a confidential approach will increase the ability to obtain truthful information about use of substances. Assessment tools provide useful information for the healthcare provider.

Nurses may encounter the substance-abusing child or adolescent in the emergency department or outpatient clinic, in schools and other community settings, or during hospitalization for an injury or other acute problem. Diagnosis includes assessment of both the family and the substance-abusing child or adolescent. Nursing assessment includes taking a thorough history from the parents and child, observing the child's behavior, and performing a physical examination. The history should include the age at which drug use began, pattern of use, length of time the drug has been used, amount of drug used, and psychologic state while on drugs. A history of parental drug use and noninvolvement in parenting the child puts the child at higher risk for substance abuse, reflecting the combined effects of genetic and environmental influences. Environmental factors such as access to the substance, use with other teens or adults, and resources for treatment are important to consider. Evaluate the home, education, alcohol, drugs, smoking, and sex practices of the teen.

PHYSIOLOGIC ASSESSMENT

Look for physical signs and symptoms of substance use, including bloodshot eyes, dilated pupils, slurred speech, and weight loss. Blood and urine levels of substances and metabolite are sometimes measured. The adolescent may appear sleepy or restless, or may show signs of clumsiness or inconsistent behavior. Consider all types of substances, including model glue, gasoline, and other sources. Consider signs of withdrawal as well as current intoxication.

PSYCHOLOGIC ASSESSMENT

Changes in social habits may indicate substance use. Parents may report a drop in the school-age child's or adolescent's grades or decreased interest in school activities. The adolescent does not introduce new friends to parents, and has less contact with parents, teachers, and other adults who were previously important. The youth may appear more energetic than usual, always "on a high," or exhibit weight loss. Note the child's current drug use, potential for violence, and motivation to make changes. Assess the degree of family support available.

FAMILY ASSESSMENT

In families with substance-using adults, children may experience neglect and abuse, as well as exposure to drugs. When family members are substance users, young children may experience periods when adults cannot provide supervision and do not encourage healthy activities, or they may be exposed to potentially unsafe or violent episodes. When parents are manufacturing products such as methamphetamine, young children are exposed to toxic chemicals and run the risk of suffering burns and other sequelae from home laboratory production and explosions. Be alert for unusual injuries, signs of inconsistent parenting, and delays in or disturbed growth and development. Be prepared to refer parents for care and for following protocols for child abuse prevention (see sections on abuse and neglect later in this chapter).

Nursing diagnoses for children and adolescents who abuse drugs or alcohol might include the following (NANDA-I © 2014):

- ***Social Interaction, Impaired,*** related to altered thought processes
- ***Self-Esteem, Chronic Low,*** related to dysfunctional family and social relationships
- ***Injury, Risk for,*** related to altered perceptions and sensorium
- ***Violence: Self-Directed or Other-Directed, Risk for,*** related to physiologic dependence on drugs, alcohol, and other substances

Planning and Implementation

Care of children and adolescents who abuse drugs, alcohol, and other substances is challenging and often frustrating. Long-term mental health counseling may be necessary to resolve underlying issues and foster lifestyle and behavioral changes.

Prevention is the most desirable intervention. The nurse can play a major role in teaching children and their families about substance abuse. Education should begin in primary school, and continue with intensification during middle school and high school. Nurses also can play a major role in community education. Various prevention programs have been developed by federal and private organizations. Referral to support organizations may be beneficial for the child, parents, and other family members. Self-help groups, available in most communities, include Alcoholics Anonymous, Narcotics Anonymous, Al-Anon, Nar-Anon, and Ala-Teen. Parents may receive support from a group such as Parents Anonymous.

The youth's protective factors can be identified and used in planning appropriate interventions. For example, a child with goals for a future career can be helped to see how substance use will interfere with goal attainment. Identifying a strong role model through a program like Big Brothers or Big Sisters can assist children who lack that strength in their families.

The child who has begun to use and abuse drugs needs an intensive intervention program. Referral to a psychiatric health specialist is needed for diagnosis and intervention. Group programs and those that integrate the family are most effective. Find out what resources are present in your community to treat youth who are using alcohol or other drugs. Nurses are active in treatment programs as well as sustaining treatment effects and avoiding relapse during visits to community agencies once the youth returns to family, school, and other surroundings.

Evaluation

Expected outcomes of nursing interventions include abstention from alcohol and street drugs, successful participation in substance abuse programs, and developmentally appropriate social and cognitive skills.

Physical Inactivity and Sedentary Behavior

In the past few decades, children have become increasingly sedentary. This change is a reflection of lifestyles in which car travel is valued, computers and televisions are part of daily life, neighborhoods are sometimes unsafe places for play, and schools do not routinely require daily physical education classes (Figure 17–5). Children and adolescents spend an astounding amount of time with media (television, computers, games, and phone applications)—an average of 2 hours of television daily for those under 6 years, and 4 hours of television and an additional 2 hours of other media use daily for older youth (KidsHealth, 2014). Excessive screen time influences behavior because there is physical inactivity during viewing, a lack of social interaction and cognition, and a tendency to eat high-fat snacks with high caloric content. While screen time increases, physical activity decreases, with only 25% of youth engaged in the recommended moderate to vigorous physical activity for 60 minutes daily (Fakhouri et al., 2014).

Physical inactivity leads to many health concerns. A primary outcome is overweight or obesity (see Chapter 14 for a definition and further information on obesity). Other outcomes can be an increased rate of type 2 diabetes (see Chapter 30), increased exposure to television/computer game violence and sexual activity at early ages, and early progression of cardiovascular disease (see Chapter 21).

However, patterns of physical activity established in childhood can lead to increased exercise behaviors in adulthood, contributing to lower rates of low back pain, overweight, osteoporosis, heart disease, diabetes, colon cancer, and high blood pressure, and also lead to a more positive self-image.

Although many children demonstrate low levels of physical activity, a profound decrease in vigorous activity is common in grades 9 through 12. Boys more commonly participate in team sports than girls. Although about 48% of students attend physical education (PE) classes at least once a week, only 29% have daily PE classes (CDC, 2014a).

Healthcare providers can integrate assessment of physical activity into all health care, and make recommendations to children and families that will help to increase opportunities for physical activity. Nurses can assess height, weight, and body mass index (BMI) to look for signs of overweight (see Chapter 14). Children should be asked about how they like to spend free time. Community and school activities should be encouraged and rewarded. Examples include fun runs, walks for benefit causes, aerobics classes, team sports, roadside cleanups, fairs, and carnivals. Help parents and children learn what they can do for physical fitness. Work with school physical education personnel to plan activities both in and out of physical education class that promote lifelong exercise routines. Work toward the goal of 60 minutes of daily moderate intensity physical activity for all children (CDC, 2014a). During health promotion visits, help children identify ways to gradually increase physical activity and decrease sedentary time.

Injury and Protective Equipment

In the discussion of causes of childhood and adolescent morbidities and mortalities in Chapter 1, unintentional injuries are listed as a common problem. In fact, a majority of deaths from age 10 years onward result from four causes: motor vehicle crashes, other unintentional injury, homicide, and suicide (National Center for Health Statistics & National Vital Statistics System, 2012). Chapters 7, 8, and 9 discuss the frequent injuries seen in children at different developmental ages, and safety precautions to avoid injuries from car crashes, falls, poisonings, and other developmentally related injuries. Many common injuries are preventable with simple use of protective gear and following of safety guidelines (Figure 17–6). Some sports and activities that require safety gear include rollerblading, skateboarding, roller hockey, ice hockey, football, soccer, baseball, scooters, all-terrain vehicles, and skiing or snowboarding fast or using jumps.

Over 8% of youth rarely or never wear car safety belts in automobiles; 22% have recently ridden with someone who had been drinking alcohol (CDC, 2014a). Emphasize safe automobile

Figure 17–5 **Role of sports in development. Physical inactivity is a growing problem among children and can contribute to poor health. It is important to balance sedentary activities, such as playing computer games, with physical and social activities. Sports are an excellent way for children to develop their psychosocial, cognitive, and motor skills.**

Families Want to Know

Physical Activity Guidelines for Youth

- Engage in moderate to vigorous physical activity (such as bike riding, walking, baseball, and rollerblading) for at least 60 minutes daily.
- Engage in vigorous activity that causes sweating and hard breathing (such as soccer, running, and ice hockey) at least 3 times weekly.
- Engage in muscle strengthening activity at least 3 times weekly.
- Engage in bone strengthening activity at least 3 times weekly.
- Encourage schools to offer physical education to all students, and have students sign up when this is an elective.
- Encourage walking and bike riding to friends' homes and stores whenever safe.
- Plan physical activities together as a family.
- Get a pet and plan to walk the pet together daily.
- Limit television and other similar sedentary activities to no more than 2 hours daily.
- On days home, allow the child to watch television for up to 1 hour, and then insist on 1 hour of reading, 1 hour of physical activity, and 1 hour of socializing with others before returning to more television.
