Figure 17–6 **Use of protective gear. What protective gear should children use for skateboarding? How would you convince them to use the protection?**

and motorcycle behaviors in adolescence, with the recognition that risks increase if driving is combined with use of alcohol and controlled substances. Adolescents sometimes engage in practices that put them at particular risk, and nurses should be alert for such activities in their communities. Examples include car surfing (standing on the trunk, hood, or roof of a moving vehicle), street racing (racing cars down a street at extremely high speed), or "extreme" sports.

About 44 million U.S. children ride bicycles, a beneficial physical activity. However, only about 12% are protected by helmet use, even though bicycling is the most common activity associated with injury (CDC, 2014a). Strategies to make helmet use more attractive to children and adolescents are needed. Nurses can play a major role in programs to educate and reward children for helmet use, and can assist families to find affordable helmets. Nurses can be active in identifying behaviors in youths in specific communities and working with schools and other community groups to support legislation for helmet use, evaluate proper fits of helmets, and work to locate sources for incentives and low-cost helmets. Efforts should also include adequate conditioning for sports, proper treatment of injuries, and prevention of overuse injuries.

A growing number of children engage in "extreme" sports—those that carry a high degree of risk and have not traditionally been common. Some examples are mountain biking, skateboarding with ramps, motocross racing, three-wheeling, ski racing, snowboarding through trees and on courses with pikes and other challenges, ice climbing, rock climbing, and wakeboarding. While the nurse is probably unable to dissuade youth from engaging in these activities, safety measures should be emphasized. Find out what protective gear the youth wears and what is recommended. Provide examples of stories of youth who have been saved by use of such gear. Encourage the youth to engage in sports activities only when others are present and to have a plan for emergencies, including a working cell phone, leaving information with an adult about plans and expected return, and planning for harsh weather with items such as emergency blankets, gear, and food. Encourage the youth to talk with parents and other adults about the risks and responsibilities of the activities.

Developing Cultural Competence Ethnic Disparity in Unintentional Childhood Injuries

Although the unintentional injury rate in children under age 19 declined 39% from 1987 to 2013, striking ethnic disparity rates exist in the rates of unintentional injury among children. These differences are mainly due to living in impoverished communities rather than any innate biologic variations. The rate of death from unintentional injury ranges from 23.8/100,000 in American Indian/Alaska Native, to 12.8 among African Americans, 11.5 among Whites, and 8.8/100,000 in Hispanics (CDC, 2012a). What are the major causes of unintentional injury in your community and state? What ethnic and age groups are at greatest risk? How can you integrate teaching in your practice that is specific to the findings in your community?

Body Art

Body art in the form of painting, tattooing, and piercing has been used by humans throughout history. In recent years, there has been a resurgence of interest in this decorative art among teens. Many adolescents have multiple body piercings and tattoos, and they may even resort to performing these decorations on themselves or friends.

Approximately 21% of adolescents and young adults have tattoos, and even more have at least one body piercing (Owen, Armstrong, Koch, et al., 2013). In some states, teens must be 18 years of age or have parental permission to obtain body art, but students often report that it is easy to have an adult present who signs and claims to be a parent. Amy, described at the opening of this chapter, had her piercing done by a friend. In some states, tattoo and body piercing businesses must be licensed and comply with certain regulations; other states have no regulations. Amy demonstrates some common characteristics of teens who choose to use body art. It may be seen as a way to establish individualism and independence, and it may help some teens to feel part of a peer group. Multiple tattoos and piercings are common, as is the case with Amy (Figure 17–7).

Body art is a common source of infections with skin pathogens. Infections can range from mild inflammatory reactions to bacterial and viral infections and serious long-term infections. Body piercing is a major method of transmission of hepatitis C, a disease that may not be manifested until years later (see Chapter 25). It can be a source of HIV if proper techniques are not followed. Serious systemic infections such as endocarditis have occurred after some piercings. Piercings in parts of the body such as the mouth or navel are most prone to bacterial infection and continued redness and irritation. The pierced site may not appear infected, but transfer of organisms can lead to serious infection and heart damage. Examples of serious infective agents include *Neisseria*, *Mycobacterium*, *Staphylococcus*, *Pseudomonas*, *Streptococcus*, *hepatitis B*, and *hepatitis C* (Juhas & English, 2013). A number of cases of *Mycobacterium chelone* skin infection from contaminated ink were identified across the country in 2012 (CDC, 2012b). When noting signs of systemic infection such as fever, weakness, malaise, and arthralgia (see Chapter 21 for full discussion of endocarditis), gather history about body piercings and refer for care to the primary healthcare provider. Pierced tongues can lead to chipped teeth or even be the cause of choking if the piercing is dislodged from the site.

Figure 17–7 Health risks to adolescents. Talk openly with adolescents about their health and teach them to avoid health risks connected with tattoos and piercing.

Another issue that teens should consider is the relationship of the tattoos to future lifestyle changes. Advise teens to avoid tattooing the name of a person or musical group since relationships change and tastes in music evolve. Be sure they know the meaning of phrases, foreign words, or Asian symbols. Consider the visibility of the tattoo and its effect on future employment. Tattoos on the face, neck, or other readily visible places may be a detriment during employment interviews. Tattoos should always be considered permanent. Methods for removal may be costly, painful, and unsuccessful.

Another form of body art that is regarded as disfigurement is *deliberate self-harm* or *nonsuicidal self-injury*. One example is *branding*, or scarification, whereby the skin is burned to result in a scar. Commonly a desired sign, symbol, or word is inscribed. Results are usually not precise and do not adhere to expected designs. This procedure is done on the self or friend, using common household metal implements heated in fires or stoves. Others cut themselves in the form of a desired design, a process called *cutting*. This type of self-harm or self-injury is performed with razor blades, knives, scissors, broken glass, needles, or sharp pencils. These practices can result in infection, often do not yield the desired result, and may indicate underlying problems. Adolescent screenings should ask about cutting or intentional injury to skin. Using a nonjudgmental attitude, the youth involved should be referred for further assessment by primary care providers or counselors (Catledge, Scharer, & Fuller, 2012; Smith, 2011).

Because teens may choose to obtain body art even if parents object and even when there are state laws to prohibit or make it difficult to do so, nursing care must focus on providing information for the teen, assessing sites, identifying infections, and referring if needed. Care is almost always provided in community settings such as clinics or schools. Consider asking teens if they are thinking about body art since they often do not seek advice before obtaining the body art and may not get adequate teaching.

Clinical Reasoning The Adolescent With Body Piercings

Amy is 15 years old and attends an alternative high school. She recently had an ear piercing and it is painful. She comes to the health room to ask the advice of the school nurse. The area around the piercing is inflamed and mildly edematous. After asking some questions, the nurse learns that Amy's ear was pierced by a friend, using a needle that had been "sterilized" by passing it through a match flame. She has had a slight fever, but otherwise feels fine.

In her home state, adolescents under 18 years of age must have the signature of a parent for body piercings and tattoos, so Amy chose to have the procedure done by a friend. She believes this is safe since her friend has done many piercings on others. She admits that her parents are not very pleased with her body art, but that they allow her to do it as long as she agrees to stay in high school. She had previously run away and spent several weeks living on the streets.

- What healthcare and social needs does Amy have?
- How can you support both Amy and her parents?
- What physical care does Amy need to treat potential infection at her piercing site?
- What systemic infectious diseases is Amy at risk of acquiring due to repeated body piercings using an unsterile technique?

Families Want to Know

Care for Tattoos and Body Piercings

Before the Procedure

- Does the studio look clean?
- Visit several studios to make comparisons of techniques, quality, and cleanliness.
- Ask to watch a tattoo or piercing done on someone else.
- What are the artist's sterilization and hygiene practices?
- Is the artist licensed? Trained?
- Look at pictures of completed art and talk with former clients.
- Insist that new, sterile equipment be opened in front of the person to be decorated.
- Consider if this permanent body decoration is desired for a lifetime.
- Consider what the tattoo or piercing will look like in several years.
- Consider the possible side effects such as infection, future dislike for the art, and allergy to dyes or metals.
- Be sure that hepatitis B vaccination is completed before the procedure.
- Be aware that no immunization is available to protect against the health risks of hepatitis C and HIV.

Care After the Procedure

- Touch the area only after carefully washing your hands.
- Keep the area elevated and use ice for the first 2 days to minimize swelling.
- Avoid contact with another person's body fluids until well healed.
- Turn the piercing jewelry gently several times daily using washed hands.
- Use antibacterial mouthwash or cleaner or ointment as recommended.
- Avoid pressure and rubbing on the site (such as belts on navel piercings).
- Watch carefully for signs of infection and report them to a healthcare provider:
  - Increased redness
  - Swelling
  - Pain
  - Hot feeling
  - Discharge
- Ask the artist how long healing will take. It varies from 2 months in the mouth or up to 6 or 8 months for a navel.
- Metal is dangerous during some medical procedures such as magnetic resonance imaging (MRI) or during surgery. Be sure to tell doctors and nurses about your piercings when you are hospitalized or receiving medical care, especially if they are in a part of the body not readily visible.
- If you decide to remove a piece of jewelry soon after it is placed, the skin may heal with only a slight scar.

Sexual Orientation

Adolescence is a time of identifying emerging sexuality. Most teens establish relationships with members of the opposite sex and learn how to interact in ways guided by their peer group, family, and culture. For some youth, the transition into adult sexuality can be more challenging if they feel an emotional and sexual attraction to people of the same sex (**homosexuality**). The term **gay** is often used for homosexual males and **lesbian** for homosexual females. Other youth are **bisexual**, or attracted to both men and women, and some are **transgendered**, or attracted to dress and act like members of the opposite sex. The abbreviation LGBT is sometimes used to refer to lesbian, gay, bisexual, or transgendered, and LGBT/Q indicates those who are questioning their sexual orientation. About 5% to 12% of persons report an experience with someone of the same sex, and about 3% identify as being LGBT/Q (Chandra, Mosher, Copen, et al., 2011). Data on youth are not often reported; however, the National Survey of Family Growth reports that about 90% of adolescents and young adults report that they are heterosexual, with the remainder reporting that they are homosexual, bisexual, or not sure (Sexuality Information and Education Council of the United States, n.d.).

Sexual attractions and practices different than the mainstream are not deviant nor symptomatic of a mental disorder but should be viewed as part of a continuum of sexual expression. No known gene, early life experience, or other event causes homosexuality (American Psychiatric Association, 2012).

LGBT/Q youth are at risk for a variety of problems related to emotional and physical health. These include rejection by family members and peers, verbal harassment, sexual abuse and physical assault, a high rate of suicide, substance abuse, a high rate of homelessness, and sexual risks of HIV and other sexually transmitted infections. Their health risks need to be identified and appropriate care provided in welcoming and nonjudgmental healthcare facilities.

Nurses can provide health care for LGBT/Q youth in a variety of settings. School nurses and clinics can display a sign to demonstrate that they are accepting of persons with minority sexual orientation. These signs are rainbows or triangles with several colors shown and can be obtained from local gay

or lesbian community groups. Terminology in assessment should be gender free. Ask "Do you have one or more sexual partners?" rather than "Do you have a boyfriend?" When youth identify as LGBT/Q, provide usual care of all kinds. This includes preventive care such as immunizations, sports assessments, and injury prevention teaching. Be alert that youth may have additional health challenges. Ask about peer and parental support; refer to support groups if needed. Provide resources for homelessness and when the teen is depressed or suicidal (see Chapter 28). Perform testing for sexually transmitted infections if the teen is having sexual contact, and teach preventive measures. Foster a positive sense of self-esteem through encouraging positive activities such as sports, music, and friendships with peers.

Effects of Violence

Violence is a threatened or actual use of physical force or power that leads to actual or potential physical or emotional trauma. Violence can be directed at oneself, another person, or against a group or community. Violence can result in injury, death, psychologic harm, disruption of development, or deprivation (Child Trends, 2015). In the past several years, adults and children alike have been shocked by violent episodes in schools. Although these incidents had much media coverage, they are just one type of violence to which children may be regularly exposed. Children can be the recipients of violence during child abuse and homicides, and they themselves can perform acts of violence on others. They may be touched by violence when parents, siblings, or other family members are killed in gang conflicts, in terrorist attacks, or in wars. The effects of violence are far reaching and ongoing; they permeate the victim's entire lifetime. This section explores some types of violence affecting children.

Schools and Communities

At a time when firearm deaths are decreasing overall, unintentional deaths and suicides have increased among children. Many of these deaths are committed with firearms found in the home. Over 4000 youth from 10 to 19 years old die from firearm homicides annually, and another approximately 15,000 die from firearm suicide. Firearm homicide is the second leading cause of injury death for youth, and firearm suicide is the fifth leading cause of injury death for youth (CDC, 2011b). Forty percent of households with children have guns (2 million children live in these homes), and in many of those homes, the firearms are stored loaded or are not secured under lock. Parents often report that children do not know firearm locations when 39% of the children are actually able to state the locations and 22% have handled the guns (Children's Defense Fund, 2014).

Homicide in children has gained attention in the past several years because of several shootings at schools, universities, and other community sites. While homicide is an extreme example, there are other types of violence. Children report being threatened verbally and with guns or knives at home, in schools, and in their neighborhoods. They may be beaten up or bullied or harassed. An estimated 3 to 10 million children are exposed to acts of domestic violence by adults in their homes. They may be subjected to dangerous situations in their neighborhoods or during times of homelessness. Date rape or other sexual violence is reported by up to 10% of teens (CDC, 2014a).

SAFETY ALERT!

When a group of children is attacked or killed in a school shooting, this tragic occurrence has the attention of the media. The tragedy of violence involving children occurs somewhere in the United States daily. A firearm kills about seven children every day in the United States, or about 50 per week. An additional 200 to 300 children suffer from nonfatal firearm injuries (Children's Defense Fund, 2014). Nurses must intervene in this national tragedy. Become familiar with firearm injury statistics in your community. Teach families, children, and youth about the dangers of firearms. Urge safe storage. Help schools establish programs to ensure safety for students.

Internationally, millions of children experience violence annually, and decreasing violence against children has become a focus of the World Health Organization and the United Nations (World Health Organization, 2014). Common forms of violence worldwide are war and terrorism. War affects children in several ways: Parents leave home to fight in wars; children may be forced to take on adult roles in families when parents leave; children become orphans when parents are killed; children may be raped, sexually trafficked, or forced to be sex slaves; and some children are trained and forced to fight in battles, carry messages, or otherwise engage in combat themselves. Children who live through wars or have a parent or sibling die in war can be permanently affected by these events. Depression and other mental health problems are common in youth who have experienced war.

Natural disasters and terrorism also take a large toll on the mental health of children and adolescents. Most children and adolescents who live through terrorism experience profound sadness, cling to adults who provide security, and have a variety of somatic complaints. Interventions should be directed at different phases of violence, such as preevent preparation (emergency preparation and training) and postevent activity (offering special services and resources).

Several resources have been developed to help families and healthcare professionals help children deal with war and violence. See the resources at the National Center for Children Exposed to Violence, Society of Pediatric Nurses, and American Academy of Child and Adolescent Psychiatry websites.

Bullying

One type of violence that frequently occurs in schools is **bullying**, or aggressive behavior that is intended to cause harm, exists in a relationship with imbalance of power, and occurs repeatedly. Bullies are aggressive, impulsive, and need to dominate others. Bullying behaviors include verbal abuse (taunting, teasing), name calling, threats, spreading rumors, social exclusion, and physical abuse (hitting, shoving, kicking, tripping). About 20% of children suffer bullying at school each year, and about 5% did not go to school at least 1 day in the previous month because of safety concerns due to bullying (CDC, 2014a). Although bullying is most commonly reported in schools, it can occur in neighborhoods as children go to and from school, on school buses, on sports teams, and in other settings.

Bullying can also occur through the Internet and is reported by 20% (with a range of 9% to 40% in various studies) of young people (Cyberbullying Research Center, 2011; Schneider, O'Donnell, Stueve, et al., 2012). **Cyberbullying** occurs when a child or adolescent is targeted by another via an Internet posting or other digital technology and threatened, tormented, harassed, humiliated, or embarrassed. Personal information

may be disclosed or fabricated, persons are excluded, offensive messages are sent, or harmful messages are sent out under the target person's name. Such attacks are socially aggressive and often anonymous.

Bullies themselves are at risk and are more likely than other youth to abuse substances, be depressed, and carry weapons to school, putting other children at risk. Bullying is associated with future delinquent behavior, depression, low self-esteem, loneliness, suicidal ideation, and suicide attempts (Tsitsika et al., 2014).

Children who are bullied are more commonly socially isolated and anxious. Health problems such as migraines, stomach pains, suicidal thoughts, and other problems can result. Academic performance commonly deteriorates and rates of school absenteeism increase (American Academy of Pediatrics, 2011). Realizing the serious effects of such behaviors, a number of states have now passed legislation that reiterates the rights of all children to attend school in a safe and peaceful manner. Some state education departments mandate school district programs for students about bullying, and clear school policies about dealing with the behavior. See the Health Resources and Services Administration (HRSA) Maternal and Child Health Bureau website at www.stopbullyingnow.hrsa.gov.

Nurses can be active in setting up school policies about bullying and integrating assessment and interventions related to bullying into health promotion visits. School programs should:

- Inform all students that bullying is not tolerated.
- Train teachers and other personnel about signs of bullying.
- Ensure adult supervision in hallways and on playgrounds, sites where bullying is most common.
- Teach children to promptly report bullying that is experienced or observed.
- Set up peer support for those who are bullied.
- Arrange therapeutic treatment through school counselors and other resources for those who bully; involve parents in the treatment plan.
- Measure incidence of bullying, monitor outcomes of policies, and use data to evaluate policies in schools.

Nurses who are in clinics, offices, and other health promotion settings can:

- Be alert for children with behavior changes (irritability, anxiety, poor self-concept).
- Consider bullying as a potential cause when fear or refusal to attend school is reported by child or parents.
- Ask questions during visits, such as "Have you ever been afraid to go to school?," "What are the best and worst things about going to your school?," and "What are the other kids in your neighborhood like?"
- Ask parents what they have done about any situations identified. Partner with the parent to act as liaison to the school or other agency.
- Refer identified bullies and victims of bullying to mental health specialists.

Incarceration

A growing number of children are entering the judicial system, and many are admitted at young ages. About 3.4% of youth in the United States are incarcerated at any given time (Annie E. Casey Foundation, 2011). Children in detention, courts, and other facilities have frequently been victims as well as perpetrators of violence. They often have multiple risks such as substance abuse, early sexual activity, multiple sexual partners, sexual abuse, lack of a healthcare home, and mental health problems. The incarceration facility itself may subject youth to additional violence, abuse, and other maltreatment (Annie E. Casey Foundation, 2011). Nurses work within the juvenile justice system to provide episodic care for children or to partner with others to establish health-related programs within facilities. Youth who are incarcerated need the following:

- Basic physical care such as immunizations, vision, and hearing screening
- Nutrition assessment and teaching
- Skin assessment and hygiene practice teaching
- Information about sexuality, sexual practices, and sexually transmitted infections
- Assessment for substance abuse
- Teaching about hazards of substance use and assistance with quitting
- Mental health services
- Developmental assessment
- Individualized education plans to meet cognitive needs

Hazing

Hazing is an activity that is forced on an individual, causes humiliation, and is required for membership in an organization or group. It can sometimes be harmful and even lead to death. Sports teams, music groups, and Greek sororities and fraternities are examples of groups commonly associated with hazing. Activities might include removing clothes, drinking large amounts of alcohol, using snuff or other substances, being locked in small places, being beaten, and many other behaviors. In spite of its common practice, many students do not know what to do about hazing practices; coaches or other adult leaders may or may not be aware of hazing practices. Youth often believe that they must experience and uphold the traditions of hazing to belong to their group (Allan & Madden, 2011). Ask during health visits if the student has ever had to do something to belong to a group or team. Ask about "scary" things others have had them do. Assist schools and colleges in setting up antihazing policies. Encourage students to report hazing. Be aware of the possibility of hazing when seeing children with traumatic injuries (Hazing Prevention, 2011).

Domestic Violence

Domestic violence occurs between members of a family. The specific type of violence known as *intimate partner abuse* occurs between adult partners in the family. It may involve the parents of a child, or one parent and a significant other. This type of abuse injures the child or adolescent because it is traumatic to witness a close family member or loved one become the recipient of violence. About 3.3 million children annually in the United States are exposed to violence against their mothers or other female care providers; children who live in homes where intimate partner abuse occurs are significantly more likely to be abused themselves (Cross, Matthews, Tonmyr, et al., 2012; Davidov, Nadorff, Jack, et al., 2012). Children may also be the direct victims of domestic violence in a family. See the section on child abuse later in this chapter.

Dating Violence

Dating violence is another type of intimate partner abuse; this type occurs in relationships among youth. Over 10% of adolescent males and females report being victims of dating violence (CDC, 2014a). Such behaviors include being hit, slammed into something, or intentionally injured with an object or weapon. Girls who reported dating violence were also more likely to report other risk behaviors, such as feeling sad, having attempted suicide, or having used substances such as tobacco and drugs. Early sexual activity, having a higher number of sex partners, and being less likely to use birth control are also associated with a higher incidence of dating violence. A risk profile with a cluster of potentially dangerous behaviors may therefore put adolescents more at risk for dating violence.

Date rape is a term used when dating violence takes the form of rape. This can be particularly harmful to females who often do not want to share the event or press charges against the attacker.

Nurses should screen for violence at each health promotion visit, including gynecologic visits and prenatal care. Ask what is going well and not going well in intimate relationships, and whether the person ever feels unsafe or is forced to do things she does not wish to do. Recognize that while not as common, males may even be victims of violence in close relationships. Recognize that alcohol and other drugs are often connected with violence in relationships so ask about their use. Organize peer discussion groups about intimacy in order to help youth develop a sense of self-confidence and self-efficacy that will empower them to refuse participation in activities in which they do not wish to engage.

TABLE 17–6 Assessment Questions to Identify Violence Risk and Protective Factors

MICROSYSTEM
• Have you been hurt by your parents or anyone else at home?
• When was the last time you were made fun of or bullied at school? What did you do?
• Have you ever brought a gun or knife or other weapon to school?
• Do you have access to guns and knives at home? At friends' houses?
• What stresses are there in your family now?
• Tell me about school—what you like and don't like.
MESOSYSTEM
• Do your parents attend school meetings? Talk with your teachers?
• Do you participate in any church, synagogue, or mosque services?
• Do you participate in any community activities?
EXOSYSTEM
• What stresses do your parents have at work, in their families, with their health or finances?
• Do you feel like your school helps to keep you safe?
• Are there plans for handling violent episodes at your school if they were to occur?
• Do you feel safe in your neighborhood?
• Where would you go or who would you call if you felt unsafe or were hurt and no one was at home?

Nursing Management

Violence

Nursing Assessment and Diagnosis

Nurses are in key positions to identify children at risk of being recipients and victims of violence. The ecologic framework can be used to assess children. Some questions that can be asked are listed in Table 17–6. It is important to detect both the risks that lead to vulnerability and the protective factors that can promote resilience and safety. (Refer to Chapter 4 for explanations of these factors and the systems that influence the child.) Adapt questions to each age group and insert them in every healthcare encounter.

Nursing care for violence is discussed in the *Nursing Care Plan*. The following nursing diagnoses may be appropriate (NANDA-I © 2014):

- ***Violence: Self-Directed, Risk for,*** related to history of violence
- ***Self-Esteem, Chronic Low,*** related to history of abuse
- ***Family Processes, Dysfunctional,*** related to situational crises
- ***Development: Delayed, Risk for,*** related to environmental deficiencies

Planning and Implementation

Prevention is an important role for the nurse. Interventions such as providing resources for family planning; teaching self-regulation/control techniques; and applying technology such as kiosks in health centers, virtual training for healthcare providers, and positive media messages are all important measures in preventing violence (Child Trends 2015). Nurses intervene with individual children, with families, and in schools and communities to increase safety and decrease violence. Help children and families meet basic needs and access resources to assist with finances, respite care, domestic violence, and other issues. Education is a key element of intervention.

PROVIDING INFORMATION

Teach the family the dangers of firearms and the necessity for using gun locks and locked cabinets, storing guns unloaded, and storing guns and ammunition in separate places. Suggest alternative activities to minimize child exposure to violence in the media. Inform parents about rating systems for television and other media, and about lockout mechanisms for televisions and computers. Discuss the harmful effects of verbal and physical abuse to the child or other family members and explore alternatives.

Present the school-age child and adolescent with information about bullying and strategies for dealing with it. Provide school and community resources where the child can go if there are threats of any kind. Discuss date rape and violence with all teens and encourage them to report it.

COMMUNITY-BASED NURSING CARE

Both in schools and in community settings, nurses can plan peer mentoring to provide assistance to children at high risk of experiencing violence. Nurses can link and coordinate school and community programs for children to provide for parent involvement and child support. Discuss safety issues, both risk factors

Nursing Care Plan: The Child and Violent Behavior

1. Nursing Diagnosis: *Violence: Other-Directed, Risk for,* related to history of family violence (NANDA-I © 2014)

GOAL: The child will demonstrate impulse control.

INTERVENTION	RATIONALE
• Identify violent behaviors in the child.	• Violence in the child usually develops over time.
• Provide a safe place for exploration of feelings by referral to school or other counseling, support groups, and other resources.	• The child needs an opportunity to explore feelings and vulnerability.
• Provide strategies for managing anger and alternative ways for coping with problems.	• Coping strategies can be learned from others and can help in dealing with a stressful home situation.

EXPECTED OUTCOME: Child will express the ability to manage problems in acceptable ways.

GOAL: The child will be secure in a safe environment.

INTERVENTION	RATIONALE
• Perform a thorough assessment of hazards to the physical and emotional state in the child's home, neighborhood, and school.	• Hazards to physical and emotional health promote violence to and from the child.
• Institute actions that will result in removal of child from unsafe situations.	• Removal from family, community, or school may be needed to ensure child safety.
• Use community resources to provide respite care, teaching for families, and safety instructions for the child.	• Stress reduction measures may help to decrease violent behaviors.

EXPECTED OUTCOME: Child will express a sense of physical and emotional safety in daily life.

2. Nursing Diagnosis: *Injury, Risk for,* related to physical or psychologic conditions in the environment (NANDA-I © 2014)

GOAL: Risk for physical and emotional injury to the child is decreased.

INTERVENTION	RATIONALE
• Identify physical and psychologic factors that affect the child's safety.	• Multiple factors in the family can contribute to risk of violence and lack of safety for the child.
• Assist family to deal with issues such as mental status challenges, fatigue, financial concern, substance abuse, and lack of adequate childcare resources.	
• Instruct family on methods of keeping the child safe.	• Families need information about the impact of unsafe settings on the child and methods that can decrease risk of injury.

EXPECTED OUTCOME: Child will not be injured in physical or emotional ways in the home or other immediate settings.

3. Nursing Diagnosis: *Post-Trauma Syndrome* related to physical or psychosocial abuse (NANDA-I © 2014)

GOAL: The child will demonstrate abuse or violence recovery.

INTERVENTION	RATIONALE
• Assess the child's affect and behaviors.	• Disturbed child behaviors can demonstrate a sense of mistrust and insecurity.
• Evaluate social interactions and sense of trust in others.	
• Assist the child in identifying feelings and coping strategies by providing counseling, art therapy, and other strategies.	• Establishment of close interactions with others demonstrates reestablishment of a sense of trust.

EXPECTED OUTCOME: Child will identify feelings related to violent episode(s) and express healing of the self.

and protective actions, in schools and community groups. Report children who are at risk. Work to establish extended programs for children so that they are safe after school. Help children learn behaviors that will help them be safe in their communities and at home. Teach positive problem-solving and conflict-management techniques to children and parents.

Youth with special needs are a special concern of nurses. Jails and detention centers often have a nurse who visits youth on a regular basis or when health problems occur. Health teaching may be provided in some facilities. Halfway houses and homeless shelters are examples of settings where violence prevention and intervention can occur with youth. Mental health centers and other programs have nurses that work with children who are victims of violence (for example, have witnessed domestic violence, have witnessed or had a family member murdered, have been abused at home or school) or perpetrators of violence. See Chapter 28 for a discussion of posttraumatic stress disorder and its effects on the child and adolescent.

Partner with families to assist them in talking to children about war and terrorism. Recognize that youth who have experienced such events themselves are more at risk for mental health disruptions with future events. Answer questions from children honestly but reassure them that many people are trying to make the situation safe. Other suggestions for parents include the following:

- Limit television viewing and other media exposure because of its constant replaying of the events of terrorism or war. Preschoolers may think the events continue to happen, rather than being a one-time occurrence. Watch with children and talk with them about what is happening.
- Continue with structured family events such as meals, recreation, and faith-based activities. Spend time with your child.
- Take cues from the child about how much to discuss. Use words the child or adolescent can understand.
- Partner with the school so teachers know what parents have discussed and parents are aware of how events are discussed at school.
- If youth decide to become active by writing letters or joining campaigns, allow them to participate in this way.
- Be alert for regression in behavior, sleep and eating problems, or other indications of stress. Consider talking with the healthcare provider or a counselor in such situations.
- Expect that even after the child has adjusted, there may be delayed reactions. Anniversaries of events, holidays, and birthdays often bring renewed pain and sadness.
- Realize that adults must care for themselves, obtain stress relief, and talk with others in order to have strength and resources available for children.

Evaluation

The expected outcomes of nursing care for violence prevention include a decrease in incidents of homicides, firearm injuries, abuse, date rape, and other violence among children. Additional outcomes are establishment of programs to decrease violence, and verbalization by all children of what to do if violence occurs and how to solve problems without becoming violent.

Child Abuse

One of the most common types of violence against children is child abuse. Children from all socioeconomic groups and both genders are victims of abuse. This type of violence can have implications for both the physical and mental health of children, and can influence their health status even long after the abuse has occurred. Awareness of the problem of child abuse is increasing. More cases are being reported; however, these are probably only a small percentage of the total.

There are 3.4 million reports of abuse and neglect annually, with 78% of them due to neglect, 18% related to physical abuse, 9% to sexual abuse, and 11% to other types of abuse; about 1640 children die annually (5 children daily) from abuse (CDC, 2014b; Childhelp, 2013). Infants have the highest rate of abuse (21.9 per 1000 children,) with decreasing rates as children get older. Twenty-seven percent of victims are under 3 years of age, and 20% are 3 to 5 years old (CDC, 2014b).

Physical abuse is only one part of a larger problem. The definition of child abuse has expanded during the past decades and includes physical neglect, emotional abuse and neglect, verbal abuse, and sexual abuse, as well as physical abuse. Abuse generally involves an act of commission—that is, actively doing something to a child physically, emotionally, or sexually, such as hitting, belittling, or molesting. Neglect more often involves an act of omission, such as not providing adequate nutrition, emotional contact, or necessary physical care, or abandoning a child. Because the evidence is often not visible, emotional abuse and neglect are more difficult to identify and prove than physical abuse or neglect. Risk factors for abuse and neglect are listed in Table 17–7.

Physical Abuse

Physical abuse is the deliberate maltreatment of another individual that inflicts pain or injury and may result in permanent or temporary disfigurement or even death. Common methods of physical abuse in children are listed in Table 17–8.

TABLE 17–7 Risk Factors for Child Abuse and Neglect

FACTORS INCREASING RISK FOR PHYSICAL ABUSE
Poverty
Violence in the family
Prematurity or low birth weight
Unrelated male primary caretaker
Parents who were abused as children
Age less than 3 years
Child disability or condition that requires a great deal of care (e.g., intellectual disability, attention deficit hyperactivity disorder)
Parental substance abuse or social isolation
FACTORS INCREASING RISK FOR SEXUAL ABUSE
Absence of natural father or having a stepfather
Being female
Mother's employment outside the home
Poor relationship with parent
Parental relationship characterized by conflict
Parental substance abuse or social isolation

TABLE 17–8 Methods of Physical Abuse in Children

Hitting, slapping, kicking, or punching

Whipping with belts, shoes, or electrical cords (***A***)

Inflicting burns with a lit cigarette or lighter (***B***)

Immersing child or body part in scalding water (commonly legs, perineal area, hands, or feet; see Figure 31–16)

Shaking the child violently ("shaken child" syndrome)

Tying the child to a fence, bed, tree, or other object

Throwing the child against a wall, down stairs, or against a window

Choking or gagging the child

Fracturing the legs, arms, ribs, or skull

Deliberately administering excessive doses of prescribed or non-prescribed drugs

Deliberately withholding prescribed medication

A

B

SOURCE: ***A,*** BioPhoto Associates/Science Source; ***B,*** Mediscan/Alamy.

Physical Neglect

Physical neglect is the deliberate withholding of or failure to provide the necessary and available resources to the child. Behaviors constituting physical neglect include failure to provide for the following basic needs: supervision appropriate for child's age, adequate nutrition and hydration, hygiene (e.g., clean diapers and clothes, bathing and toileting facilities), shelter (e.g., warmth in winter), and appropriate health care (e.g., immunizations, dental care, medications, eyeglasses).

Abandoned Babies

There are no accurate statistics on numbers of babies that are abandoned in dumpsters, on doorsteps, and in other locations. This tragedy has been addressed by Safe Haven laws in some states that allow women to drop unwanted babies at certain locations such as hospitals and fire stations without legal recrimination. In spite of these laws, babies continue to be abandoned, perhaps because mothers do not know about the laws or because they do not believe they will not be found guilty. Young teen mothers may not want others to know they had a baby. In addition, placement of these babies in adoptive homes is difficult because of paternity suits. Nurses should know their state's Safe Haven law details. Inform adolescents and young women about the law and post information in community sites frequented by women. Partner with young pregnant women to link them to resources such as adoption agencies when they might not want to keep a baby.

Emotional Abuse

Emotional abuse usually involves shaming, ridiculing, embarrassing, or insulting the child. It can also include the destruction of a child's personal property, such as tearing up the child's favorite family photographs or letters or harming, killing, or giving away the child's pet. These actions are frequently used as a means of frightening or controlling the child.

Verbal abuse is a common method of emotional abuse. Words can be a violent and volatile weapon against a child, eroding the child's fragile sense of self and destroying self-esteem. Common examples of verbal abuse include yelling obscenities at the child, calling the child names, threatening to "put the child away" or to give away or kill the child's pet, telling the child "I wish you were never born" or "You're worthless," and using words to humiliate, shame, or degrade the child.

Emotional Neglect

Emotional neglect is characterized by the caretaker's emotional unavailability to the child. The usual style of interaction is cold and lacking in sensitive personal attention. The child suffers from a lack of nurturance and failure of the parent or caretaker to meet basic dependency needs. An example of emotional neglect is the parent who is mentally ill, or abusing alcohol or other substances, and cannot respond adequately to the child's developmental needs.

Sexual Abuse

Child sexual abuse is the exploitation of a child for the sexual gratification of an adult. About 1.2 per 1000 children (almost 100,000) children in the United States are sexually abused each year. Approximately 10% of schoolchildren report that they have been sexually abused. Many children who are sexually abused are under the age of 5 years, some as young as 3 months. The perpetrator is often the parent, stepparent, or someone else known to the child such as a friend, neighbor, or babysitter. Methods of sexual abuse may be sexual acts, allowing others to commit sexual abuse, threats, exploitation via video or other means, and a variety of other actions (Childhelp, 2013; National Center for PTSD, 2011). Use of the word *child* in relation to sexual abuse and molestation refers to anyone who has not reached the age of consent, even if a teenager. **Incest** is sexual activity between close family members, so that marriage would be legally or culturally

prohibited. Abusers often threaten to harm or kill the child or another family member if the child discloses the abuse. Some abusers are pedophiles, people who have sexual impulses toward preadolescent children. The pedophile is at least 16 years of age and is at least 5 years older than the victim, and the victim is 13 years of age or younger. Another form of sexual abuse is *exhibitionism*, or obtaining sexual arousal by exposing one's genitals to a stranger. Some children are victims of prostitution, forced to offer themselves for money or the pleasures of others, either in person or through videos and Internet sources.

Clinical Tip

Following are common forms of sexual abuse:

- Oral–genital contact
- Fondling and caressing the genitals
- Anal intercourse/sodomy
- Sexual intercourse
- Rape
- Prostitution
- Forced viewing of or participation in pornography such as sexually explicit or nude photographs
- Encouraging nude photos or sexual activity via Internet or video

ETIOLOGY AND PATHOPHYSIOLOGY

Regardless of the type of abuse, the most common abuser is the child's parent or guardian or a male friend of the child's mother. Substance abuse is a major contributor to the problem, with one half of cases related to parental alcohol or drug abuse (Childhelp, 2013). Risk factors associated with abusive behavior in adults include the following:

- Psychopathology, such as drug addiction or alcoholism, low self-esteem, poor impulse control, and other personality disorders
- Poor parenting experiences, such as abuse in the abuser's own childhood, rejection by the abuser's own parent(s), lack of knowledge of alternative methods of discipline, strong belief in or family tradition of harsh discipline, and lack of parental affection
- Marital stressors and problems with partners, such as hostile-dependent, abusive, or nonsupportive relationships, and one-sided decision making
- Environmental stressors, such as legal, financial, medical, or housing problems
- Social isolation, such as few friends and limited use of sitters, family, or other resources
- Inappropriate expectations for the developmental level of the child

CLINICAL MANIFESTATIONS

See Table 17–9 for clinical manifestations of physical abuse in children and adolescents. Behaviors inconsistent with developmental stage may be apparent. For example, the toddler or preschool child may be indiscriminately friendly with unfamiliar adults, including healthcare providers, rather than demonstrating shyness or anxiety. For the infant or young child with shaken baby syndrome or shaken child syndrome, the symptoms are those of central nervous system injury from repeated coup and contrecoup injury (see Chapter 27). These may include vomiting, irritability, fatigue, poor feeding, bradycardia, apnea, enlarged fontanelle, and seizures. Bruises are usually not present, but computerized tomography (CT) is often definitive for the diagnosis with radiographs and MRI used to provide a thorough diagnostic profile (National Center for PTSD, 2011).

TABLE 17–9 Clinical Manifestations of Physical Abuse in Children and Adolescents

- Multiple bruises in various stages of healing
- Scald burns with clear lines of demarcation and in a glove or stocking distribution (see Figure 31–16)
- Rope, belt, or cord marks, usually seen on the mouth, buttocks, back, legs, and arms (see Figure A in Table 17–8)
- Burn scars in various stages of healing
- Multiple fractures in various stages of healing, spiral fractures not explained by accident
- Shortness of breath and distress upon being moved, indicating chest contusions and possible rib fractures
- Sedation from overmedication
- Exacerbation of chronic illness (such as diabetes or asthma) because of withholding of medication
- Cranial and abdominal injuries
- Change in behavior or school performance
- Fear and avoidance of certain people or situations

Manifestations of physical neglect include undernourishment (evidenced by constantly feeling hungry, hoarding or stealing food, and being underweight), unclean clothes and body, poor dental health (extensive cavities or generally poor condition of teeth), and inappropriate clothing for the season.

Manifestations of emotional abuse, verbal abuse, and emotional neglect include fear, poor physical growth, and failure to meet appropriate developmental milestones. The child may have difficulty relating to adults, impaired communication skills, and developmental delays. Behavioral manifestations include anxiety, fear, shame, aggression, delinquency, and depression.

Children who have been sexually abused may exhibit a variety of physical and behavioral signs and symptoms (Table 17–10). Bruising, bleeding, and laceration of the genital area are obvious signs of trauma (National Center for PTSD, 2011). However, sexual abuse does not always result in apparent injury. Among the many long-term consequences of child sexual abuse are ongoing feelings of shame, guilt, anger, and hostility; decreased self-esteem, which leads to increased self-destructive behavior, risk of suicide, and decreased ability to establish positive relationships in adulthood; recurrence of victimization experiences; substance abuse; and eating disorders. The results can be long lasting, with children experiencing posttraumatic stress disorder (PTSD) or substance abuse in adulthood. Factors associated with greater psychologic harm to the child include (1) a long period of abuse, (2) use of violent force or threat of violence, (3) abuse involving penetration (intercourse or oral–genital sex), and (4) abuse involving family members, especially the father or stepfather.

CLINICAL THERAPY

Diagnosis of abuse is made on the basis of a careful history and thorough physical examination. X-ray, CT, and MRI studies may be ordered to identify signs of recurrent abuse (e.g., healed fractures). Laboratory studies may involve urine culture for signs of infection or screening for sexually transmitted infections; they can also rule out other causes of bleeding such as hemophilia. Genitourinary examination may be performed if sexual abuse

TABLE 17–10 Clinical Manifestations of Sexual Abuse in Children and Adolescents

- Vaginal discharge
- Blood-stained underpants or diaper
- Genital redness, pain, itching, or bruising
- Difficulty walking or sitting
- Urinary tract infection
- Sexually transmitted infection
- Somatic complaints, such as headaches or stomachaches
- Sleeping problems, such as nightmares or night terrors
- Bed-wetting
- Unwillingness to go to babysitter, family member, neighbor, or other person
- New or excessive sexual curiosity or play
- Fear of strangers
- Constant masturbation
- Curling into fetal position
- Phobias about particular places, people, or things
- Abrupt changes in school performance and attendance
- Changes in eating habits
- Abrupt changes in behavior (especially withdrawal)
- Child or adolescent female acts like a wife or mother
- Excessively seductive behavior

is suspected. Some children are admitted directly to the hospital with the diagnosis of suspected abuse or neglect. Less obvious as a victim of abuse is the child admitted with a skull fracture who "fell off a chair."

Clinical Tip

About 8000 to 9000 U.S. children are hospitalized with fractures each year, and it is estimated that 20% to 25% of children under 1 year of age and 6% to 7% of older children experience abuse as the cause of fracture. Current guidelines of the American Academy of Pediatrics recommend skeletal survey in fractures known to be due to abuse, domestic violence, or being hit by a toy, or when there is no history of trauma that caused the fracture. From 12 to 23 months, all fractures must be evaluated by skeletal survey, and in children older than 24 months, the fracture type determines the need for skeletal survey (Wood et al., 2014).

Neglect, which is more difficult to define and identify, frequently requires hospitalization with a comprehensive medical, social, and psychiatric evaluation. Five basic categories must be considered when attempting to diagnose neglect: (1) medical care neglect (lack of necessary medical care), (2) gross safety neglect (lack of appropriate supervision), (3) physical neglect (lack of food and shelter), (4) emotional neglect, and (5) educational neglect.

All 50 states have extensive, complex statutes about reporting child abuse and neglect. A specialist must be consulted, especially if the child's testimony will be used in court.

Children do not routinely make false allegations of abuse. If indeed there is reason to believe the allegations are false, a child and adolescent therapist (psychiatrist, psychologist, psychiatric clinical nurse specialist, or social worker) with special expertise should be consulted to determine the truth. Keep in mind that children who withdraw their accusations may have been threatened or coerced into doing so. Because children who have been physically, emotionally, or sexually abused are at risk for major depression, they require skilled care by mental healthcare providers who are specially trained in this area. Initially, the treatment goals include prevention of self-destructive or other dangerous acts. Children must be encouraged to express their fears and feelings in a safe and supportive environment. Equally important is the child's need to build coping skills and self-esteem. These children must be reassured and convinced that they are in no way responsible or to blame for what happened.

Professionalism in Practice Laws Regarding Child Abuse Reporting

Every state has a child abuse law specifying the particular behaviors that define every type of abuse. Any professional who works with children and reasonably suspects that a child has been abused is required to report suspicions of abuse or neglect to the local agency for child protective services. Reports made in good faith are not liable to countersuits. However, professionals who suspect abuse and do not report it may be held responsible by the judicial system. In some states, all citizens are mandated to report suspected abuse. Check the law in your state to learn those particular details. See the U.S. Department of Health and Human Services website for state laws (www.childwelfare.gov/systemwide/laws_policies/state/can).

Individual treatment with art therapy is used initially because it is the least threatening method in the early stages of treatment, it can easily be tailored to meet the child's individual needs, and it prepares the child for other forms of treatment such as family and group therapy (Figure 17–8). Family or group therapy may be of benefit in exploring the child's concerns and feelings. Anger is common, especially in children who were abused by a trusted adult such as the father or stepfather.

Figure 17–8 Clinical interventions with children. Therapeutic strategies with young children involve various methods of communication, such as dramatic play and art.

Nursing Management

Child Abuse and Neglect

Nursing Assessment and Diagnosis

Nursing assessment in instances of suspected child abuse or neglect requires a comprehensive history and physical examination, with documentation of findings. Consultation with social service agencies in the community is important if the family is receiving services.

Obtaining the history can be stressful for both the nurse and the parent. Use of therapeutic communication techniques and a quiet, unhurried environment are helpful. Be open, nonjudgmental, and calm. A statement such as "Hello, Mr. S. My name is Joan T. I'm Jonathan's nurse, and I will be asking you some questions about his overall health" may be a good start. It is important to differentiate true child abuse from cultural variations that might inaccurately be assumed to indicate abuse (Figure 17–9***A*** and ***B***). Obtaining information about abusive and neglectful behaviors requires a trusting relationship with parents, who are often afraid to trust any healthcare professional.

The health history sequence should include (1) parental concerns, (2) general family history, and (3) specific child history. This sequence begins with nonthreatening topics and allows the nurse to demonstrate concern before asking about abuse-related concerns. Obtain details about how injuries occurred. Document the parents' and child's own words verbatim using quotation marks. Compare reports obtained from each family member for lack of consistency and details that change over time.

It is desirable to interview the parent and child separately as well as together. Parent–child interaction during an intensive history-taking session provides an opportunity to observe the child's behavior and the parent's method of handling and responding to the child.

Data gathered during history taking are particularly important in light of physical findings. Are there discrepancies between the history and physical assessment data? Do the parents give a history of an uncontrollable, inattentive toddler when the nurse observes a child who is attentive throughout a 15-minute examination? Assess the child's general appearance, including dress and behavior during the assessment. How do the child's affect, behavior, and development compare with those of other children the same age? Document all lesions and bruising, including site, size, and color. Be aware of Mongolian spots that can mistakenly be interpreted as a sign of child abuse (see Chapter 5). If there are fractures, follow the guidelines given earlier regarding need for skeletal survey. Be alert for the signs of shaken child syndrome; this most often appears as a subtle neurologic condition. Measure head circumference and perform a neurologic examination (see Chapter 27).

Documentation of findings is important in all situations but is essential in cases of suspected child abuse and neglect. Each person who handles a laboratory specimen or other item (e.g., clothing soiled with semen) in cases of suspected child abuse must be identified in the client's record, and the specimen must never be left unattended. Record physical findings as observed. Use figure diagrams to document skin injuries. Take photographs as directed to document the location, nature, and extent of injuries.

Among the nursing diagnoses that might be appropriate for the physically abused or neglected child are the following (NANDA-I © 2014):

- ***Pain, Acute,*** related to inflicted injuries
- ***Skin Integrity, Impaired,*** related to inflicted injuries
- ***Development: Delayed, Risk for,*** related to lack of supportive parenting and environment
- ***Nutrition, Imbalanced: Less than Body Requirements,*** related to inadequate caloric intake

A

B

Figure 17–9 **It is important to differentiate cultural practices, such as *A*, cupping, and *B*, coining, from signs of child abuse. Traditional treatment practices are sometimes mistaken for signs of physical abuse. Inquire about what treatments have been tried for the child at home. If unfamiliar with the treatment, ask the family members to explain what they have done. When there is lack of clarity, work with other healthcare professionals to decide if child abuse is a potential concern.**

SOURCE: ***A,*** © doc-stock/Alamy; ***B,*** Biophoto Associates/Science Source.

- ***Health Maintenance, Ineffective,*** related to lack of parental provision of child's essential needs
- ***Fear*** related to actual physical harm or repeated risk of injury
- ***Injury, Risk for,*** related to physical abuse
- ***Violence: Other-Directed, Risk for (Parent),*** related to inability to manage anger

Additional diagnoses that might apply to the emotionally abused or neglected child include the following (NANDA-I © 2014):

- ***Coping, Defensive,*** related to psychologic impairment
- ***Self-Esteem, Chronic Low,*** related to lack of appropriate emotional support from parents
- ***Coping: Family, Disabled,*** related to dysfunctional family dynamics and pattern of physical abuse

Diagnoses that might apply to the sexually abused child include the following (NANDA-I © 2014):

- ***Anxiety*** related to potential separation from parent
- ***Rape-Trauma Syndrome*** related to sexual exploitation
- ***Role Performance, Ineffective,*** related to domestic violence
- ***Personal Identity: Disturbed,*** related to disturbance of usual activities of childhood

Developing Cultural Competence Cupping and *Cao Gio*

Traditional treatment practices are sometimes mistaken for signs of physical abuse. The Chinese practice of cupping, which involves heating a bamboo cup and placing it on the skin, is a traditional treatment for headaches or abdominal pain. The Vietnamese practice of *cao gio* ("rubbing out the wind"), in which a coin or the fingers are forcefully rubbed on the chest, back, or neck, is used to treat minor ailments. Ask about marks on the skin, how they occurred, and what health practices the family uses.

Planning and Implementation

Nursing care focuses on helping to remove the child from an abusive environment, preventing further injury, providing supportive care, and reinforcing the importance of follow-up care and counseling.

PREVENT FURTHER INJURY

Work with social services and community agencies to assess the child's home environment, individuals living in the home, and the actions surrounding the abuse. Assist in removing the child from the home to temporary custody of the court or foster care of another relative if indicated. Counsel family members about abuse and refer them for appropriate therapy.

PROVIDE SUPPORTIVE CARE

Protect and treat the child's injuries (e.g., fractures, burns). Include parents in the child's treatment plan, and keep them informed about the child's progress. Even if suspected of inflicting injuries to the child, the parent is still the child's primary caretaker. Talk with the parent as you would with any parent. Be supportive of any guilt expressed. Encourage the parent to assist with the child's care. Observe parent–child interactions and document supportive behaviors and the child's response to the parent versus other healthcare providers.

Interacting nonjudgmentally with a parent suspected of child abuse can be difficult. Nurses should talk with a colleague about any anger they feel toward such a parent or about the child's injuries or specific actions surrounding the abuse. Use team meetings to develop strategies that enable healthcare providers and other professionals to work with the parents and child.

Clinical Tip

When children have been abused, they are often frightened in new situations. Sexually abused children may resist removing clothes and may become very anxious during a physical examination or medical test. They may distrust members of the gender that abused them. When aware of a history of abuse, ask the parents or guardians how to best facilitate the child's health care. Be sensitive to fears and allow the child to wear clothing, have a support person present, or whatever may provide a sense of security. Consistency of nurses assigned to the child and the presence of a counselor may help to increase rapport and trust.

HOME CARE TEACHING

If there is any question about the child returning to a potentially dangerous situation, support the child's removal from the situation. The child may receive supervised care in the home by court order. Day care, home nursing, and social worker visits may be arranged. Parents should be referred to parent effectiveness classes, family therapy, and support groups as necessary. When a neighbor or friend is the abuser, the family may need support and legal advice when a term of incarceration is finished and the perpetrator returns to the community. Some states and communities have sexual offender laws that publicize the presence of an offender on parole within neighborhoods.

Encourage the family to inform other care providers when the child's abuse history may affect a response to care. They should be alert to signs of PTSD so they can seek assistance if the child has continuing problems (see Chapter 28).

Evaluation

Expected outcomes of nursing care for the child who has been abused or neglected include the following:

- The child maintains normal growth and development.
- A positive sense of self-esteem emerges in the child.
- Parents are provided with information and resources for stress relief.
- The child is provided with a nurturing environment.
- The child experiences no further episodes of abuse.

Münchausen Syndrome by Proxy (Factitious Disorder)

Münchausen syndrome by proxy is a potentially deadly form of child abuse that involves the fabrication of signs and symptoms of a health condition in a child. In most cases, the mother creates these fictitious signs in her child (the proxy). The victim is usually less than 6 years old, and commonly less than 1 year of age. Frequently, the child's symptoms of illness are used to gain entry into the medical system to meet the abuser's own psychologic

needs for attention. The perpetrator may induce illness by giving the child medications or perform other actions such as adding blood to the child's urine specimen (National Center for Biotechnology Information, 2011).

The issues of abuse are multidimensional. The child is a victim of the feigned illness, repeated hospitalizations, and invasive procedures. Equally disruptive is the deprivation of the child's daily routine caused by the periodic medical crises.

Münchausen syndrome by proxy should be suspected when unexplained, recurrent, or extremely rare conditions occur; illness is unresponsive to treatment; and the history and clinical findings are inconsistent. The most commonly reported signs and symptoms are central nervous system dysfunction, apnea, diarrhea, vomiting, fever, seizures, signs of bleeding (in urine or stool), and rashes. The parent may overdose the child on medications, such as nonprescription drugs and even syrup of ipecac, causing a variety of side effects. The symptoms occur in the presence of the same caretaker and disappear when the child is separated from that caretaker.

The child often appears uncooperative, extremely anxious, fearful, and negative. The caretaker, who in contrast appears very cooperative, competent, and loving, often expresses a desire for the child to recover. The caretaker may even suggest diagnostic procedures to try to determine "what's wrong." Characteristically, the caretaker thrives in the healthcare environment.

The cause of factitious disorder is often complex and rooted in the caretaker's own abusive or neglectful childhood. The disorder occurs in all socioeconomic classes. Often the perpetrator has some type of healthcare background, such as nursing or another allied health profession. The abuser is often young and married, and appears very involved with and interested in the child (National Institutes of Health, 2013).

A suspicion of Münchausen syndrome by proxy requires a coordinated evaluation by a collaborative care team. Members of the team must organize and communicate a strategic plan regarding collection of evidence, confrontation of the abuser, and management of the hospitalized child. The child's safety is the ultimate concern. The case must also be reported to the appropriate child protective services. Remember also that some health conditions are very hard to diagnose and that sometimes unexplained health problems are related to an underlying disease.As one possible example, see mitochondrial disease that is described in Chapter 30.

Nursing Management

Take special care to maintain a trusting relationship with the parent or guardian so that person does not become suspicious and leave the hospital. Often the best person on the team to function in the role of "trusted other" is a member of the psychiatric consultation team.

Careful documentation of parent–child interactions, presence or absence of symptoms, and other pertinent observations is essential. The child must be closely monitored. If blood is present in the child's urine, stool, or vomitus, carefully document whether the nurse was present or whether the sample was provided by the parent. Covert video surveillance may be ordered by the hospital when the syndrome is highly suspected in a particular situation. Expert consultants may be needed to ensure legal requirements for investigation are met. When enough evidence is collected to prove Münchausen syndrome by proxy, the caretaker is confronted by the healthcare provider or a member of the psychiatric team in planning with law enforcement officials.

Environmental Influences on Child Health

Environmental contaminants, poisoning, and accidental respiratory ingestion are discussed in this section. See Chapter 10 for a discussion of the effects of disasters on children and related nursing management.

Environmental Contaminants

Contaminants are **toxins**, harmful or poisonous chemicals produced by metabolism or an organism (e.g., ricin), or **toxicants**, harmful natural or synthetic chemicals not metabolically produced by an organism (Genius, Sears, Schwalfenberg, et al., 2013). These products are commonly produced during industrial manufacture, but could be released as a form of terrorism. Children are generally more vulnerable than adults to such exposures because of their developing bodies. They consume high amounts of food, water, and air per unit of body weight. Consequences to the neurologic system are particularly important to developmental and behavioral outcomes (Magzamen, Van Sickle, Rose, et al., 2011).

Knowledge of environmental contaminants and their effects on children is limited. Environmental contaminants may be found in the air, water, soil, food, complementary therapies, and various objects, such as jewelry. Ground and surface water can be contaminated by manufacturing processes, agricultural and urban runoff into streams, sewage treatment plants, landfills, and particulates in the air. Some toxicants associated with deleterious effects on the child's developing nervous system include phthalates, bisphenol A, brominated flame retardants, polycyclic aromatic hydrocarbons, and gas cooking (Jurewicz, Polanska, & Hanke, 2013).

Contaminants in the environment can influence children in complex ways. Prenatal exposure can affect the developing fetus. Exposure during lactation may bring contaminants to the breastfed baby. Environmental effects may occur as the child grows through skin contact, inhalation, or food and water ingestion. Because children are exposed to many chemicals on a daily basis, harmful exposures are often difficult to identify. One example of a known harmful agent is environmental tobacco smoke (ETS). The mother who smokes or is exposed to ETS runs an increased risk of having a baby that is small for gestational age or who dies of sudden infant death syndrome (SIDS) (see Chapter 20). The child exposed to ETS has an increased risk of occurrence and severity of asthma and other respiratory diseases. The homes of smokers have higher nicotine levels even if adults are not smoking in the house (Kassem et al., 2014).

One to 2 million migrant workers travel from their homes, often in Central or South America, to work in the U.S. farm industry each year (Schmalzried & Fallon, 2012). The children of migrant farm workers constitute a group that is at particular health risk. The farm industry presents many environmental health risks: exposure to pesticides, unsanitary drinking water, overcrowding, insect exposure, equipment hazards, poor transportation, social isolation, and poverty (Shelton et al., 2014). Children living in migrant farm worker families are more likely to have respiratory and ear infections, gastroenteritis, intestinal parasites, skin infections, unmet dental needs, poor nutrition and anemia, delayed development, and occupation injuries (Schmalzried & Fallon, 2012). Families travel frequently; provision of coordinated health care is therefore difficult, leading to low immunization rates and academic challenges. Adolescents may even travel alone, lacking supervision by parents or other adults.

Some potentially harmful environmental exposures across various settings include the following (American Academy of Pediatrics Council on Environmental Health, 2011; Karr, 2012; Meadows-Oliver, 2012):

- Pesticides such as organophosphates, organochlorine, chlorpyrifos, dialkyl phosphates, carbamates, pyrethroids (Children may be exposed through home use, parents who work in pesticide manufacturing, garden/farm/agricultural use, and ingestion through food treated with pesticides.)
- Outdoor air pollution from automobiles, power plants, and other sources (Children spend time outside and therefore have increased exposure.)
- Indoor air pollution from dust mites, molds, lead particles from old housing, wood smoke, and other sources
- Heavy metal exposure, including lead, mercury, arsenic, and chlorine
- Substances such as polychlorinated biphenyls (PCBs) stored in fatty tissues of the mother and causing fetal exposure or in animal fats; also present in electrical wiring
- Phthalates used to make flexible plastic products, such as catheters, intravenous tubing and bags, food packaging, and toys
- Bisphenol A (BPA) used to make hard plastics, such as baby bottles, containers used for microwaving, toys, and linings of food cans (Recent legislation mandates that BPA can no longer be used in baby bottles.)

Nursing Management

Nurses are instrumental in identifying exposure to environmental toxic agents. Inquire about:

- Parental work with harmful substances such as dust and chemicals
- Age of home (homes built before 1978 or renovated in the last 6 months are at risk for contamination with chemicals.)
- Safety items in home such as radon, carbon monoxide, and smoke alarms
- Child and family member with hobby requiring use of toxic materials, such as lead with stained glass work or glue with model building
- Child's consumption of nonfood products

Nurses in public health agencies often coordinate care for migrant farm workers. Evaluating living conditions and hazards through home visits is necessary. Provision of care and electronic and paper records can enhance care with distant sites where the family spends part of the year. Screening for health and developmental progression should be carried out whenever children are evaluated. In some northern U.S. communities, Head Start or other daycare centers open additional facilities during summer months when migrant families need such care while adults work in fields.

For children in all settings, consider the possibility of environmental exposure and refer for blood testing and further evaluation whenever delayed development or behavioral problems are evident. Test blood levels for contaminants such as lead (see later section). Hair, urine, and other testing may be possible as well. Identification of the toxic exposure and its removal from the environment are critical. Removal from the body by drug treatment is possible for some substances. Instruct the family in prevention of further exposure. Perform periodic growth and developmental measurements on the child and ensure return for further blood tests and other monitoring.

Poisoning

Young children are at risk for ingestion of foreign substances because of their characteristic behaviors, which involve exploration of the environment. Poisonings are the second leading cause of unintentional home-injury death and account for nearly one third of all unintentional home injuries. Annually, over 2 million calls are made for human ingestions to poison control centers, 80% for children under 6 years of age. About 130,000 visits to emergency departments occur, and over 800 children die from poisoning (Bronstein, Spyker, Cantilena, et al., 2012; CDC, 2013c).

Infants and toddlers commonly place objects in their mouths. Although most poisons are ingested, other routes of contamination include dermal, inhalation, and ocular. The Poison Prevention Packaging Act of 1970 mandates child protective devices for all potentially toxic substances, such as household cleansers and medications. However, many are still ingested by children.

The most dangerous toxic substances a small child may ingest include iron, antidepressants, hypoglycemic agents, cardiovascular drugs, salicylates, anticonvulsants, and illicit drugs. The five most common classifications of poisons ingested by children less than 5 years of age are cosmetics and personal care products, analgesics, household cleaning products, miscellaneous foreign bodies and toys, and topical preparations (Bronstein et al., 2012). Other common causes of poisoning include vitamins, cold and cough preparations, pesticides, and plants (e.g., Boston ivy, poinsettia, philodendron, lily-of-the-valley, daffodil bulbs, azalea, and rhododendron). Some household items are nontoxic and cause little harm; however, items that contain caustic agents or toxic chemicals can cause irreversible damage or death. Substances most often associated with a fatality in children less than 6 years of age include analgesics, plants, cold and cough preparations, and hydrocarbons (Bronstein et al., 2012).

SAFETY ALERT!

Most of the deaths resulting from poisoning occur in teens and are related to use or abuse of prescription pain medications. Pain relievers, tranquilizers, sedatives, and stimulants are frequently available in homes and pose a risk for young children who take them out of curiosity and teens who may take them in an experimental manner (CDC, 2013c). When youth combine alcohol with prescription medications, the outcomes can be even more serious. Another contemporary exposure involves marijuana; states that have legal medical and personal-use marijuana practices create another potential exposure for children. The median age for children requiring care for marijuana exposure is 1.5 to 2 years (Wang et al., 2014). Nurses should inquire about toxic substances in the homes of all youth and provide safety teaching regarding ways to keep children of all ages from having access to these substances.

CLINICAL MANIFESTATIONS

The manifestations of poisoning depend on the toxin. Some common effects include altered mental status, respiratory or cardiac symptoms, seizures, vital sign changes, and gastrointestinal symptoms. See Table 17–11.

TABLE 17–11 Clinical Manifestations of Commonly Ingested Toxic Agents

TYPE	SOURCES	CLINICAL MANIFESTATIONS	CLINICAL THERAPY
Corrosives (strong acids and alkaline products that cause chemical burns of mucosal surfaces)	Batteries Oven and drain cleaners Clinitest tablets Denture cleaners Bleach Toilet bowl cleaners Hair relaxers	Severe burning pain in mouth, throat, or stomach Swelling of mucous membranes; edema of lips, tongue, and pharynx (respiratory obstruction) Violent vomiting; hemoptysis Drooling; inability to clear secretions Signs of shock Anxiety Agitation	• Do not induce vomiting! • Dilute toxin with water to prevent further damage.
Hydrocarbons (organic compounds that contain carbon and hydrogen; most are distillates of petroleum)	Gasoline Kerosene Furniture polish Lighter fluid Paint thinners	Gagging Choking Coughing Nausea Vomiting Alteration in sensorium (lethargy) Weakness Respiratory symptoms of pulmonary involvement, tachypnea, cyanosis, retractions, grunting	• Do not induce vomiting! (Aspiration of hydrocarbons places the child at high risk for pneumonia.) • Use gastric lavage for highly toxic hydrocarbons. • Provide supportive respiratory care. • Decontaminate skin by removing clothing and cleansing skin.
Acetaminophen	Many over-the-counter products	Nausea Vomiting Sweating Pallor Hepatic involvement (pain in upper right quadrant, jaundice, confusion, stupor, coagulation and bilirubin abnormalities)	• Administer the antidote *N*-acetylcysteine, which binds with the metabolite, preventing absorption and protecting the liver. • Activated charcoal may be used.
Salicylate	Products containing aspirin	Nausea Disorientation Vomiting Dehydration Diaphoresis Hyperpnea Hyperpyrexia Bleeding tendencies Oliguria Tinnitus Convulsions Coma	• Depends on amount ingested. • Induce vomiting. • Administer intravenous sodium bicarbonate, fluids, and vitamin K.
Mercury	Broken thermometers Chemicals Paints Pesticides Fungicides	Tremors Memory loss Insomnia Weight loss Diarrhea Anorexia Gingivitis	• Similar to that for lead poisoning (see text discussion).

TYPE	SOURCES	CLINICAL MANIFESTATIONS	CLINICAL THERAPY
Iron	Multiple vitamin supplements and therapeutic iron tablets	Vomiting Hematemesis Diarrhea Bloody stools Abdominal pain Metabolic acidosis Shock Seizures Coma	• Activated charcoal may be used. • Administer intravenous fluids and sodium bicarbonate. • Deferoxamine chelation therapy.

Cardiac medications	Calcium channel blockers
	Beta blockers
	Digoxin
		Bradycardia, arrhythmias, heart block
		Hypotension
		Dizziness, unsteady gait
		Altered mental status, seizures
		Nausea, vomiting
			• Administer IV fluids.
			• Administer prescribed medications:
			  • Vasopressor therapy
			  • Calcium chloride
			  • Glucagon, or high-dose regular insulin with supplemental glucose to achieve euglycemia
			  • Digoxin immune Fab

Hypoglycemic agent	Sulfonylurea	Hypoglycemia
		Tachycardia
		Diaphoresis, clammy skin
		Mental status changes, coma
			• Administer prescribed medications:
			  • Glucagon
			  • Octreotide

Toxicology: Pearls and pitfalls in the use of antidotes. *Emergency Medical Clinics of North America*, *28*, 149–161.

CLINICAL THERAPY

Specific information about the poison is obtained from the parent to guide medical management. Blood and urine toxicology screens, as well as arterial blood gas and electrolyte testing, are performed. Testing of vomitus for the presence of medication or other poisonings may be helpful in determining the amount ingested. Other tests may include serum glucose, an electrocardiogram, serum electrolytes, and arterial blood gases. Testing of vomitus for the presence of medications or poisons may be helpful in determining the amount ingested.

In the emergency department the child's airway, breathing, circulation, and level of consciousness are assessed. The goal of treatment is to prevent further absorption of the poison and to reverse or eliminate its effects. The Poison Control Center is consulted to obtain guidance for treatment. An antidote is prescribed if one is available. Gastric lavage and activated charcoal are no longer routine therapy but may be used in some children if within 1 hour of ingestion. Cathartics or whole bowel irrigation with polyethylene glycol may be used for heavy metals or for long-acting or sustained-release medications. Syrup of ipecac is no longer recommended for treating suspected poisoning. Vomiting is rarely induced because too much of the poison may be absorbed before the agent used to cause vomiting is effective. In addition, vomiting is actually harmful when corrosives have been ingested and must absolutely be avoided in these situations.

Children with severe poisoning are admitted to the intensive care unit to carefully monitor the child and provide supportive care for the toxin's effects (e.g., arrhythmias, depressed respirations, seizures, hypotension, hypoglycemia, and electrolyte abnormalities). Potential complications of poisoning, depending on the type of poison, include respiratory and/or cardiac arrest, hypovolemic shock, liver failure, renal failure, seizures, and esophageal or tracheal burns.

Nursing Management

Poisoning

Nursing care focuses on initial emergent care and stabilization of the child with poisoning, followed by family education to reduce the risk of repeated poisoning.

Nursing Assessment and Diagnosis

Parents who suspect that their child has ingested a poison should immediately call the Poison Control Center (PCC). The PCC will advise parents about treatment to begin at home, and if the child needs treatment in the emergency department. If the child has vomited, the vomitus should be brought to the emergency department. With older children, the possibility of intentional ingestion needs to be considered.

Take a history from the family about the child's suspected ingestion substance, time, amount, and symptoms. Initial assessment focuses on airway, vital signs, and neurologic status. Assess for the following:

- Drooling, diaphoresis, and increased or depressed respirations
- Wheezing, respiratory distress, or stridor
- Decreased responsiveness and seizure activity
- Heart rate, skin color, capillary refill, peripheral and central pulses, and blood pressure
- Pupils (abnormally large or pinpoint pupils may be observed)

- Mouth, lips, and tongue for corrosive burns or edema and breath for unusual odor
- Vomiting and diarrhea (vomitus for presence of medication or other ingested substances)
- Height and weight

Nursing diagnoses for the child with ingestion of a toxic substance may include (NANDA-I © 2014):

- ***Airway Clearance, Ineffective,*** related to excessive secretion effect of toxic substance
- ***Gas Exchange, Impaired,*** related to depressed neurologic status
- ***Aspiration, Risk for,*** related to depressed neurologic status and vomiting
- ***Cardiac Output, Decreased,*** related to effects of toxic substance
- ***Injury, Risk for,*** related to repeated occurrence of poisoning
- ***Family Processes, Interrupted,*** related to poisoning of a family member

Planning and Implementation

Emergency care focuses on airway and hemodynamic stability, removal of toxic agents, and support of the family. The child is attached to pulse oximetry and cardiorespiratory monitors. An intravenous line is started for the administration of fluids and an antidote, if available. When activated charcoal is prescribed, it may be in a ready-to-drink solution in an opaque container, or it may need to be mixed with sorbitol or apple juice to encourage the child to drink it. Cover the cup so the child does not see the black liquid, and provide a straw to prevent spillage. Once immediate care has been provided, nursing care shifts to providing emotional support and preventing recurrence.

PROVIDE EMOTIONAL SUPPORT

Wait until the child is out of immediate danger before questioning parents in detail about the incident. Encourage parents to express feelings of anger, guilt, or fear about the incident.

PREVENT RECURRENCE

Discuss with parents the need to supervise infants and young children at all times. Ask parents how medicines and cleaning agents are stored and whether the house contains any plants. Teach parents proper methods of childproofing the home. Have the PCC number readily available. Suggest measures for preventing recurrence of poisoning. (See *Families Want to Know: Avoiding Childhood Poisoning*.)

The toll-free number for the American Association of Poison Control Centers (AAPCC) is 1-800-222-1222. The number can be accessed from anywhere in the United States and Puerto Rico, and the caller will be connected to the nearest poison control center.

Evaluation

Expected outcomes for nursing care of the child with poisoning include:

- The child maintains an open airway, effective gas exchange, and ventilatory function.
- The child is free from wheezing, coughing, pneumonia, or other signs indicating aspiration.
- The child's heart rate and blood pressure remain stable and appropriate for age.
- Neurologic status is appropriate for age.
- The family and child (if older) verbalize understanding of preventive measures and demonstrate measures to improve home environment safety.

Ingestion of Foreign Objects

There are about 100,000 cases of ingestion of foreign objects by children under 5 years of age annually in the United States. Coins, parts of toys, buttons, batteries, and glass are common objects ingested by young children (Bronstein et al., 2012). Adults often witness infants and young children ingesting foreign bodies, and older children will usually report swallowing a foreign object. Most small, round, smooth objects may not cause any clinical distress. However, if the foreign body is lodged in the esophagus, children may present with substernal pain, drooling, and dysphagia. Some children may exhibit respiratory symptoms including wheezing or coughing.

Serious complications can occur following foreign body ingestion. These complications include perforation of the intestinal tract, the most serious sequela of foreign body ingestion. Sharp objects are associated with a higher perforation rate than dull objects; perforations commonly occur in the region of the ileocecal

Families Want to Know

Avoiding Childhood Poisoning

Families with children require instructions for avoiding childhood poisoning. Teach family members these interventions to help avoid childhood poisonings:

- Place household cleaners, medications, vitamins, and other potentially poisonous substances out of the reach of children or in locked cabinets.
- Keep alcohol, marijuana, and prescription medications out of access for all youth, including teens.
- Use warning stickers such as "Mr. Yuk" on all containers.
- Buy products with child-resistant caps.
- Store products in their original containers.
- Never place household cleansers or other products in food or beverage containers.
- Remove all houseplants from the child's play areas.
- Put the Poison Control Center phone number by every phone in the house.
- Use caution when visiting other settings that are not childproofed (e.g., grandparents' homes). Remember that visitors may have pills in their purses or pockets that are easily reached by children.

valve. Development of strictures at the site of a retained foreign body may also occur. Respiratory complications arise if the object becomes lodged in the trachea, bronchi, or lungs. See Chapter 20 for care of the child with a foreign body airway obstruction.

Many ingested foreign bodies in children are radiopaque, so radiographs of the neck, chest, esophagus, and abdomen are useful tools for verifying ingestion and identifying the location of the object. Most foreign bodies pass spontaneously through the gastrointestinal system and are eliminated through stool. However, foreign bodies may become lodged in the esophagus and pose a significant risk to the child. Endoscopic examination and retrieval of the ingested foreign body may be necessary. Potentially harmful objects such as batteries, sharp objects, and magnets are removed surgically.

Nursing Management

Nursing care centers on supporting the child, providing collaborative assistance in the identification and removal of the foreign body, and teaching the child and family measures to reduce reoccurrence. Assess the child for drooling, wheezing, substernal pain, dysphagia, and coughing. Obtain a thorough history from the family. Determine, if possible, what was ingested, when the ingestion occurred, and any symptoms that the child experienced. Assess breath sounds.

Prepare the child for radiologic studies. Explain the procedures and reassure the child and family during the studies. Prepare for endoscopic examination and/or retrieval if necessary. If the foreign object is in the stomach and the child is to be observed for natural excretion of the object, explain monitoring of stools to parents. Suggest the use of tongue blades to examine stools for presence of the foreign body and to report if the object has not been passed within the expected time frame (generally 48 hours). Encourage the family to return for further radiologic examinations to determine the foreign object's progress of passage.

Partner with the family and assist them in establishing a safe home environment for the child. Encourage the family to keep all small items out of the child's reach and to ensure the child is monitored at all times. Expected outcomes for nursing care of the child who has ingested a foreign body include removal of the foreign body, reduction in risk, and family verbalization of preventive measures to reduce risk of ingestion of foreign bodies.

Lead Poisoning

Lead poisoning has been successfully prevented in many areas of the United States, with a substantial decline in lead levels from the mid-1970s. The average blood lead level for children is now 1.9 mcg/dL, down from 15 mcg/dL in 1976. Approximately 450,000 U.S. children (1%) from 1 to 5 years of age have blood lead levels above the recommended upper level of 5 mcg/dL. There is no safe level of lead exposure—even children with blood lead levels lower than 5 mcg/dL have been reported to have a decrease in cognition (CDC, 2012c; AAP Council on Environmental Health, 2016).

Lead in paint is the most common source of lead exposure for preschool children. Children are also exposed to lead when they ingest contaminated food, water, and soil or when they inhale dust contaminated with lead. A recent infiltration of lead into the water supply in Flint, Michigan, and in school water supplies in other communities points out the dangers of aging lead-lined pipes (U.S. Department of Health & Human Services, 2016). Paints on toys and crafts from some foreign countries may contain lead; unless such products are certified safe they should not be used by children.

Children are at greater risk for lead poisoning because they absorb and retain more lead in proportion to their weight than adults do. Lead is particularly harmful to children under the age of 7 years.

CLINICAL MANIFESTATIONS

Lead interferes with normal cell function, primarily of the nervous system, blood cells, and kidneys, and adversely affects the metabolism of vitamin D and calcium. Clinical manifestations depend on the degree of toxicity. Neurologic effects include decreased IQ scores, cognitive deficits, impaired hearing, and growth delays. Impaired mental function can occur with blood levels even lower than 5 mcg/dL. Lead ingestion by a woman during pregnancy can result in fetal malformations, reduced birth weight, and premature birth. Severe lead poisoning, which can result in encephalopathy, coma, and death, is now rare in developed countries.

Once in the body, lead accumulates in the blood, soft tissues (kidney, bone marrow, liver, and brain), bones, and teeth. Lead that is absorbed by the bones and teeth is released slowly; thus exposure to even small doses, over time, can result in dangerously high levels of lead in the body. See Table 17–12.

CLINICAL THERAPY

An environmental history should be obtained for all children. For those with risk of elevated lead (Pb) levels (living in homes completed before 1978, receiving Medicaid, in communities where schools or homes have been shown to have high levels of lead, and/or living in poverty), blood screening should be considered (CDC, 2012c, 2014c; U.S. Department of Health & Human Services, 2016). Follow-up testing is required in 2 to 3 months. Because most children are asymptomatic, careful history and identification of risk factors will guide healthcare providers in identifying children who need blood testing for lead.

TABLE 17–12 Clinical Manifestations of Lead Poisoning

LEVEL	CLINICAL MANIFESTATIONS
Less than 9 mcg/dL	Generally asymptomatic although subtle neurologic effects may be present with any exposure
10–19 mcg/dL	Mild impairment in growth, fine motor skills, and cognition Anemia
20–44 mcg/dL	General fatigue and motor impairment Difficulty concentrating Paresis or paralysis, tremor Headache Diffuse abdominal pain, vomiting, weight loss, constipation Anemia
45–69 mcg/dL	Colic (intermittent, severe abdominal cramps), anorexia, vomiting Hyperirritability Increased lethargy Lead line (blue-black) on gingival tissue
Over 70 mcg/dL	Encephalopathy, which may lead abruptly to seizures, changes in consciousness, coma, and death Ataxia

Source: Adapted from Agency for Toxic Substances & Disease Registry. (2011). *Lead toxicity clinical evaluation*. Atlanta, GA: Author.

Children with elevated Pb levels require a full medical evaluation, including a detailed environmental and behavioral history, physical examination, and tests for iron deficiency. Interventions to remove sources of lead from the child's environment are necessary. Blood screening is performed at ages 12 and 24 months, as well as for children in these groups who are 36 to 72 months old but not previously screened. A venous blood sample is preferred because it reduces the risk of specimen contamination from lead on the skin. Capillary specimens are used in some cases with careful skin preparation. Any elevation in a capillary specimen must be confirmed by a venous sample. A blood Pb level below 5 mcg/dL is considered acceptable, although it may still not screen out all children with impaired development due to lead. *Healthy People 2020* objectives aim at decreasing blood levels of children and the number of children with elevated levels (USDHHS, 2011).

Healthy People 2020

(EH-8.1) Eliminate elevated blood levels in children

(EH-8.2) Reduce the mean blood levels in children from 1 to 5 years to 1.4 mcg/mL

Children with very high blood Pb levels require medical treatment. For levels above 45 mcg/dL, chelation therapy is considered for administration. Children with blood Pb levels greater than 70 mcg/dL are critically ill from lead poisoning and require immediate chelation therapy and interventions to provide a lead-free environment.

Chelation is a reaction in which an organic compound, containing carbonyl (CO) and hydroxyl (OH) groups, coordinates with a metal to form a firmly bound ringlike structure. Chelation therapy for lead poisoning involves the administration of an agent that binds with lead, decreasing its effects and increasing its rate of excretion from the body. Calcium disodium ethylenediamine tetraacetate ($CaNa_2$ EDTA) IM or IV, dimercaprol (BAL) deep IM, penicillamine PO, or succimer (DMSA) PO may be used. Children with blood Pb levels between 25 and 69 mcg/dL receive $CaNa_2$ EDTA for 5 to 7 days, followed by a rest period and then a second chelation treatment. Children with Pb-B levels greater than 70 mcg/dL are given both BAL and $CaNa_2$ EDTA, followed by a rest period and a second chelation treatment using $CaNa_2$ EDTA alone. Chelation therapy has the potential for serious side effects. $CaNa_2$ EDTA can cause tubular necrosis and cardiac arrhythmia; IM administration is painful, so it is generally given IV. BAL can lead to hypertension, tachycardia, headache, fever, or nephrotoxicity. Penicillamine is used only when treatment with other drugs is not effective because of its multisystem side effects. Succimer is associated with GI side effects, rash, headache, and neurologic symptoms. Long-term follow-up of children receiving chelation therapy is essential. The child should never be discharged unless a lead-free home environment has been ensured.

Nursing Management

Nursing care centers on screening, education, and follow-up. Nurses often work with state and local health officials to plan screening for children at high risk of lead exposure. Ask parents about the child's development and eating habits and be alert for risk of lead exposure. Educate parents about sources of lead in the environment and techniques to reduce exposure. Make home visits to evaluate exposure to lead and to perform individualized teaching. Emphasize the importance of housekeeping interventions to reduce exposure to lead dust. These interventions include damp mopping of hard surfaces, floors, window sills, and baseboards; washing the child's hands and face before meals; and frequent washing of toys and pacifiers. Be alert that home renovation can significantly increase the levels of lead in dust.

Teach parents the importance of including foods high in iron and calcium in the child's diet to counteract losses of these minerals associated with lead exposure. The child should eat meals at regular intervals because lead is absorbed more readily on an empty stomach.

Be sure that parents understand the importance of follow-up testing of lead levels. If the child is developmentally delayed, refer the family to an infant stimulation or early intervention program. Referral to social services and either a visiting nurse or home healthcare nurse may also be appropriate.

Nurses who administer chelating drugs are challenged by the complexity of treatment and required care. Chelation should always be managed by experts in such care, and in consultation with the Lead Poisoning Prevention Branch of the National Center for Environmental Health of the CDC. Careful monitoring of liver and kidney function, cardiac, GI, and neurologic systems is needed for all chelating drugs. Administration for some drugs is via IM route and is painful; children will need skilled nursing and child life specialist care.

Expected outcomes of nursing care for the child with lead or other poisoning include the following:

- The child exhibits normal growth and development, including cognition.
- Adequate nutritional intake is ensured for the child.
- Lead or other poisons are removed from the child's environment.
- The family expresses understanding of measures to establish a safe environment for the child.

Chapter Highlights

- Many of the major morbidities and mortalities of childhood and adolescence are related to social and environmental factors.
- The theories of ecologic development and resilience provide frameworks to assess interactions of children and their environments, and to mitigate risk factors.
- Poverty and homelessness are pervasive and influence many health outcomes.
- Substance use, particularly of alcohol and drugs, poses risks to youth and requires screening, prevention, and cessation programs appropriate for developmental age.
- Violence can be directed at children, and children can be the perpetrators of violence. The nurse plans interventions for an array of abusive situations such as child abuse, sexual abuse, and domestic violence.
- Environmental contaminants affect the health of children, from the prenatal period through childhood. Medicines, plants, pesticides, lead, and other household products pose risks at all ages, even though most poisonings occur in children under 5 years of age.

Clinical Reasoning in Action

You are working at the inpatient adolescent psychiatric unit where there are approximately 20 teens between the ages of 12 and 17 years old. The teens are admitted for several different diagnoses, including depression, suicide attempts, bipolar disorders, and eating disorders. The nurses are in charge of medication administration, vital signs, unit safety issues, physical assessments, and basic therapeutic interventions. You are working with a client named Cindy, 15 years old, who was admitted because of a suicide attempt and has been given a dual diagnosis of bulimia nervosa and depression. She has had extreme weight loss and gain over the past year and is currently 67 inches tall and weighs 140 lb. She has stated she tried to commit suicide with a knife because she was upset over the loss of her boyfriend. She thought she was fat and was trying to lose weight by using laxatives and vomiting after meals. There is a family history of depression and substance abuse, but Cindy denies any substance use. She lives with her mother and has no contact with her father. She does not feel she has anyone to discuss her feelings with, and states her mother is gone from the house frequently. Cindy admits to often eating fast food and snacking on other junk food and soda. She has been in the hospital for 2 weeks and was resistant to treatment at first, but seems to be improving with therapy and medication. She has lost 3 lb while she has been hospitalized, and her average vital signs are temperature 98.7°F, pulse 70, respirations 12, and blood pressure 110/70 mmHg. (Review the content on bulimia in Chapter 14 to answer the following questions.)

1. What are some of the signs of bulimia Cindy may exhibit?
2. What can you tell the mother about Cindy's vital signs and stability at this time? How can you explain the weight loss?
3. What behavioral signs of bulimia should be part of your nursing assessment of Cindy while she is hospitalized?
4. What are the treatment recommendations for Cindy?

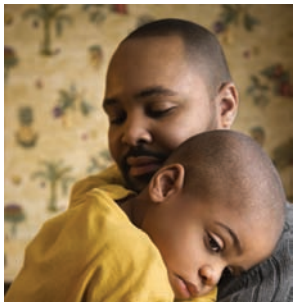
Chapter 18
Alterations in Fluid, Electrolyte, and Acid–Base Balance



Iofoto/Shutterstock

LeShan always likes to eat, so when he won't even drink I know he is sick. We just didn't know how sick he was or that he had gotten dehydrated. I wonder if we should have done something else for him at home.

—Father of LeShan, 18 months old

Learning Outcomes

18.1 Describe normal fluid and electrolyte status for children at various ages.

18.2 Identify regulatory mechanisms for fluid and electrolyte balance.

18.3 Interpret threats to fluid and electrolyte balance in children.

18.4 Describe acid–base balance and recognize disruptions common in children.

18.5 Analyze assessment findings to recognize fluid-electrolyte problems and acid–base imbalance in children.

18.6 Plan appropriate nursing interventions for children experiencing fluid-electrolyte problems and acid–base imbalance.

A thorough understanding of fluid, electrolyte, and acid–base homeostasis and imbalances is essential when providing nursing care to children like LeShan described in the chapter opener. This chapter presents information about the processes that maintain fluid and electrolyte balance and describes the common imbalances that may occur in children. It also describes how the body regulates acid–base status and explains the management of acid–base imbalances.

Many health conditions cause changes in body fluids that must be regulated and managed. Sometimes management of fluid status in the home or in a short-term ambulatory facility can prevent more serious illness or hospitalization.

FLUID VOLUME IMBALANCES

When fluid excretion and losses are balanced by the proper volume and type of fluid intake, fluid balance will be maintained. However, if fluid output and intake are not matched, fluid imbalance may occur rapidly. The major types of fluid imbalances are:

- Extracellular fluid volume deficit (dehydration)
- Extracellular fluid volume excess
- Interstitial fluid volume excess (edema)

Text continues on page 409

FOCUS ON:
Fluid, Electrolyte, and Acid–Base Balance

Physiology of Fluid and Electrolyte Balance

Fluid in the body is in a dynamic state. In persons of all ages, fluid continuously leaves the body through the skin, in feces and urine, and during respiration. Much of the human body is composed of water. **Body fluid** is body water that has solutes dissolved in it. Some of the solutes are **electrolytes**, or charged particles (ions). Electrolytes such as sodium (Na^+) potassium (K^+) calcium (Ca^{2+}) magnesium (Mg^{2+}) chloride (Cl^-) and inorganic phosphorus (Pi) ions must be present in the proper concentrations for cells to function effectively.

In persons of all ages, body fluid is located in several compartments. The two major fluid compartments contain the **intracellular fluid** (fluid inside the cells) and the **extracellular fluid** (fluid outside the cells). The extracellular fluid is made up of **intravascular fluid** (the fluid within the blood vessels) and **interstitial fluid** (the fluid between the cells and outside the blood and lymphatic vessels). Extracellular fluid accounts for about one third of total body water, and intracellular fluid accounts for about two thirds. The concentrations of electrolytes in the fluid differ depending on the fluid compartment. For example, extracellular fluid is rich in sodium ions; intracellular fluid, by contrast, is low in sodium ions but rich in potassium ions (Table 18–1).

TABLE 18–1 Electrolyte Concentrations in Body Fluid Compartments

	EXTRACELLULAR FLUID (ECF)		INTRACELLULAR FLUID (ICF)
COMPONENTS	VASCULAR	INTERSTITIAL	
Na^+	High	High	Low
K^+	Low	Low	High
Ca^{2+}	Low	Low	Low (higher than ECF)
Mg^{2+}	Low	Low	High
P_i	Low	Low	High
Cl^-	High	High	Low
Proteins	High	Low	High

Buffers

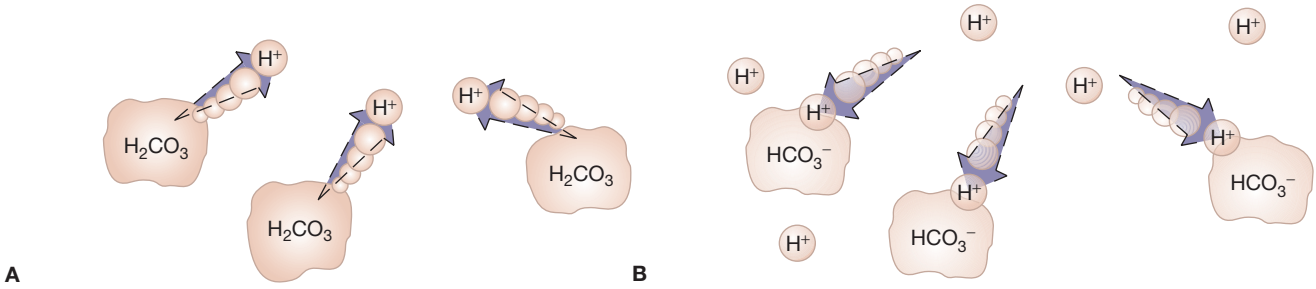
The maintenance of hydrogen ions within the normal range relies heavily on buffers. A **buffer** is a compound that binds hydrogen ions when their concentration rises and releases them when their concentration falls (see *Pathophysiology Illustrated: Buffer Responses to Excess Acid or Base*). Several kinds of buffers are present in the body (Table 18–2). Various body fluids have buffers to meet their special needs. The bicarbonate buffer system neutralizes metabolic acids (see *Pathophysiology Illustrated: The Bicarbonate Buffer System*); however, it cannot neutralize carbonic acid.

TABLE 18–2 Important Buffers

BUFFER	MAJOR LOCATIONS IN THE BODY
Bicarbonate	Plasma; interstitial fluid
Protein	Plasma; inside cells
Hemoglobin	Inside red blood cells
Phosphate	Inside cells; urine

Fluid moves between the intravascular and interstitial compartments by a process called filtration. Water moves into and out of the cells by the process of osmosis. These processes are discussed later in the chapter. Electrolytes move over cell membranes both by **diffusion** of particles from a location of greater to less concentration and by active transport that is effective even against the concentration gradient.

Pathophysiology Illustrated: **Buffer Responses to Excess Acid or Base**

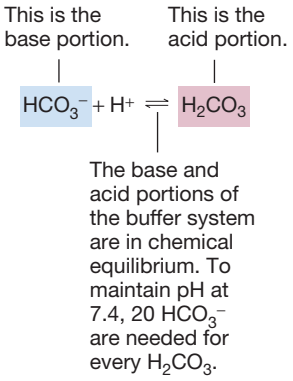


A, **How buffers respond to an excess of base. If the blood has too much base, the acid portion of a buffer pair (e.g., H_2CO_3 of the bicarbonate buffer system) releases hydrogen ions (H^+) to help return the pH to normal.**

B, **How buffers respond to an excess of acid. If the blood has too much acid, the base portion of a buffer pair (e.g., HCO_3^- of the bicarbonate buffer system) takes up hydrogen ions (H^+) to help return the pH to normal.**

(*continued*)

Pathophysiology Illustrated: The Bicarbonate Buffer System



Physiology of Acid–Base Balance

Normal acid–base balance is necessary for proper function of the cells and the body. The number of hydrogen ions (H^+) present in a fluid determines its acidity. Increasing the hydrogen ion concentration makes a solution more acidic. Because the hydrogen ion concentration in body fluids is very low, acidity is expressed as **pH** (the negative logarithm of the hydrogen ion concentration) rather than as the hydrogen ion concentration itself. The range of possible pH values is 1 to 14. A pH of 7 is neutral. The lower the pH, the more acidic the solution. A pH above 7 is basic or alkaline. The higher the pH, the more basic the solution. Body fluids are normally slightly basic.

The pH of body fluids is regulated carefully to provide a suitable environment for cell function. The pH of the blood influences the pH inside the cells. **Acidemia** refers to a blood pH below normal levels, whereas **alkalemia** is an increased blood pH. Normal arterial blood pH ranges are 7.36 to 7.42 for infants, 7.37 to 7.43 for children, and 7.35 to 7.41 for adolescents. For the enzymes outside the cells to function optimally, the pH must be in the normal range. If the pH inside the cells becomes too high or too low, then the speed of chemical reactions becomes inappropriate for proper cell function. Cell protein function relies on the correct level of hydrogen ions. Thus, acid–base imbalances result in clinical signs and symptoms. In severe cases, they may cause death.

In the course of their normal function, all cells in the body produce acids. Cells produce two kinds of acids: carbonic acid (H_2CO_3) and metabolic (non-carbonic) acid. These acids are released into the extracellular fluid and must be neutralized or excreted from the body to prevent dangerous accumulation. They can be neutralized to some degree by the buffers in body fluids. Carbonic acid is excreted by the lungs in the form of carbon dioxide and water. Metabolic acids are excreted by the kidneys. Examples of metabolic acids are pyruvic, sulfuric, acetoacetic, lactic, hydrochloric, and beta-hydroxybutyric acids.

All buffer systems have limits. For example, if there are too many metabolic acids, the bicarbonate buffers become depleted. The acids then accumulate in the body until they are excreted by the kidneys. Clinically, this is seen as a decreased serum bicarbonate concentration and decreased blood pH.

Role of the Lungs

The lungs are responsible for excreting excess carbonic acid from the body. A child breathes out carbon dioxide and water, the components of carbonic acid, with each breath. With faster and deeper breaths, more carbonic acid is excreted. Because carbonic acid is converted in the body to carbon dioxide and water by the enzyme carbonic anhydrase, an indirect laboratory measurement of carbonic acid is Pco_2, the partial pressure of carbon dioxide in arterial blood.

Although a child can voluntarily increase or decrease the rate and depth of respirations, they are usually involuntarily controlled. The Po_2 (partial pressure of oxygen in arterial blood), Pco_2, and pH of the blood are monitored by chemoreceptors in the hypothalamus of the brain and in the aorta and carotid arteries. The input from the chemoreceptors is combined with other neural input to change breathing according to needs. Rate and depth increase or decrease according to the amount of carbonic acid that needs to be excreted.

If a child has a condition that decreases the excretion of carbonic acid or causes breathing to be too slow or shallow (such as overmedication following surgery), carbonic acid accumulates in the blood. Clinically, this is seen as an increased blood Pco_2 and is a form of respiratory acidosis. The reverse will also be true in the child breathing excessively or deeply. This leads to decreased Pco_2 and respiratory alkalosis.

Role of the Kidneys

The kidneys regulate metabolic acids from the body in two ways: They reabsorb filtered bicarbonate to prevent its loss in the urine, and they regenerate bicarbonate when needed to restore balance. Bicarbonate is formed when acids and ammonium combine with extra ions. The blood bicarbonate concentration is an indicator of the amount of metabolic acids present, because bicarbonate is used in buffering the acids. When the concentration is normal, metabolic acids are present in usual amounts (see *Pathophysiology Illustrated: The Kidneys and Metabolic Acids*).

In a healthy child, the result of these renal processes is excretion of metabolic acids and maintenance of blood bicarbonate concentration within normal limits. These processes may take several hours to days to be effective in restoring balance when acidosis occurs. In the child whose kidneys are not producing enough urine, metabolic acids may not be effectively excreted. Accumulation of these acids uses up many of the available bicarbonate buffers, resulting in a decreased serum bicarbonate concentration and metabolic acidosis.

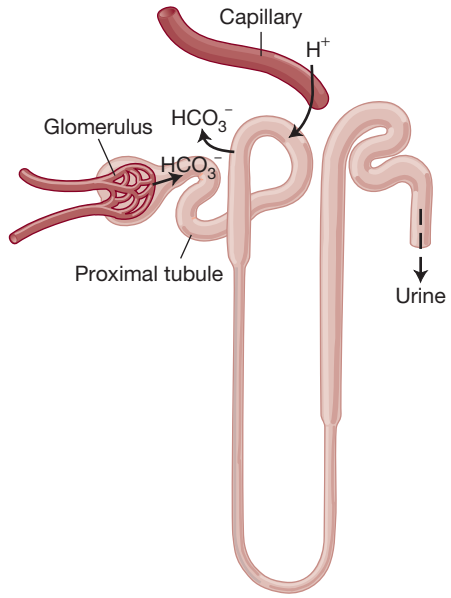
Role of the Liver

The liver plays a role in maintaining acid–base balance by metabolizing protein, which produces hydrogen ions. It also synthesizes proteins needed to maintain osmotic pressures in the fluid compartments.

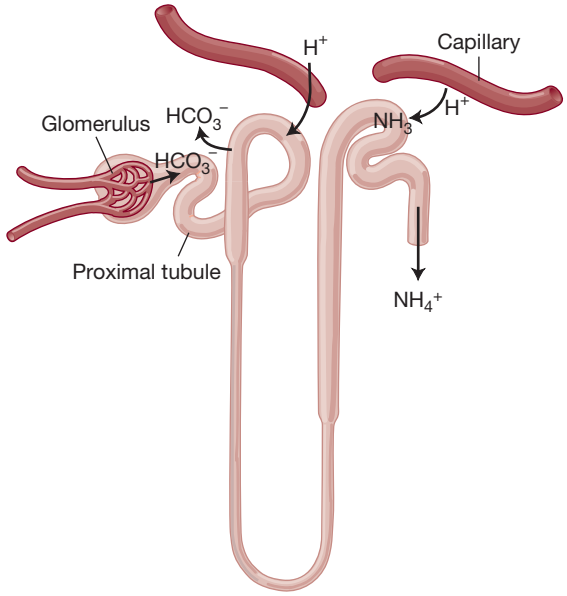
Pediatric Differences

Infants and young children differ physiologically from adults in ways that make them vulnerable to fluid, electrolyte, and acid–base imbalances. The percentage of body weight that is composed of water varies with age (Figure 18–1). The percentage is highest at birth (and higher in premature than in full-term infants) and decreases with age (see *As Children Grow: Fluid and*

Pathophysiology Illustrated: **The Kidneys and Metabolic Acids**



A



B

A, Recycling of bicarbonate by the kidneys. Bicarbonate ions that are in the blood are filtered into the renal tubules at the glomerulus. In the proximal tubules, bicarbonate ions are reabsorbed into the blood at the same time that hydrogen ions are transported from the blood into the renal tubular fluid.

B, Secretion and buffering of hydrogen ions in the kidneys. If the urine is too acidic, the cells that line the urinary tract could be damaged. To prevent this problem, hydrogen ions secreted into the distal tubules are neutralized by phosphate buffers or bound to ammonia and excreted in the form of ammonium ions.

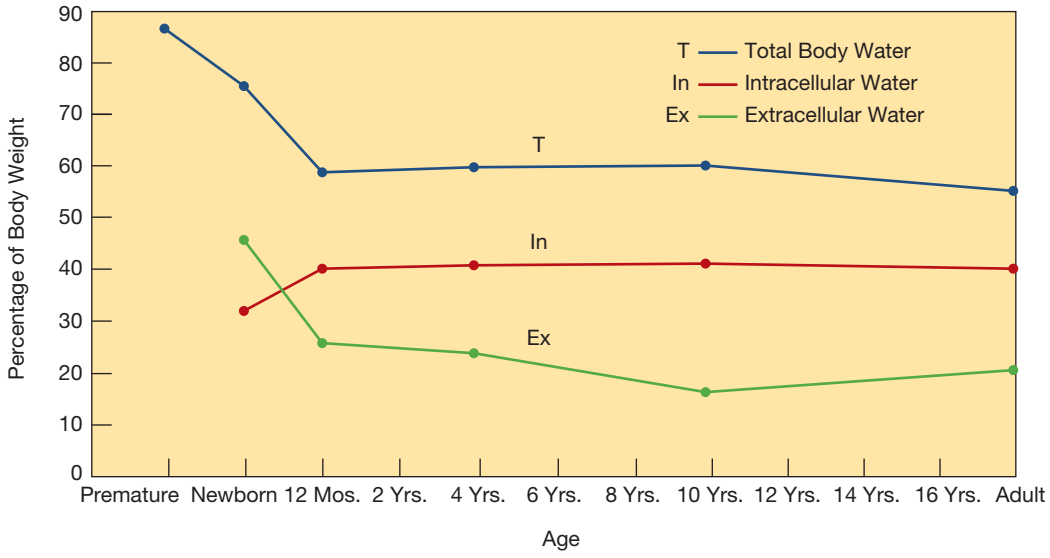


Figure 18–1 The major body fluid compartments. Extracellular fluid is composed mainly of intravascular fluid (fluid in blood vessels) and interstitial fluid (fluid between cells and outside the blood and lymphatic vessels). Intracellular fluid is that within cells.

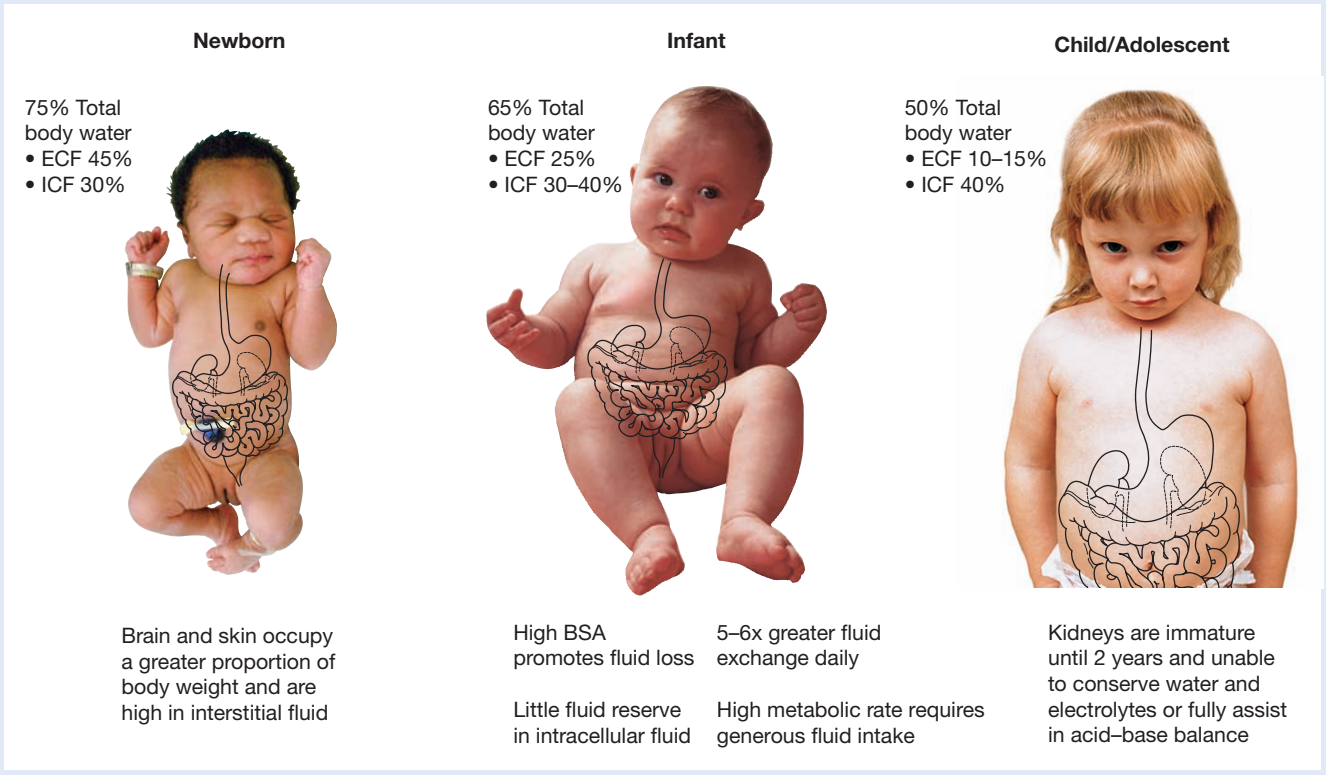
(*continued*)

As Children Grow: **Fluid and Electrolyte Differences**



The newborn and infant have a high percentage of body weight composed of water, especially extracellular fluid, which is lost from the body easily. Note the small stomach size, which limits a newborn's ability to rehydrate quickly.

Electrolyte Differences). Neonates and young infants have a proportionately larger extracellular fluid volume than older children and adults because their brain and skin (both rich in interstitial fluid) occupy a greater proportion of their body weight. Much of our extracellular fluid is exchanged each day. During infancy, there is a high daily fluid requirement with little fluid volume reserve; this makes the infant vulnerable to dehydration. As an infant grows, the proportion of water inside the cells increases, the extracellular amount decreases in comparison, and the risk of fluid imbalance begins to decrease.

Infants and children under 2 years of age lose a greater proportion of fluid each day than older children and adults and are thus more dependent on adequate intake. They have high **sensible fluid loss** (measurable loss such as through urine or wound drainage) and **insensible fluid loss** (immeasurable loss such as through skin and respiratory tract). They have a greater amount of skin surface or body surface area (BSA; relationship between height and weight measured in squared meters) and thus have greater insensible water losses through the skin. Because of this large BSA, they are also at greater risk when burned.

In addition, respiratory and metabolic rates are high during early childhood. These factors lead to greater water loss from the lungs and greater water demand to fuel the body's metabolic processes (Figure 18–2). Because of these factors, the exercising child dehydrates easily and must consume more fluid during physical activity, particularly during hot weather (Mayo Clinic, 2011).

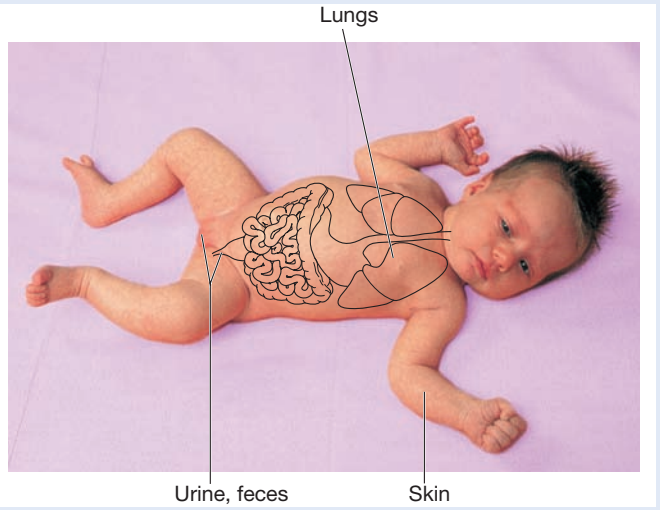


Figure 18–2 Normal routes of fluid excretion from infants and children.

When fluid status is compromised, a number of body mechanisms are activated to help restore balance. Several of these mechanisms occur in the kidneys. The kidneys conserve water and needed electrolytes while excreting waste products and drug metabolites. However, in children under 2 years of age, the glomeruli, tubules, and nephrons of the kidneys are immature. They are

thus unable to conserve or excrete water and solutes effectively (see Chapter 26). Because more water is generally excreted, the infant and young child can become dehydrated quickly or develop electrolyte imbalances. In addition, infants have a weaker transport system for ions and bicarbonate, placing them at greater risk for acidosis and acid–base imbalances. Children under 2 years of age also have difficulty regulating electrolytes such as sodium and calcium. Renal response to high solute loads is slower and less developed, with function improving gradually during the first year of life.

Diagnostic and laboratory tests for fluid and electrolyte status include:

- Arterial blood gases
- Serum electrolyte panel
- Urinary specific gravity

See Appendices D and E for more information about diagnostic and laboratory tests.

Use the following guidelines to perform a nursing assessment of fluid and electrolyte status.

ASSESSMENT GUIDE | The Child With a Fluid, Electrolyte, or Acid–Base Alteration

Assessment Focus	Assessment Guidelines
Body weight	• Has weight decreased since the last measurement or weight reported by the family? • If so, how much? What percent of body weight is the weight loss?
Skin and mucous membranes	• What are the temperature, turgor, and moistness of the skin? • Describe moistness of oral mucous membranes. • Describe moistness of the eyes and presence of tears. • Is edema present in any body parts?
Cardiovascular and respiratory systems	• What are pulse and blood pressure? • Test capillary refill and small-vein filling times. • What is the respiratory rate? Is the rate regular?
Gastrointestinal system	• Does the child have nausea, vomiting, or diarrhea? If so, how often and for how long has it continued? • Is the child eating and drinking? How much and what types of foods and fluids?
Urinary system	• What is the child's urinary output? Number of wet diapers/day? • What is the urine specific gravity?
Musculoskeletal system	• Describe muscle tone and symmetry.
Neurologic system	• Describe the child's state of alertness and any changes observed. • What is the level of consciousness? • Is the anterior fontanelle at the skin surface or does it appear sunken?

Extracellular Fluid Volume Imbalances

Extracellular Fluid Volume Deficit (Dehydration)

Extracellular fluid volume deficit occurs when there is not enough fluid in the extracellular compartment (vascular and interstitial). Depending on the cause of dehydration, sodium may be at normal, low, or elevated levels. (Hyponatremia and hypernatremia are described later in the chapter.) The state of body water deficit is called **dehydration**. There are three major types of dehydration:

- **Isotonic dehydration** (or **isonatremic dehydration**) occurs when fluid loss is not balanced by intake, and the loss of water and sodium are in proportion. The serum sodium is therefore within normal limits or slightly low even though the circulating blood volume is lowered. Most of the fluid lost is from the extracellular component. This type of dehydration is commonly manifested in the illnesses of young children such as vomiting and diarrhea.
- **Hypotonic dehydration** (or **hyponatremic dehydration**) occurs when fluid loss is characterized by a proportionately greater loss of sodium than water. Serum sodium is below normal levels. Compensatory fluid shifts occur from the extracellular to intracellular components in an attempt to establish normal proportions, thus leading to even greater extracellular dehydration. Severe and prolonged vomiting and diarrhea, burns, and renal disease can lead to this condition, as well as administration of intravenous fluid without electrolytes in treatment of dehydration.
- **Hypertonic dehydration** (or **hypernatremic dehydration**) occurs when fluid loss is characterized by a proportionately greater loss of water than sodium. Serum sodium is above normal levels. Compensatory fluid shifts occur from the intracellular to extracellular components in an attempt to establish normal proportions. The extracellular component therefore remains fairly normal, delaying the onset of signs and symptoms of dehydration until the condition is quite serious. Neurologic symptoms reflecting intracellular imbalance may occur simultaneously with more common symptoms of dehydration. The condition may be caused by health problems such as diabetes insipidus (see Chapter 30) or administration of intravenous fluid or tube feedings with high electrolyte levels.

The body continuously attempts to compensate for fluid and electrolyte imbalance by shifting fluid and electrolytes from one component to another. Therefore, it is rare for only one type of dehydration to occur; the child's fluid and electrolyte status and symptoms are constantly changing. Ongoing assessment and management are needed.

ETIOLOGY AND PATHOPHYSIOLOGY

Extracellular fluid volume deficit is usually caused by the loss of sodium-containing fluid from the body. Vomiting, diarrhea, nasogastric suction, hemorrhage, and burns most often cause loss of fluid containing sodium. Vomiting and diarrhea are common manifestations of disease in children throughout the world, and each year up to 5 million children die from dehydration related to diarrhea. In the United States, about 300 to 500 die annually from this problem, about 220,000 are hospitalized, and 1.5 million receive outpatient care (Kinlin & Freedman, 2012).

Type 1 diabetes may become a cause of dehydration as the child exhibits polydipsia and polyuria (see Chapter 30 for a detailed description of diabetes). Another cause of extracellular fluid volume deficit in infants is increased water loss in low–birth-weight infants kept under radiant warmers to maintain heat (Figure 18–3). Less frequently, adrenal insufficiency, accumulation of extracellular fluid in a "third space" such as the peritoneal cavity, and overuse of diuretics may be the cause. The latter etiology is most often seen in adolescents with bulimia (see Chapter 14).

Excessive exercise during very hot weather without sufficient fluid replacement can lead to fluid and electrolyte imbalance. Physiologic differences can place children at high risk, especially when they have vigorous outdoor activity in extreme heat with inadequate rest periods. Children may not feel thirsty and therefore may fail to drink adequately even when dehydrated. Additional risk factors include obesity and a combination of high temperature, high humidity, wind, and exposure to radiant heat (American Academy of Pediatrics [AAP] Council on Sports Medicine and Fitness & Council on School Health, 2011).

Burns and gastroenteritis are characterized by initial dehydration in the first 3 days due to a high loss of extracellular fluid. About 80% of the fluid loss is extracellular and only about 20% is intracellular. However, with time, the relationship begins to change, so that in illnesses over 3 days, about 60% of fluid loss is extracellular while 40% is intracellular (Engorn & Flerlage, 2014). Since the electrolyte composition of extracellular and intracellular fluids differs (see Table 18–1), electrolyte management will need to change for long-term conditions.

Figure 18–3 Fluid loss from overhead warming. Use of an overhead warmer or phototherapy increases insensible fluid excretion through the skin, thus increasing the fluid intake needed.

CLINICAL MANIFESTATIONS

The signs of dehydration relate to the severity or degree of the body water deficit (Table 18–3). They are a result of both the decreased fluid (e.g., diminished turgor and mucous membrane moisture) and the body's response to the fluid deficit (e.g., pulse and blood pressure changes).

TABLE 18–3 Severity of Clinical Dehydration

	MILD	MODERATE	SEVERE
Percentage of body weight lost	Up to 5% (40–50 mL/kg)	6–9% (60–90 mL/kg)	10% or more (100 mL/kg)
Level of consciousness	Alert, restless, thirsty	Irritable or lethargic (infants and very young children); alert, thirsty, restless (older children and adolescents)	Lethargic to comatose (infants and young children); often conscious, apprehensive (older children and adolescents)
Blood pressure	Normal for age	Normal or low; postural hypotension (older children and adolescents)	Low to undetectable
Pulse	Regular and strong	Rapid	Rapid, weak to nonpalpable
Skin turgor	Immediate	Poor	Very poor
Mucous membranes	Moist	Dry	Parched
Urine	Usual output	Decreased output (<1 mL/kg/hr); dark color; increased specific gravity	Very decreased or absent output
Thirst	Slightly increased	Moderately increased	Greatly increased unless lethargic
Fontanelle	Normal	Sunken	Sunken
Extremities	Warm; rapid capillary refill	Delayed capillary refill (>2 sec)	Cool, discolored; delayed capillary refill (>3–4 sec)
Respirations	Regular, usual rate	Usual or rapid rate	Changing rate and regularity
Eyes	Normal	Slightly sunken, decreased tears	Deeply sunken, absent tears

TABLE 18–4 Clinical Manifestations of Extracellular Fluid Volume Deficit

CLINICAL MANIFESTATIONS	ETIOLOGY
Weight loss	Decreased fluid volume; 1 L of fluid weighs 1 kg
Postural blood pressure drop (older children)	Inadequate circulating blood volume to offset the force of gravity when in upright position
Increased small vein filling time	Decreased vascular volume
Delayed capillary refill time	Decreased vascular volume
Flat neck veins when supine (older children)	Decreased vascular volume
Dizziness, syncope	Inadequate circulation to brain
Oliguria	Inadequate circulation to kidneys
Thready, rapid pulse	Cardiac reflex response to decreased vascular volume
Sunken fontanelle (infants)	Decreased fluid volume
Decreased skin turgor	Decreased interstitial fluid volume

Mild dehydration is hard to detect because children appear alert and have moist mucous membranes. Infants may be irritable and older children are thirsty. In moderate dehydration, the child is often lethargic and sleepy, but there may be periods of restlessness and irritability, especially in infants. Skin turgor is diminished, mucous membranes appear dry, and urine is dark in color and diminished in amount. Pulse rate is usually increased, and blood pressure can be normal or low. Severe dehydration is manifested by increasing lethargy or nonresponsiveness, markedly decreased blood pressure, rapid pulse, nonelastic skin turgor, dry mucous membranes, sunken and dry eyes, and markedly decreased or absent urinary output (Feld & Kaskel, 2012). See Table 18–4.

CLINICAL THERAPY

Diagnosis of dehydration is best accomplished by clinical observations. Medical management depends on accurate identification of the degree of dehydration. In addition to physical signs and symptoms (see Table 18–3), elevated blood urea nitrogen (BUN) (over 17 mg/dL) and low serum bicarbonate (16–17 mEq/L or mmol/L) are useful to identify dehydration from moderate and severe diarrhea (Corbett & Banks, 2013; Dzierba & Abraham, 2011). The treatment of extracellular fluid volume deficit is administration of fluid containing sodium, by oral rehydration therapy or by intravenous fluids.

Oral rehydration is the treatment of choice to treat mild and moderate dehydration in children. The therapy successfully treats the dehydration caused by many gastrointestinal illnesses and prevents hospitalization for many infants and young children (Engorn & Flerlage, 2014; Freedman, Ali, Oleszczuk, et al., 2013; Jablonski, 2012). Commercially available solutions contain water, carbohydrate (sugar), sodium, potassium, chloride, and lactate. Examples include Pedialyte, Infalyte, Rehydralyte, Ricelyte, Resol, Nutrilyte, Hydralyte, and Lytren. Some clinicians allow lactose-free milk, breast milk, or half-strength milk to be given in addition to oral rehydration therapy solution. Oral rehydration may be accompanied by ondansetron to decrease vomiting in the child and its resultant continued dehydration (Freedman et al., 2013). In developing countries, an oral rehydration solution with zinc added has been effective in diarrhea treatment (Frohna, 2011). Prebiotics (oral supplements that stimulate growth of probiotic bacteria to positively alter intestinal flora) have also been found to be effective in decreasing the number of diarrheal stools in children with acute gastrointestinal disease (Frohna, 2011).

When the child is severely dehydrated, electrolytes are measured by laboratory analysis, and isotonic intravenous fluid is given, often accompanied by oral rehydration. The intravenous fluid is commonly lactated Ringers or dilute saline, such as one half or one quarter normal saline (see Table 18–5 for types of intravenous fluids and their uses). The fluid combination replenishes the extracellular fluid volume and adds solutes to return the body fluid back to normal. Note that only isotonic solutions are used for rapid infusion, and D_5W is avoided for this treatment (Carcillo, 2014; Engorn & Flerlage, 2014; Wang, Xu, & Xiao, 2014). The child may be hospitalized or treated with intravenous fluids in a short-stay unit until the dehydration is controlled. Once hydrated, the child resumes an age-appropriate diet.

Growth and Development

Urine specific gravity may increase in older children who are dehydrated, but children under 2 years of age are not able to concentrate urine effectively. A rising specific gravity may not be seen in the younger dehydrated child.

Nursing Management

For the Child With Extracellular Fluid Volume Deficit (Dehydration)

Nursing Assessment and Diagnosis

Weigh the child daily with the same scale and without clothing. Compare to past weights and calculate weight loss. Carefully measure intake and output, urine specific gravity, level of consciousness, pulse rate and quality, skin turgor, mucous membrane moisture, quality and rate of respirations, and blood pressure. For older children and adolescents, the nurse can compare the blood pressure when the child is supine with the pressure when the child is sitting with legs hanging down or standing. If the child is dehydrated, the sitting or standing blood pressure will be lower than the supine blood pressure because blood accumulates in the dependent legs. Obtain samples of urine and blood as needed for dehydration evaluation. Urinalysis can usually be completed on a very small urine sample, such as 1 mL.

The nursing diagnosis ***Fluid Volume: Deficient*** applies to all children who have an extracellular fluid volume deficit. Other diagnoses depend on the severity of the condition and the age of the child. Several nursing diagnoses that might be

TABLE 18–5 Common Intravenous Solutions, Uses, and Components

IV SOLUTION	USES	COMPONENTS							
		CHO (g/100 mL)	PROTEIN (g/100 mL)	CAL/L	Na^+ (mEq/L)	K^+ (mEq/L)	Cl^- (mEq/L)	HCO_3^- (mEq/L)	Ca^{2+} (mEq/L)
D_5W	Restores water loss, plasma volume, and calories; lowers sodium levels	5	—	170	—	—	—	—	—
Normal saline (0.9% NaCl)	Restores water and sodium loss; maintains sodium and chloride at present levels	—	—	—	154	—	154	—	—
Lactated Ringers solution	Expands intracellular fluid; replaces extracellular losses	0–10	—	0–340	147	4	155.5	—	4
Lactated Ringers solution	Replaces fluid loss from burns, bleeding, and severe diarrhea	0–10	—	0–340	130	4	109	28	3
Albumin 25% (salt-poor albumin)	Restores major plasma protein in blood loss that has been treated with NS (plasma expander)	—	25	1000	100–160	—	<120	—	—

Note: A normal saline (NS) solution is a salt solution that has the same percentage of salt as the human body. This is a 0.9% solution of sodium chloride. The term *normal* indicates that there is the same weight, in grams, of sodium and chloride in the solution. Variations and combinations are available to tailor intake to needs of the child. For example, ½ NS (0.45% NaCl) or ¼ NS (0.225% NaCl) is often used in young children; the lower sodium content helps to avoid inadvertent hypernatremia. D_5 ½ NS and D_5 ¼ NS are combinations of D_5W and NS; they provide both carbohydrate and sodium.

appropriate for the mildly to severely dehydrated child are included in the accompanying *Nursing Care Plans*. Additional care of the child with dehydration from gastroenteritis can be found in Chapter 25. Nursing diagnoses might include the following (NANDA-I © 2014):

- ***Fluid Volume: Deficient*** related to active fluid volume loss or failure of regulatory mechanisms
- ***Tissue Perfusion: Peripheral, Risk for Ineffective,*** related to hypovolemia
- ***Injury, Risk for,*** related to postural hypotension

Clinical Reasoning The Dehydrated Child

LeShan is 18 months old. Several days ago he developed vomiting and diarrhea. His parents tried to get him to eat, but he had little appetite. He drank a little water and a few sips of juice, but the next morning he was listless and would not drink anything. The diarrhea continued.

His father has brought him to the urgent care center. LeShan is irritable on arrival, and his father reports that he has been alternately irritable and lethargic. His mucous membranes and tongue appear dry, and his skin turgor over the abdomen is slightly decreased. His father notes that LeShan has had only two wet diapers today and says the urine in his diaper was dark in color. He also reports that LeShan weighed 12 kg (26 lb) at the clinic last week. However, when the nurse weighs him, the scale reads only 11 kg (24.5 lb). What do LeShan's symptoms suggest about his degree of dehydration? What nursing interventions should be planned?

Planning and Implementation

Nursing care of the dehydrated child focuses first on prevention of the problem, and then on providing oral rehydration fluids, teaching parents oral rehydration methods, and, if necessary, administering intravenous fluids to restore fluid balance. The accompanying *Nursing Care Plans* summarize care of the child with mild to severe dehydration.

Clinical Tip

To obtain urine from an infant for testing specific gravity, place two cotton balls in the diaper. When they are wet, push them into a 10-mL syringe and squeeze out the urine with the plunger. Remember to use gloves for this procedure.

PREVENT DEHYDRATION

Nursing care can often prevent dehydration. Carefully monitor temperature probes in radiant warmers and isolettes for newborns to prevent overheating and resulting dehydration. Teach parents proper clothing for infants to prevent overheating. Nurses play an important role in educating parents, youth, school personnel, and coaches about the dangers of heat-related illness. Prevention is essential, so that children can exercise safely. Prior to a new exercise regimen, assessment for risk factors is performed. This includes medical conditions that put the child at high risk, such as cystic fibrosis, diabetes, obesity, or intellectual disability. Prior history of heat-related illness or recent change from a cooler to a hotter environment increases risk. Long exercise periods increase the stress on the body. The major nursing interventions are partnering with families and athletic coaches to prevent problems and to recognize and treat them promptly.

Nursing Care Plan: The Child With Mild or Moderate Dehydration

1. Nursing Diagnosis: *Health Management, Family, Ineffective,* related to knowledge deficit about diarrhea and vomiting (NANDA-I © 2014)

GOAL: The parents will describe appropriate home management of fluid replacement for diarrhea and vomiting.

INTERVENTION	RATIONALE
• Explain how to replace body fluid with an oral rehydration solution. Encourage parents to keep the solution at home and begin use with the first sign of diarrhea.	• Use of an oral rehydration solution can enable successful treatment of vomiting and diarrhea at home.
• Teach parents to continue the child's normal diet in addition to providing replacement fluids for diarrhea.	• Diet plus fluid supplementation leads to faster recovery.
• Provide verbal and written instructions to parents at each well-child visit. Teach hand hygiene for general use and during illness.	• Parents are provided with a reference for later use. Hand hygiene is the most effective measure to prevent illness that leads to dehydration.

EXPECTED OUTCOME: Parents will be able to treat successfully the child's diarrhea and vomiting at home.

2. Nursing Diagnosis: *Knowledge, Deficient (Parent),* related to causes of dehydration (NANDA-I © 2014)

GOAL: The parents will state common causes of childhood dehydration.

INTERVENTION	RATIONALE
• Teach parents childhood conditions that commonly lead to dehydration.	• If parents recognize situations that can lead to dehydration, they will be more alert to its appearance.

EXPECTED OUTCOME: Parents will recognize conditions of risk for dehydration in children.

3. Nursing Diagnosis: *Fluid Volume: Deficient, Risk for,* related to worsening of child's condition (NANDA-I © 2014)

GOAL: The parents will seek health care for the child's worsening condition.

INTERVENTION	RATIONALE
• Teach parents to seek care when the child's vomiting or diarrhea worsens, when urine output via diaper or toilet decreases, or when the child's mental alertness changes.	• Severe dehydration may occur if milder forms are not successfully treated.

EXPECTED OUTCOME: Parents will seek prompt attention for the child's worsening condition, preventing the development of severe dehydration.

Nursing Care Plan: The Child With Severe Dehydration

1. Nursing Diagnosis: *Fluid Volume: Deficient* related to excess losses and inadequate intake (NANDA-I © 2014)

GOAL: The child will return to normal hydration status and will not develop hypovolemic shock.

INTERVENTION	RATIONALE
• Monitor weight daily. Assess intake and output every shift. Assess heart rate, postural blood pressure, skin turgor, small vein filling time, capillary refill time, fontanelle (infant), and urine specific gravity every 4 hours or more frequently as indicated.	• Frequent assessment of hydration status facilitates rapid intervention and evaluation of the effectiveness of fluid replacement.
• Administer intravenous fluid as ordered. Monitor for crackles in dependent portions of the lungs.	• Replace fluid lost from the body. Excessive replacement of sodium-containing fluids could cause extracellular fluid volume excess.

EXPECTED OUTCOME: The child will exhibit signs of normal hydration.

Nursing Care Plan: The Child With Severe Dehydration (*continued*)

2. Nursing Diagnosis: *Injury, Risk for,* related to decreased level of consciousness (NANDA-I © 2014)

GOAL: The child will not experience injury.

INTERVENTION	RATIONALE
• Raise the side rails of the bed. Ensure that a small child does not become tangled in bed covers.	• Safety measures protect the child.
• Monitor level of consciousness every 2–4 hr or more often as indicated.	• Frequent assessment provides evidence of the need for safety interventions and of the effectiveness of therapy.
• Monitor serum sodium concentration daily or more often.	• Elevated serum sodium concentration causes brain cell shrinkage and decreased level of consciousness.
• Have the child sit before rising from bed and assist to stand slowly.	• Slow adjustment to upright posture reduces lightheadedness from decreased blood volume.

EXPECTED OUTCOME: Child will not fall or suffer other injuries.

3. Nursing Diagnosis: *Activity Intolerance* related to bed rest immobility (NANDA-I © 2014)

GOAL: The child will engage in normal activity for age.

INTERVENTION	RATIONALE
• Plan activities appropriate for the age of the child that can be done in bed.	• Activities will provide distraction and promote recovery.
• Group nursing interventions to provide time for the child to rest.	• The child will require more rest than usual.
• Provide assistance during meals and other activities as needed.	• Prevention of overexertion will conserve body fluid and promote healing.

EXPECTED OUTCOME: Child will engage in normal developmental activities and receive adequate rest.

PROVIDE ORAL REHYDRATION FLUIDS

In mild or moderate dehydration, oral rehydration fluid is the first intervention. It is given in frequent small amounts; for example, 1 to 3 teaspoons of fluid every 10 to 15 minutes is a useful guideline for starting oral rehydration. For the first 2 to 4 hours of treatment, 50 mL of fluid for each kilogram of the child's weight should be the target intake (Children's Mercy Hospital, 2011). Instruct parents to continue to administer 1 teaspoon every 2 to 3 minutes even if the child vomits, because small amounts of the fluid may still be absorbed. Table 18–6 outlines guidelines for oral rehydration therapy.

TEACH PARENTS ORAL REHYDRATION METHODS

Instruct parents about the types of fluids and amounts to be given. Begin teaching with parents of all newborns and reinforce

TABLE 18–6 Oral Rehydration Therapy Guidelines

CHILD'S CONDITION	RECOMMENDATION
No diarrhea, no dehydration	Continue on age-appropriate diet.
Minimal dehydration	If the child weighs less than 22 lb (10 kg), give 60–120 mL oral rehydration solution (ORS) for each diarrheal stool or vomiting episode; if over 22 lb (10 kg) in weight, give 120–240 mL ORS for each diarrheal stool or vomiting episode. Meanwhile, continue breastfeeding, or resume age-appropriate diet after initial hydration. Start slowly, administering 3–5 mL in a small cup or spoon every few minutes. Increase amounts gradually if no vomiting occurs. Recommend or provide samples of ORS; suggest ready-to-feed or powdered forms to use by parents.
Moderate dehydration	Give 50–100 mL/kg ORS in 3–4 hr in addition to replacing fluids lost as described above.
Severe dehydration	The child is hospitalized and treated with intravenous fluids. When hydrated adequately or concurrently with intravenous rehydration, begin oral rehydration therapy with 100 mL/kg of fluid in 4 hr and stool replacement as described above. Recalculate fluid needs after first 4 hr and adjust as needed.
Rehydration complete	Resume normal diet.

Source: Data from Children's Mercy Hospital. (2011). *Guidelines for oral rehydration*. Retrieved from http://www.childrensmercy.org/Content/view.aspx?id=8130

teaching at each well-child visit. Advise parents to continue the child's normal diet in addition to providing the rehydration solution. Cereal, starches, soup, fruits, and vegetables are all allowed. Tell parents to avoid simple sugars, which can worsen diarrhea because of osmotic effects. This includes soft drinks (if used, they should be diluted with equal parts of water), undiluted juice, Jell-O, and sweetened cereal.

SAFETY ALERT!

Encourage parents to keep an oral rehydration solution in liquid or powder form on hand at all times and to use these solutions rather than juice, soda, or other drinks when the child first develops diarrhea or vomiting.

If an oral rehydration solution is too concentrated, it can make diarrhea worse. Juice, cola, and many sports drinks are very concentrated and should be diluted to half strength if they are the only fluids available to be given to a child who has diarrhea. Sugar facilitates the absorption of sodium in oral rehydration fluids. In addition, tell parents not to give diet beverages for oral rehydration because they contain no sugar and will not be effectively absorbed.

Repeated vomiting of large volumes of fluid, increasing diarrhea, or a worsening of the child's condition can indicate the need for intravenous therapy. Teach parents when to seek further medical care. If the child's condition worsens or does not improve after 4 hours of oral rehydration therapy, parents should contact a healthcare provider. Dizziness or lethargy are symptoms that can be manifestations of dehydration and indicate the need for further health care.

MONITOR INTRAVENOUS FLUID ADMINISTRATION

The hospitalized child usually requires intravenous fluids. Use volume control devices for measuring and monitoring intake. Be sure that the amount of fluid administered corresponds with the diagnosed dehydration state of the child (Table 18–7). Usually, about one half of the 24-hour total maintenance and replacement needs is given in the first 6 to 8 hours, with a slower rate infused for the remainder of the 24 hours. During the first 1 to 3 hours, the infusion rate may be highest to rapidly expand the vascular space. Electrolytes, such as potassium, are not added until the child has voided a sufficient quantity of urine for age in order to avoid hyperkalemia. Rapid infusion of a bolus of isotonic fluid (normal saline or lactated Ringers but *not* D_5W) in the amount of 20 mL/kg over 20 minutes is sometimes used in outpatient settings, followed by oral fluids (Kliegman, Stanton, St. Geme, et al., 2011). Careful monitoring of intake and output is needed to ensure that the intravenous line remains in place until the child is tolerating oral fluids and taking in enough to maintain hydration. Verify that the type of fluid prescribed is being administered. When oral fluids are maintained, the child may be discharged and hospitalization avoided.

Maintain the intravenous line carefully so fluid infusion can be kept on schedule (refer to the *Clinical Skills Manual* SKILLS). Use a pump to prevent inadvertent, rapid infusion, which can lead to fluid overload and electrolyte imbalance (Figure 18–4). Play with the toddler and preschool child frequently and use diversionary methods as necessary to distract the child from the intravenous line. Monitor the child carefully and implement safety precautions as necessary. Once the child begins to tolerate some oral fluids, substitute oral rehydration therapy for intravenous fluids. Frequent administration of appropriate fluids is needed.

TABLE 18–7 Calculation of Intravenous Fluid Needs

STEP	CALCULATION	
Calculate the maintenance fluid needs of the child, using guidelines at right.	Usual Weight	Maintenance Amount
	Up to 10 kg	100 mL/kg/24 hr
	11–20 kg	1000 mL + (50 mL/kg for weight above 10 kg)/24 hr
	>20 kg	1500 mL + (20 mL/kg for weight above 20 kg)/24 hr
Calculate replacement fluid for that lost, using formula at right to obtain mL/kg/24 hr required.	Percentage of body weight loss × 10 × normal weight = mL/kg/24 hr required	
Calculate continued losses; add them to total of maintenance and replacement needs.		

DISCHARGE PLANNING AND HOME CARE TEACHING

Prior to discharge, parents need instructions about types of fluids and amounts to encourage. Teach the signs of dehydration (see Table 18–3) so that if the child does not take in adequate fluids, parents can seek help immediately. Instruct them to begin the child's normal diet once hydration is completed, determined by adequate urinary output and normal behaviors. Review methods of minimizing the child's chance of acquiring gastrointestinal infections (e.g., avoiding contact with other children who are infected; using careful hand washing and dishwashing procedures when another child in the home is sick). During well-child visits, encourage all parents to keep oral rehydration fluids at home in case they are needed; they are available in most grocery stores and pharmacies. Address the needs for increasing fluids in hot weather and when the child is exercising. See *Evidence-Based Practice: Treatment for Mild and Moderate Dehydration.*

Figure 18–4 **The use of a volume control device with an intravenous saline solution is important to prevent a sudden extracellular fluid volume overload.**

EVIDENCE-BASED PRACTICE | Treatment for Mild and Moderate Dehydration

Clinical Question

In spite of recommendations that children with mild or moderate dehydration be treated with oral rehydration therapy for gastroenteritis, many healthcare facilities and providers administer intravenous fluids to these children. How can nurses work to improve dehydration treatment to be consistent with current guidelines?

The Evidence

In the United States alone, gastroenteritis leads to 1.5 million healthcare visits annually and 200,000 hospitalizations. Most children can effectively be treated with an oral solution of glucose, electrolytes, and water. Such treatment is less invasive and painful than intravenous therapy for young children and is safe, effective, and easy to administer in the home setting. It is also recommended by the World Health Organization (WHO, 2014) and the American Academy of Pediatrics (AAP, 2013). However, many healthcare providers continue to use intravenous fluid treatment for mild to moderate rehydration (Jablonski, 2012). Even though nasogastric feeding is recommended when oral rehydration fails, all healthcare providers in a study of 113 emergency department personnel bypassed nasogastric feeding and began an intravenous line (Freedman, Keating, Rumatir, et al., 2012). A majority of 75 parents who visited an emergency department with a child who had gastroenteritis and dehydration expected the child to have an intravenous line, even when dehydration was mild or moderate (Nir, Nadir, Schechter, et al., 2013). A meta-analysis of 19 studies on use of oral rehydration solution found that social marketing, media education, and distribution of product increased parental acceptance and use of oral rehydration therapy (Lenters, Das, & Bhutta, 2013).

Best Practice

Nurses can partner with other healthcare providers to establish clinical pathways for dehydration treatment that follow recommendations for oral or nasogastric feedings. Implementing oral rehydration therapy immediately after assessment of the child assists in effective treatment. Appropriate oral rehydration solutions should be available on pediatric units, in emergency departments, and in all homes with children. Educate parents and healthcare providers about the benefits of oral rehydration for mild or moderate dehydration.

Clinical Reasoning

What questions can you ask a parent and what assessments can you perform to accurately evaluate if the child has mild or moderate dehydration? What oral rehydration solutions can the parent have available in the home setting? How will you inform colleagues of the current recommendations for the treatment of mild or moderate dehydration? How will you teach parents to administer oral rehydration in the home and what symptoms indicate that they need to seek additional care for the child?

Evaluation

Expected outcomes of nursing care include the following:

- Water and electrolytes in intracellular and extracellular compartments show adequate balance.
- The child has normal urinary output.
- The child maintains adequate fluid intake for maintenance needs.
- Vital signs remain within normal limits.

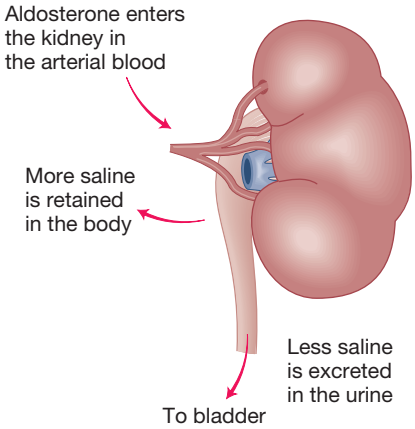
Extracellular Fluid Volume Excess

Extracellular fluid volume excess occurs when there is too much fluid in the vascular and interstitial compartment. This imbalance may also be called saline excess or extracellular volume overload. If this disorder occurs by itself (without saline disturbance), the serum sodium concentration is normal. There is simply too much extracellular fluid, even though it has a normal concentration.

Infants and children who develop an extracellular fluid volume excess have a condition that causes them to retain **saline** (sodium and water) or have been given an overload of sodium-containing isotonic intravenous fluid (Figure 18–5). What conditions cause retention of saline? The hormone aldosterone is secreted by the adrenal cortex. One of its normal functions is to cause the kidneys to retain saline in the body (see *Pathophysiology Illustrated: Aldosterone Effects*). Saline excess can be caused by any condition that results in excessive aldosterone secretion, such as adrenal tumors that secrete aldosterone, congestive heart failure, liver cirrhosis, and chronic renal failure. Most glucocorticoid medications (such as prednisone) have a mild saline-retaining effect when taken on a long-term basis. Intravenous fluid volume regulation is important, especially in young children. Either inaccurate calculation of needed fluid or inadvertent infusion of excess fluids can cause overload.

Figure 18–5 **Preventing extracellular fluid volume overload. If isotonic fluid containing sodium is given too rapidly or in too great an amount, an extracellular fluid volume excess will develop. Carefully monitor fluid intake, excretion, and retention in infants and children.**

Pathophysiology Illustrated: **Aldosterone Effects**



Aldosterone has a saline-retaining effect. Increased aldosterone secretion can be caused by adrenal tumors or congestive heart failure.

Extracellular fluid volume excess is characterized by sudden weight gain. A gain of 0.5 kg (1 lb) in a day is related to fluid, and represents 500 mL of saline. An overload of fluid in the blood vessels and interstitial spaces can cause clinical manifestations such as bounding pulse, distended neck veins in children (not usually evident in infants), periorbital edema, hepatomegaly, dyspnea, orthopnea, and lung crackles. Edema is the sign of overload of the interstitial fluid compartment. In an infant, edema is often generalized (Figure 18–6). Edema in children with extracellular fluid volume excess occurs in the dependent parts of the body—that is, in the parts closest to the ground. Thus, edema is evident in sacral areas in a child supine in bed. Scrotum or labia may be edematous. (Edema that develops from other causes is described in the next section of this chapter.)

The clinical therapy for extracellular fluid volume excess focuses on treating the underlying cause of the disorder. For example, a child who has congestive heart failure is given medications to strengthen the heart's ability to contract. Managing the cause also helps reduce the extracellular fluid volume excess. Diuretics may be given to remove fluid from the body, thus reducing the extracellular fluid volume directly.

Figure 18–6 **This infant with congenital heart disease has signs of generalized edema. Note the fluid retention in the face and abdomen.**

Nursing Management

Rapid weight gain is the most sensitive index of extracellular fluid volume excess. Therefore, daily weighing with the same scale and articles of clothing is an important nursing assessment. Measure the child's intake and output. For babies in diapers, a diaper is weighed dry and then wet, with grams of weight increase equal to urine volume in milliliters. When treatment is successful, output is greater than intake. Assess the character of the pulse and observe for neck vein distention when the child is sitting (usually visible only in older children). Monitor for signs of pulmonary edema (an indication of severe imbalance) by listening to lung sounds in the dependent lung fields (crackles) and assessing for respiratory distress (rapid respiratory rate, use of accessory muscles of respiration). Observe for edema.

A child may develop a fluid overload whenever an isotonic intravenous solution containing sodium, such as normal saline or lactated Ringers solution, is administered. Therefore, monitor the infusion rate frequently and carefully and use a volume control device and pump whenever possible to aid in accurate administration. Use only small bags (e.g., 250 or 500 mL) for infants and young children, and check pumps frequently. If an excess of fluid has already developed, administer the medical therapy as prescribed and monitor for any complications of the medical therapy. For example, many diuretics increase potassium excretion in the urine, which may lead to an abnormally low plasma potassium concentration unless potassium intake is increased. (Refer to the discussion of hypokalemia later in this chapter.) It is also important to monitor for the development of extracellular fluid volume deficit as a result of diuretic therapy.

If edema is present, provide careful skin care and protection for edematous areas. Teach parents how to provide skin care and perform position changes at home. See the following section for additional interventions related to edema.

If a child has a long-term condition such as chronic renal failure that predisposes to extracellular fluid volume excess, a dietary fluid and sodium restriction may be prescribed (see Chapter 26 for further details). Teach parents how to manage sodium restriction. Plan low-sodium meals that fit the family's cultural practices. If the child is old enough to participate, incorporate games into the teaching. If a scale is available, teach parents to take and record an accurate daily weight.

Desired outcomes include electrolyte balance, maintenance of intact skin, and dietary intake as prescribed.

Interstitial Fluid Volume Excess (Edema)

Edema is an abnormal increase in the volume of the interstitial fluid. It may be caused by an extracellular fluid volume excess or it may result from other causes.

The causes of edema are best understood in the context of normal capillary dynamics. Fluid moves between the vascular and interstitial compartment by the process of **filtration**. Filtration is the net result of forces that tend to move fluid in opposing directions. The strongest forces determine the direction of fluid movement.

At the capillary level, two forces (blood hydrostatic pressure and interstitial osmotic pressure) tend to move fluid from the capillaries into the interstitial fluid, while two other forces (blood colloid osmotic pressure and interstitial fluid hydrostatic pressure) tend to move fluid in the opposite direction (from the interstitial fluid into the capillaries). The net result of these forces usually moves fluid from the capillaries into the interstitial compartment at the arterial end of the capillaries, and fluid from the interstitial compartment back into the capillaries at the venous end of the capillaries. This process brings oxygen and nutrients to the cells and removes carbon dioxide and other waste products.

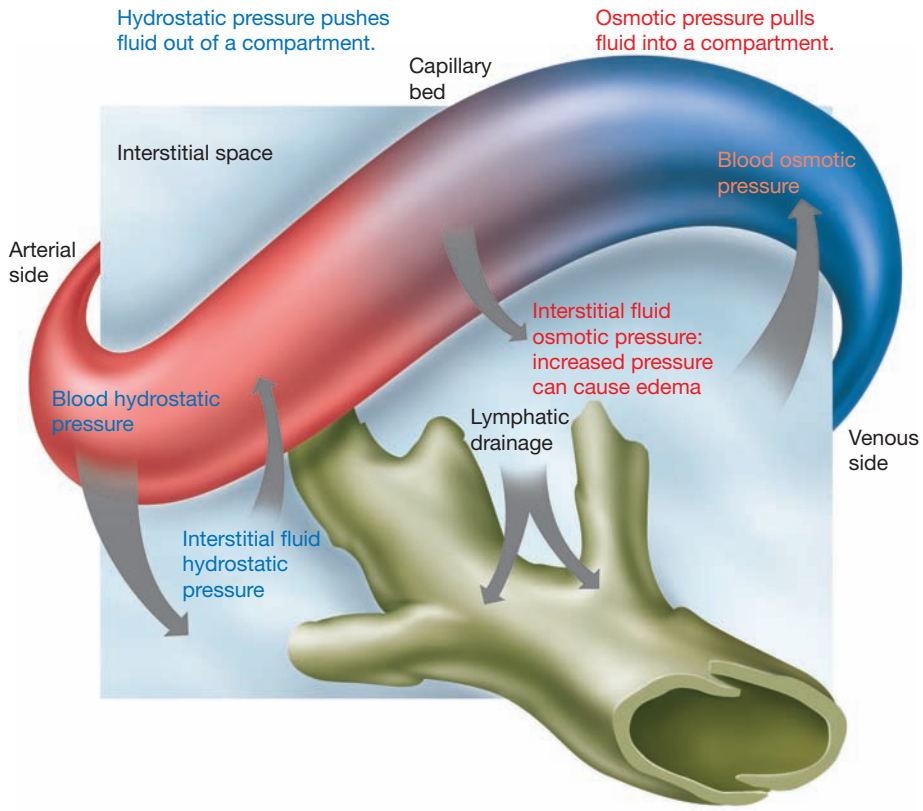
Developing Cultural Competence Low-Sodium Diets

To adapt teaching about low-sodium diets to the cultural practices of a family, ask clients what types of food they usually eat. Help them choose low-sodium foods from their diets and avoid high-sodium foods. This approach is more effective than giving the same list of restricted foods to each family.

For example, some Asians may use monosodium glutamate to flavor foods and can be encouraged to add this at the table for family members who can have extra sodium rather than during cooking. Many Hispanic groups use large amounts of cheese, which can provide significant sodium. Encourage them to look for low-sodium cheese and substitute cottage cheese for other types since it is lower in sodium.

Canned foods tend to have high sodium, so teach all families to use fresh or frozen produce rather than canned when possible. Low-sodium milk is available and is a good option for young children. Teach families how to read and interpret food labels to identify salt (sodium) content.

Pathophysiology Illustrated: **Capillary Dynamics and Edema**



Normally, lymphatic drainage removes small proteins and excess interstitial fluid. Blocked lymphatic drainage can cause edema.

With normal capillary dynamics, fluid moves out of the compartment by the force of hydrostatic pressure in the blood vessel and is pulled out by interstitial osmotic pressure. Fluid is forced into the compartment by interstitial hydrostatic pressure and pulled in by compartment osmotic pressure. Abnormal capillary dynamics can cause edema.

TABLE 18–8 Clinical Conditions That Cause Edema

CONDITION	RESULTING HEMODYNAMIC CHANGE	RESULT
Increased blood hydrostatic pressure	Increased capillary blood flow	Inflammation
		Local infection
	Venous congestion	Extracellular fluid volume excess
		Right heart failure
		Venous thrombosis
		External pressure on vein
		Muscle paralysis
Decreased blood osmotic pressure	Increased albumin excretion	Nephrotic syndrome (albumin leaks into urine)
		Protein-losing enteropathies (excess albumin in feces)
	Decreased albumin synthesis	Kwashiorkor (low-protein, high-carbohydrate starvation diet provides too few amino acids for liver to make albumin)
		Liver cirrhosis (diseased liver unable to make enough albumin)
Increased interstitial fluid osmotic pressure	Increased capillary permeability	Inflammation
		Toxins
		Hypersensitivity reactions
		Burns
Blocked lymphatic drainage	Venous congestion	Tumors
		Goiter
		Parasites that obstruct lymph nodes
		Surgery that removes lymph nodes

Edema occurs if the balance of these four forces is altered so that excess fluid either enters or leaves the interstitial compartment (see *Pathophysiology Illustrated: Capillary Dynamics and Edema*). This may occur through:

1. Increased blood hydrostatic pressure
2. Decreased blood colloid osmotic pressure
3. Increased interstitial fluid osmotic pressure
4. Blocked lymphatic drainage

Many clinical conditions are associated with these altered forces (Table 18–8), as described in the following list:

1. Increased blood hydrostatic pressure. When extracellular fluid volume excess occurs, the increased fluid volume in the vascular compartment congests the veins. The pressure against the sides of the capillary is increased and more fluid then enters the interstitial compartment.
2. Decreased blood colloid osmotic pressure. Much of the osmotic pressure that pulls fluid into the capillaries is a result of the presence of albumin and other plasma proteins made by the liver. The part of the blood osmotic pressure that results from plasma proteins is often called **oncotic pressure**, or blood colloid osmotic pressure. Any condition that decreases plasma proteins will decrease blood colloid osmotic pressure and cause edema. For example, if a clinical condition causes large amounts of albumin to leak into the urine, the liver will not be able to make albumin fast enough to replace it. As a result the plasma protein level will fall, decreasing the blood osmotic pressure. Without this pulling force to return fluid to the capillaries, edema will occur. This is the cause of edema in children who have nephrotic syndrome (see Chapter 26).
3. Increased interstitial fluid osmotic pressure. Ordinarily, only a few small proteins enter the interstitial fluid, and the interstitial fluid osmotic pressure is small. However, if the capillary becomes abnormally permeable to proteins, the influx of large amounts of proteins into the interstitial fluid causes a dramatic increase in interstitial fluid osmotic pressure. The increased pulling force keeps an abnormal amount of fluid in the interstitial compartment. This mechanism plays an important part in the edema caused by a bee sting or a sprained ankle. It occurs to a greater extent in burns, leading to swelling at the same time that there is a great loss of fluid volume through the burned skin (see Chapter 31).
4. Blocked lymphatic drainage. The lymph vessels normally drain small proteins and excess fluid from the interstitial compartment and return them to the blood vessels. If lymph vessels are blocked, fluid accumulates in the interstitial compartment. This may occur when a tumor blocks lymphatic drainage.

Edema causes localized or generalized swelling, which may cause pain and restrict motion. Edema due to extracellular fluid volume excess or right-sided heart failure usually occurs in the dependent portion of the body. In a child who is walking, dependent edema is observed in the ankles; in a bedfast, supine child, it is seen in the sacral area. The skin over an edematous area often appears thin and shiny.

The main focus of clinical therapy for edema is to treat the underlying condition that caused the edema. Such conditions are discussed throughout this book. The edema from inflammation of an injury is initially treated with cold to reduce capillary blood flow and thus reduce blood hydrostatic pressure.

Nursing Management

A child or parent may make comments that alert the nurse to the development of edema. Shoes may become tight by the end of the day (dependent edema); the waistband of pants or a skirt may be "outgrown" suddenly (generalized edema or ascites [accumulation of fluid in the peritoneal cavity]); the eyes may be puffy (periorbital edema); a ring may be too tight; fingers may "feel like sausages." In many cases, visual inspection is sufficient to recognize edema. Observe for **pitting**

Figure 18–7 **Care of edematous tissue. Edematous tissue is easily damaged. It must be kept clean and dry and free of pressure.**

edema, a "pit" or concave indentation that remains after an edematous area is pressed downward by the examiner's fingers. To detect changes in the amount of swelling, measure around the edematous part. If the edema is caused by extracellular fluid volume excess, daily measurements of weight and intake and output are a necessary part of the daily assessment. Nursing assessment should also focus on the integrity of the skin, presence of pain, restricted motion, and alterations in the child's body image.

Elevation of an area of localized edema helps to reduce the swelling. The skin over an edematous area needs extra care because it is fragile and prone to breakdown (Figure 18–7). Carefully position an infant or child on bed rest and turn frequently to prevent pressure sores. Perform turning carefully to avoid skin abrasion by rubbing against the sheets. Pat the skin dry after cleansing rather than rubbing it. Trim the child's fingernails smooth to prevent scratching. Teach parents skin care for the child at home. Teach older children to inspect their skin carefully to identify areas needing special care.

If restricted mobility is a problem, make specific plans to help the child manage activities. For example, if an edematous finger restricts the motion of a hand, food can be cut into bite-sized portions before the meal is served, so that the child can still eat independently.

Discomfort from edema may require creative nursing interventions. Distraction with toys or activities appropriate to the child's developmental level can be useful. Interventions to treat the underlying problem can also reduce the edema and its accompanying discomfort. Interventions for edema should be added to the nursing management of the underlying condition that causes the edema. Administration of the prescribed medical therapy and observation for the complications of therapy are nursing responsibilities.

Discuss with school-age children and adolescents feelings of embarrassment about the edematous appearance. They need to understand the reason for edema and be able to explain it to peers. Arrange for the child to meet other children with similar concerns.

Desired outcomes of care include maintenance of intact skin, normal respiratory sounds and effort, and normal weight patterns.

ELECTROLYTE IMBALANCES

All body fluids contain electrolytes, although the concentration of those electrolytes varies depending on the type and location of the fluid. When a serum electrolyte value is reported from the laboratory, it provides information about the concentration of that electrolyte in the blood. It may not necessarily reflect the concentration of the electrolyte in other body compartments. Refer to Table 18–1 to see which electrolytes have the highest and lowest concentrations in the blood and other fluid compartments.

Electrolytes are normally gained and lost in relatively equal amounts so that the body remains in balance. However, when a child has an abnormal route of loss, such as vomiting, wound drainage, or nasogastric suction, electrolyte balance can be disturbed. In addition, supplementation with electrolytes via intravenous fluids in proportions different than body fluids can also cause electrolyte imbalance. Children with disease states that interfere with normal mechanisms of electrolyte regulation, such as renal disease, also have disturbance in electrolyte levels. Monitoring for signs of imbalance becomes important in all of these situations.

Sodium Imbalances

The serum sodium concentration reflects the **osmolality** of body fluids—that is, their degree of concentration or dilution. It refers to the number of moles of the substance per kilogram of water in the solution. Serum sodium concentration reflects the proportion of water and sodium in the extracellular compartment. When the osmolality of body fluids becomes abnormal, the cells swell or shrink. These cell size changes are due to **osmosis**, the movement of water across a semipermeable membrane into an area of higher particle concentration. Sodium levels are maintained at high extracellular and low intracellular levels by the sodium-potassium pump, which moves these electrolytes against their expected concentration gradients (Figure 18–8).

Hypernatremia

Hypernatremia is a condition of increased osmolality of the blood. The body fluids are too concentrated, containing excess sodium relative to water. Sodium level generally falls between 132 and 141 mmol/L, and a serum sodium level above 146 mmol/L in children (146 mmol/L in newborns) is diagnostic of hypernatremia (Engorn & Flerlage, 2014; Greenbaum, 2011) (Table 18–9).

Hypernatremia is caused by conditions that cause the body to lose relatively more water than sodium or to gain relatively more sodium than water (Table 18–10). Special circumstances in which a high solute intake may occur without adequate water include an infant formula that is too concentrated or one that is prepared with salt instead of sugar. A breastfed baby not receiving adequate breast milk who has normal water loss may develop hypernatremic dehydration. This is a risk at 2 to 3 days of age, when babies generally have a diuresis, if the baby does not feed well or the mother does not yet produce an adequate amount of breast milk (Bolat et al., 2013).

An infant or child who has hypernatremia is generally thirsty. The urine output is small unless the hypernatremia is caused by diabetes insipidus. A decreased level of consciousness manifested by confusion, lethargy, or coma results from shrinking of the brain cells. Seizures can occur when hypernatremia occurs rapidly or is severe. Severe hypernatremia can be fatal.

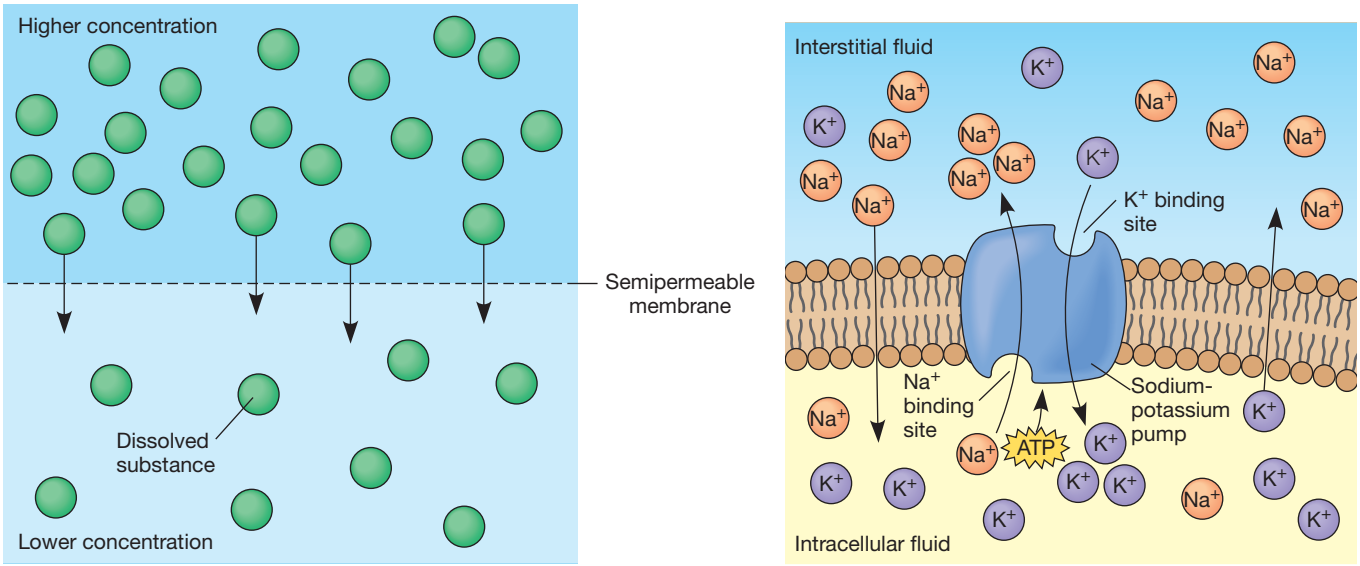


Figure 18–8 The sodium-potassium pump. *A,* Water balance is maintained by the simple passage of molecules from greater to lesser concentration across cell membranes. *B,* Sodium levels are maintained by an active transport system, the sodium-potassium pump, which moves these electrolytes across cell membranes in spite of their concentration.

TABLE 18–9 Normal Serum Values

BLOOD COMPONENT	VALUES
Sodium	Newborn: 131–144 mmol/L Children: 134–143 mmol/L
Potassium	Premature infants: 4.5–7.2 mmol/L Full-term infants: 3.2–5.7 mmol/L Children: 3.7–5.0 mmol/L
Calcium (total)	Premature infants: 1.7–2.3 mmol/L (6.9–9.2 mg/dL) Full-term infants: 1.98–2.68 mmol/L (7.9–10.7 mg/dL) Children: 2.18–2.68 mmol/L (8.7–10.7 mg/dL)
Magnesium	Infants: 0.65–1.02 mmol/L or 1.6–2.5 mg/dL Children: 0.66–0.99 mmol/L or 1.6–2.4 mg/dL
Arterial pH	Infants: 7.18–7.5 Children: 7.27–7.49 Adolescents: 7.35–7.41
Arterial Po_2	Infants: 60–70 mmHg (8–9.3 pKa) Children: 80–108 mmHg (10.7–14.4 pKa) Adolescents: 80–100 mmHg (4.3–6.4 pKa)
Arterial Pco_2	Infants: 27–41 mmHg (3.6–5.5 pKa) Children and adolescents: 32–48 mmHg (4.3–6.4 pKa)
Arterial bicarbonate	Infants: 19–24 mmol/L Children: 18–25 mmol/L Adolescents: 20–29 mmol/L

Note: Laboratories may have slightly different levels for normal depending on assays performed. Always consult the normal values for your particular laboratory.

TABLE 18–10 Causes of Hypernatremia

LOSS OF RELATIVELY MORE WATER THAN SODIUM	GAIN OF RELATIVELY MORE SODIUM THAN WATER
Inadequate breastfeeding intake with normal output	Inability to communicate thirst
Diabetes insipidus (not enough antidiuretic hormone)	Limited or no access to water
Diarrhea or vomiting without fluid replacement	High solute intake without adequate water (e.g., tube feedings)
Excessive sweating without fluid replacement	Intravenous hypertonic saline
Increased aldosterone	Improper formula preparation leading to excessive concentration

Serum sodium, specific gravity of urine, antidiuretic hormone (ADH), and 24-hour urine are common diagnostic tests. Hypernatremia is treated by intravenous administration of **hypotonic fluid**, or fluid that is more dilute than normal body fluid. This therapy dilutes the body fluids back to normal concentration. If a child is dehydrated, **isotonic fluids** (those with the osmolality of body fluids) may be administered first to replenish the volume, followed by hypotonic fluid to correct the osmolality. The underlying cause of the disorder is also treated.

Nursing Management

Monitor serum sodium level and measure intake and output and urine specific gravity. Normal specific gravity under 2 years is 1.001 to 1.018, while in children over 2 years 1.001 to 1.030 is the normal range (Corbett & Banks, 2013). Specific gravity changes toward normal levels as therapy progresses. Frequently assess responsiveness to monitor the effect of hypernatremia on brain cells. As the concentration of body fluids returns to normal, the child will become more alert and responsive. Watch for rebound hyponatremia while monitoring the fluid replacement.

Families Want to Know

Preparing Infant Formula

Careful teaching about how to mix powdered formula is needed so that it is not too concentrated; this can help to prevent hypernatremia in the infant. Demonstrate the technique so that parents are well informed. Pictures are an important teaching tool if the parents are not able to read labels or instructions. When families use concentrated formula, equal amounts of concentrate and water should be mixed. Caution parents that even if an infant is premature or small, they should mix the formula as instructed. A useful strategy is to have the parents bring the formula being used to a healthcare visit and ask them to mix it as you watch. Any errors in technique can easily be corrected.

Implement safety interventions such as raised bed rails for protection. Ensure adequate rest and introduce developmentally appropriate activities when the child is alert.

Water deprivation is a form of child neglect or abuse. In neglect, the parents simply do not provide adequate water for the child. A form of child abuse that sometimes includes water deprivation is Münchausen syndrome by proxy (see Chapter 17). A small child who is hospitalized with hypernatremia that does not have a detectable cause may be subject to water deprivation. Assess the child's general condition, developmental tasks, the family dynamics, and the parents' understanding of formula preparation and the child's fluid intake needs.

Teaching can prevent many cases of hypernatremia. Be sure the breastfeeding mother has instruction and resources about lactation before discharge after birth. If the newborn is discharged soon after birth, schedule an appointment to check weight within the first few days, and alert the parents to expected output of at least six wet diapers daily. By about 10 days, newborns should have regained the birth weight.

When an infant is sick or developing slowly, parents sometimes want to feed the infant more concentrated formula to make the baby stronger. Parents and caregivers of bottlefed babies should be taught never to give undiluted formula concentrate or evaporated milk. Parents should be cautioned to keep salt out of reach, since eating handfuls of salt has caused hypernatremia. Teach parents to offer extra fluids during hot weather. Teach oral rehydration therapy for use at home during mild vomiting and diarrhea.

Nurses can prevent hypernatremia in hospitalized infants and children by administering water between tube feedings, keeping water available, and offering it frequently. Offering frequent small amounts and using popsicles and other creative interventions can increase children's intake.

Desired outcomes of treatment for hypernatremia include balance of electrolytes and fluid in the intracellular and extracellular compartments and an alert level of consciousness.

Hyponatremia

In hyponatremia, the osmolality of the blood is decreased. The body fluids are too dilute, containing excess water relative to sodium. Hyponatremia is the most common sodium imbalance in children (Kliegman et al., 2011). A serum sodium level below 134 to 135 mmol/L in children (131 mmol/L in newborns) is diagnostic of hyponatremia (Greenbaum, 2011).

ETIOLOGY AND PATHOPHYSIOLOGY

Hyponatremia is caused by conditions that cause gain of relatively more water than sodium or loss of relatively more sodium than water (Table 18–11). Oral intake of water causes hyponatremia in unusual conditions such as forced fluid intake. More commonly, parents feed an infant only water or dilute formula to save money instead of using regular-strength formula or breast milk. Excessive swallowing of swimming pool water by an infant can have the same effect. Infants are vulnerable to the type of hyponatremia caused by water intoxication since they have a poorly developed thirst mechanism and may continue to drink, and then are unable to excrete excess water quickly because of immature kidney function. Forced water intake is another cause and form of child abuse. Exercise-induced hyponatremia can occur when people in prolonged physical activity such as marathon running consume hypotonic fluids in the form of water or sports drinks above the levels lost in respiratory, gastrointestinal, skin, and urinary routes (AAP Council on Sports Medicine and Fitness & Council on School Health, 2011).

TABLE 18–11 Causes of Hyponatremia

GAIN OF RELATIVELY MORE WATER THAN SODIUM	LOSS OF RELATIVELY MORE SODIUM THAN WATER
Excessive intravenous D_5W (5% dextrose in water)	Diarrhea or vomiting with replacement by tap water only instead of fluid containing sodium
Excessive tap water enemas	Excessive sweating
Irrigation of body cavities with distilled water	Diuretics, especially thiazides
Excessive antidiuretic hormone	
Forced excessive oral intake of tap water	
Congestive heart failure	

CLINICAL MANIFESTATIONS

The child with hyponatremia has a decreased level of consciousness, which results from swelling of brain cells. This can manifest as anorexia, nausea, vomiting, headache, muscle weakness, decreased deep tendon reflexes, agitation, lethargy, or confusion. The condition can progress to respiratory arrest, dilated pupils, decorticate posturing, and coma. If hyponatremia arises rapidly or is extreme, seizures may occur. Hyponatremia is a frequent cause of seizures in infants under 6 months of age. Severe hyponatremia can be fatal.

CLINICAL THERAPY

Laboratory studies are the same as those used to diagnose hypernatremia. In most cases, hyponatremia is treated by restricting the intake of water. This therapy allows the kidneys to correct the imbalance by excreting excess water from the body. If a child is having seizures from hyponatremia, intravenous **hypertonic saline** (more concentrated than body fluid) may be administered. Use of this concentrated fluid rapidly increases body fluid concentration, but the process must be monitored carefully because it can easily cause rebound hypernatremia. For exercise-associated hyponatremia, intravenous access is established at the first-aid site, hypertonic saline is administered, and oxygen is delivered (AAP Council on Sports Medicine and Fitness & Council on School Health, 2011). In cases of diabetes insipidus, treatment for the condition is needed (see Chapter 30).

Nursing Management

For the Child With Hyponatremia

Nursing Assessment and Diagnosis

Hyponatremia should be prevented in hospitalized children receiving intravenous solutions (particularly postoperatively) by administering isotonic rather than hypotonic solutions. Monitor serum sodium level and measure intake and output. If an infant with hyponatremia has normal antidiuretic hormone (ADH) levels, and other causes have been ruled out, carefully question parents about proper preparation of formula and feeding practices. A toddler or school-age child may be subjected to forced fluid intake as a form of child abuse. Sensitive interviewing and a caring manner can help identify such problems in a family.

Because hyponatremia is characterized by a decreased level of consciousness, frequently assess responsiveness to monitor the response to therapy. The child will become more alert and responsive as the concentration of body fluids returns to normal.

The highest priority nursing diagnosis for hyponatremia is ***Injury, Risk for,*** as it relates to the child's decreased level of consciousness. The following diagnoses might also apply (NANDA-I © 2014):

- ***Self-care Deficit: Dressing and Feeding*** related to weakness and tiredness
- ***Health Maintenance, Impaired,*** related to parental misinterpretation about infant formula preparation
- ***Breastfeeding, Ineffective,*** related to inadequate sucking by infant or inadequate milk production

Planning and Implementation

Nurses can prevent hyponatremia in hospitalized children by using normal saline instead of distilled water for irrigations and by avoiding tap water enemas. Verify intravenous fluid types and amounts and question use of hypotonic fluids in a child with no intake of sodium. Help the child comply with any prescribed fluid restrictions. Allow the child to choose favorite fluids to drink. Teach parents to replace body fluids lost through diarrhea or vomiting with oral electrolyte solutions.

Evaluation

Expected outcomes are maintenance of safety, balance of fluid and electrolytes, and establishment of adequate formula or breastfeeding intake.

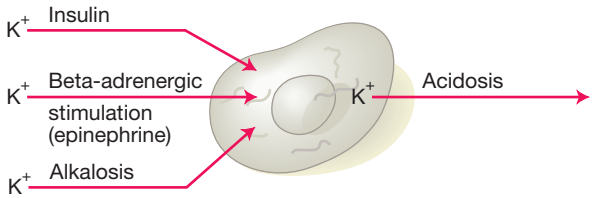
Potassium Imbalances

Potassium, an essential electrolyte, performs many necessary functions in the body such as muscle contraction and enzymatic reactions. Potassium intake in healthy children comes from potassium-rich foods such as fruits and vegetables. Potassium is absorbed easily from the intestine. A normal potassium distribution is important for proper function.

A potassium imbalance arises when the serum potassium concentration rises or falls outside the normal range. Potassium imbalances are caused by alterations in potassium intake, distribution, or excretion, or by loss of potassium through an abnormal route such as burns, emesis, or renal failure.

Most potassium ions in the body are found inside the cells. The sodium-potassium pump in cell membranes moves potassium ions into cells to maintain the high intracellular potassium concentration. Potassium ions can be shifted into or out of cells by various physiologic factors (see *Pathophysiology Illustrated: Potassium Ions*). Potassium is excreted from the body through urine, feces, and sweat. The hormone aldosterone increases potassium excretion in the urine.

Pathophysiology Illustrated: **Potassium Ions**



Factors that shift potassium ions into or out of cells.

Hyperkalemia

Hyperkalemia is an excess of potassium in the blood. Potassium levels generally range from 3.2 to 5.7 mmol/L for newborns, and 3.7 to 5.0 mmol/L for infants and children. Hyperkalemia is reflected by a level above 5.7 mmol/L in newborns or above 5.5 mmol/L in children (see Table 18–9).

ETIOLOGY AND PATHOPHYSIOLOGY

Hyperkalemia is caused by conditions that include increased potassium intake, shift of potassium from cells into the extracellular fluid, and decreased potassium excretion. Renal insufficiency is a primary cause of hyperkalemia. Premature infants commonly have low systemic blood flow and resultant poor renal function, leading to hyperkalemia. Increased potassium intake is frequently due to intravenous potassium overload. Excessive or too rapid intravenous administration of potassium-containing solutions can occur if the potassium requirement is overestimated or if the intravenous infusion runs in too fast.

Blood transfusion is another source of potassium intake that may cause hyperkalemia. Potassium ions leak out of red blood cells that are stored in a blood bank. The longer the blood is stored, the more the potassium leaks out of cells and accumulates in the fluid portion of the transfusion. Hyperkalemia from administration of stored blood arises when multiple units are transfused, as when infants receive exchange transfusions or children receive multiple blood transfusions after a serious injury or during surgery.

Shift of potassium from cells into the extracellular fluid occurs when there is massive cell death, as with a crush injury, in sickle cell disease (hemolytic crisis), or when chemotherapy for a malignancy is rapidly effective (tumor lysis syndrome). In these situations, the dead cells release their high-potassium contents into the extracellular fluid. Potassium ions also shift out of cells in metabolic acidosis caused by diarrhea and in diabetes mellitus when insulin levels are low.

Decreased potassium excretion occurs with acute or chronic oliguria during renal failure, severe hypovolemia, and conditions that decrease the secretion of aldosterone by the adrenal cortex (lead poisoning, Addison disease, hypoaldosteronism). Several medications can cause hyperkalemia, including some cancer chemotherapies, potassium-sparing diuretics, angiotensin-converting enzyme inhibitors, and nonsteroidal anti-inflammatories.

CLINICAL MANIFESTATIONS

The clinical manifestations of hyperkalemia are all related to muscle dysfunction since potassium plays a vital role in muscle activity. Hyperactivity of gastrointestinal smooth muscle causes intestinal cramping and diarrhea in some children. The skeletal

muscles become weak, typically beginning with leg weakness and ascending. Weakness can progress to flaccid paralysis. The child is often lethargic. Dysfunction of cardiac muscle causes cardiac arrhythmias such as tachycardia and may result in heart failure and cardiac arrest. Abnormalities in the electrocardiogram include a prolonged QRS complex, a peak in T waves, atrioventricular block, and ventricular dysrhythmia (Engorn & Flerlage, 2014).

CLINICAL THERAPY

The major diagnostic test is the serum potassium level. Hyperkalemia is treated by management of the underlying condition that caused the imbalance. If the serum potassium concentration is very high or is causing dangerous cardiac arrhythmias, treatment to decrease the serum potassium level may be ordered. These treatments may remove potassium from the body or drive it from the extracellular fluid into the cells. Potassium is removed from the body by peritoneal dialysis or hemodialysis, by potassium-wasting diuretics, or with a cation exchange resin (Kayexalate) administered orally or rectally. Medical treatments that drive potassium ions into cells are intravenous sodium bicarbonate, intravenous insulin, glucose, and calcium gluconate.

Nursing Management

For the Child With Hyperkalemia

Nursing Assessment and Diagnosis

Monitor serum potassium levels with prescribed laboratory analysis. Ongoing assessment of muscle strength is important because the muscle weakness may progress to flaccid paralysis. This paralysis is reversible on correction of the potassium imbalance. Diarrhea can occur in infants and children. An older child may complain of intestinal cramping. Monitor the pulse rate carefully.

Nursing diagnoses for a child who has hyperkalemia depend on the severity of the clinical manifestations. The cause of the imbalance may also lead to useful diagnoses that guide teaching for the child and the parents. The following nursing diagnoses may apply (NANDA-I © 2014):

- ***Activity Intolerance*** related to decreased cardiac output secondary to cardiac arrhythmias
- ***Injury, Risk for,*** related to muscle weakness
- ***Self-care Deficit: Bathing and Dressing*** related to neuromuscular impairment
- ***Anxiety*** related to change in health status
- ***Health Maintenance, Ineffective,*** related to parental lack of exposure about potassium intake in chronic renal failure
- ***Health Management, Family, Ineffective,*** related to complexity of therapy

Planning and Implementation

Nursing care includes measures to prevent hyperkalemia from developing in hospitalized children. If hyperkalemia does develop, care shifts to administering intravenous solutions, monitoring cardiopulmonary status, ensuring safety, promoting adequate nutrition, and preparing the child and family for discharge.

PREVENT HYPERKALEMIA

Any child receiving an intravenous infusion that contains potassium is at risk for hyperkalemia. Check that urine output is normal (1 to 2 mL/kg/hr) before administering intravenous potassium solutions. Turn over intravenous solutions to which potassium has been added several times to mix the contents thoroughly before connecting them to the infusion tubing. Double-check the potassium order and intravenous dosage with another nurse. Observe the child closely and perform cardiorespiratory monitoring.

Be sure blood or packed red blood cells are fresh, especially for the child receiving multiple transfusions and for all newborns. Use a cardiac monitor during infusion of these products to watch for arrhythmias.

Growth and Development

The nursing diagnoses for hyperkalemic children will prompt a nurse to provide safety measures appropriate to the child's developmental level and to assist the child with activities that muscle weakness makes difficult. It is important to provide play and diversional activities that take into account the child's degree of muscle strength as well as the appropriate developmental level.

ADMINISTER INTRAVENOUS SOLUTIONS

Once a child is diagnosed as being hyperkalemic, ensure that any infusions with added potassium are stopped. Several other infusions may need to be managed, including those containing glucose, sodium bicarbonate, and calcium gluconate. Maintain these infusions at the prescribed rates and monitor the child's condition frequently.

MONITOR CARDIOPULMONARY STATUS

Upon diagnosis of hyperkalemia, an electrocardiogram is performed and a cardiac monitor applied. Monitor for any changes in cardiac status and for cardiac arrhythmias. Report abnormal rate and character of pulse as well as shortness of breath.

ENSURE SAFETY

Since the child is weak, raise side rails. Position the child carefully. Assist the child with activities requiring leg muscle strength, such as climbing into bed or pushing up in bed. Encourage quiet activities with frequent rest periods. Document and report any change in muscle weakness.

PROMOTE ADEQUATE NUTRITIONAL INTAKE

Adequate caloric intake is necessary to prevent tissue breakdown and the resultant potassium release from cells. If the child's appetite is decreased, offer nourishing snacks. Restrict potassium-rich foods.

DISCHARGE PLANNING AND HOME CARE TEACHING

If the child has chronic renal failure or another condition that decreases aldosterone secretion, teach parents and children to restrict foods high in potassium. Most oral rehydration solutions, including Pedialyte, contain potassium and should not be used to provide fluid for the child. Instruct the family not to use salt substitutes, which commonly contain potassium. Parents should check with the healthcare provider and pharmacist before giving even over-the-counter products to the child because some of these medications contain potassium. Management of renal failure at home with frequent visits for dialysis and other treatments can be challenging. Refer to Chapter 26 for further suggestions to help parents handle this condition.

Evaluation

Expected outcomes for the child with hyperkalemia include the following:

- The child returns to a state of fluid and electrolyte balance.
- The child's safety is maintained.
- The child has adequate nutritional intake to provide essential potassium.
- The child maintains normal cardiac rate and rhythm.

Hypokalemia

Hypokalemia occurs when the serum potassium concentration is too low. Total body potassium may be decreased, normal, or even increased when the serum level is low, depending on the cause of the imbalance. Serum potassium levels below 3.7 mmol/L in children (3.2 mmol/L for newborns) are diagnostic of hypokalemia.

ETIOLOGY AND PATHOPHYSIOLOGY.

Hypokalemia is caused by increased potassium excretion, decreased potassium intake, shift of potassium from the extracellular fluid into cells, and loss of potassium by an abnormal route.

Increased potassium excretion through the gastrointestinal tract is the major cause of hypokalemia in children. In addition to diuretics and other medications, causes of increased urinary potassium excretion are osmotic diuresis (glucose present in urine), hypomagnesemia, increased aldosterone (hyperaldosteronism, congestive heart failure, nephrotic syndrome, cirrhosis), and increased cortisol (Cushing disease and syndrome) (Engorn & Flerlage, 2014). Eating large amounts of black licorice increases renal excretion of potassium.

Decreased potassium intake will lead to hypokalemia slowly or more rapidly if combined with increased excretion or loss of potassium. Hospitalized children who are placed on NPO status and receive prolonged intravenous therapy should have added potassium. Adolescents concerned about weight loss or those with anorexia nervosa may embark on fad diets low in potassium.

A shift of potassium from the extracellular fluid into cells occurs in alkalosis and hypothermia (unintentional or induced for surgery). Hyperalimentation often causes hypersecretion of insulin, which also shifts potassium into cells.

Vomiting is a route for the loss of potassium; for example, self-induced vomiting in bulimia can cause hypokalemia. Nasogastric suctioning (Figure 18–9) and intestinal decompression can cause potassium loss. Hypokalemia can also be caused by several medications (Crawford & Harris, 2011a) (Table 18–12).

CLINICAL MANIFESTATIONS

Since the ratio of intracellular to extracellular potassium determines the responsiveness of muscle cells to neural stimuli, it is not surprising that the clinical manifestations of hypokalemia involve muscle dysfunction. Gastrointestinal smooth muscle activity is slowed, leading to abdominal distention, constipation, or paralytic ileus. Skeletal muscles are weak and unresponsive to stimuli, and weakness may progress to flaccid paralysis. The respiratory muscles may be impaired. Cardiac arrhythmias can occur. Symptoms may range from mild fatigue to flat or absent T waves. Polyuria results from changes in the kidney caused by hypokalemia.

Figure 18–9 **Nasogastric tubes and potassium levels. Because this child has a nasogastric tube in place, it is important to monitor his potassium levels.**

CLINICAL THERAPY

Serum measurement of potassium is the major diagnostic tool, and electrocardiograph may be used. Medical management of hypokalemia focuses on replacement of potassium while treating the cause of the imbalance. Potassium replacement may be given intravenously or orally.

Nursing Management

For the Child With Hypokalemia

Nursing Assessment and Diagnosis

Monitor serum potassium levels. Observe for muscle weakness, which is frequently detected first in the legs. Parents may report that muscle weakness restricts the child's activities and impairs interactions with peers. Skeletal muscle strength can be difficult to assess if the child is lethargic.

Muscle weakness may affect the respiratory muscles. Assess the child frequently to determine the need for assisted ventilation. Cardiac monitoring is important for continued assessment of hypokalemia-associated arrhythmias. Apical pulse rate should be monitored.

TABLE 18–12 Drugs That May Cause Electrolyte Disturbance

HYPERKALEMIA	HYPOKALEMIA	HYPOCALCEMIA	HYPERMAGNESEMIA	HYPOMAGNESEMIA
Potassium-containing medications	Beta-adrenergic agonists	Antacids (if overused)	Magnesium antacids	Magnesium-wasting diuretics
Potassium-sparing diuretics	Insulin	Laxatives (if overused)	Magnesium-containing cathartics	Antineoplastics
Angiotensin-converting enzyme inhibitors	Potassium-wasting diuretics	Oil-based bowel lubricants		Systemic antifungals
Cytotoxic agents	Parenteral penicillins	Anticonvulsants		Aminoglycoside antimicrobials
	Glucocorticoids	Phosphate-containing preparations		Laxatives
	Aminoglycoside antimicrobials	Protein-type plasma expanders during rapid infusion		
	Systemic antifungals	Antineoplastics		
	Antineoplastics			
	Laxatives			

Assess for diminished bowel sounds. Ask the parents if the child has recently been awakening to use the toilet at night or has begun bed-wetting after previously being dry at night. These may be symptoms of polyuria associated with chronic hypokalemia.

The most important nursing diagnoses in the child with severe hypokalemia relate to cardiac arrhythmias and respiratory muscle weakness. The following nursing diagnoses may apply (NANDA-I © 2014):

- ***Activity Intolerance, Risk for,*** related to decreased cardiac output secondary to cardiac arrhythmia
- ***Breathing Pattern, Ineffective,*** related to respiratory musculoskeletal impairment
- ***Injury, Risk for,*** related to muscle weakness
- ***Self-care Deficit: Bathing and Dressing*** related to neuromuscular impairment
- ***Constipation*** related to decreased motility
- ***Anxiety*** related to change in health status
- ***Health Maintenance, Ineffective,*** related to management of potassium supplements or high-potassium diet
- ***Health Management, Family, Ineffective,*** related to complexity of potassium therapy
- ***Nutrition, Imbalanced: Less than Body Requirements,*** related to lack of basic nutritional knowledge regarding safe weight-loss diet

Planning and Implementation

Nursing care of the child with hypokalemia focuses on ensuring adequate potassium intake, monitoring cardiopulmonary status, promoting normal bowel function, ensuring safety, providing dietary counseling, and preparing the child and family for discharge.

Growth and Development

Bradycardia occurs at a different level for children of various ages. For infants, a pulse rate below 100 is considered bradycardia. For young children, 80 may be the identified number, whereas for adolescents, a pulse below 60 is bradycardia. Look at the child's age and normal pulse range to find changes that indicate bradycardia.

ENSURE ADEQUATE POTASSIUM INTAKE

Since potassium is excreted from the body every day, daily potassium intake is necessary to prevent hypokalemia. A hypokalemic child who is able to eat should be given a high-potassium diet. Teach parents (and the child if old enough) which foods are high in potassium and how to incorporate them into the daily diet (Table 18–13).

Children who have no oral intake for a period of time should receive intravenous fluids that contain potassium. Calculate the dosage to be sure it is accurate. Ensure that the infusion runs on schedule. Sometimes the child will complain of burning along the vein when potassium is infused. The infusion may need to be slowed temporarily to allow it to continue. Check serum potassium to watch for high or low potassium levels. Monitor urine output. A child with oliguria can develop hyperkalemia when receiving supplements.

MONITOR CARDIOPULMONARY STATUS

Hypokalemia potentiates digitalis toxicity. A hypokalemic child receiving digitalis needs careful surveillance for digitalis toxicity, which is manifested as anorexia, nausea, vomiting, and bradycardia. Observe for these effects. Take the pulse rate and rhythm regularly. Monitor respirations and ease of breathing to watch for decreased respiratory muscle activity.

PROMOTE NORMAL BOWEL FUNCTION

Ensure adequate fluids and fiber in the diet. Monitor and record the number of stools and report inadequate stools.

ENSURE SAFETY

Keep bed side rails up. Assist the child as needed to move into and out of bed. Reposition the child frequently to preserve skin integrity of limbs that are not moved regularly. Perform passive range of motion if the child is not moving. Use supportive pillows to position the child properly.

PROVIDE DIETARY COUNSELING

The adolescent trying to lose weight and not consuming a nutritious diet needs dietary teaching. More intensive treatment will be needed for teens who are anorexic or bulimic (see Chapter 14 for interventions).

DISCHARGE PLANNING AND HOME CARE TEACHING

Teach parents how to give potassium supplements, if prescribed. Liquid or powdered potassium supplements can be mixed with juice or sherbet to improve the bitter taste. The parent should call the mixture "medicine" so that the child does not learn to dislike all juices. Teach the parents signs of hypokalemia and hyperkalemia and whom to call to report these symptoms. These signs must be reported promptly so medications can be adjusted.

Evaluation

Expected outcomes for the child with potassium imbalance include normal rate and rhythm of heart and respiratory system, regular bowel movements, maintenance of safety, and knowledge of child and family regarding food sources of potassium.

TABLE 18–13 Food Sources of Electrolytes

POTASSIUM-RICH FOODS		CALCIUM-RICH FOODS		MAGNESIUM-RICH FOODS
Apricots	Orange juice	Milk	Legumes	Whole-grain cereal
Bananas	Peaches	Cheese	Nuts	Dark green vegetables
Cantaloupe	Potatoes	Yogurt	Figs	Soy
Cherries	Prunes	Pudding	Chicken	Almonds
Dates	Raisins	Egg yolks	Salmon (canned with bones)	Peanut butter
Figs	Strawberries	Grains (cream of wheat, farina, bran muffins)	Tofu	Bananas
Molasses	Tomato juice	Sardines (canned)	Fruit drinks with added calcium	Egg yolk

Calcium Imbalances

A normal serum calcium concentration is important for many physiologic functions, including muscle and nerve function, secretion of hormones, bone formation and strength, and clotting of the blood. Calcium is the most abundant mineral in the body, with about 98% of it being present in bones (AAP, 2013). There are three forms of calcium in plasma: calcium bound to protein, calcium bound to small organic ions (e.g., citrate), and free ionized calcium (Ca^{2+}), which is physiologically active. A discussion of dietary calcium intake and its importance in bone formation can be found in Chapter 14. (See *Developing Cultural Competence: Calcium Intake and Osteoporosis*.)

Calcium imbalances are caused by alterations in calcium intake, absorption, distribution, or excretion. Calcium absorption requires vitamin D for maximum efficiency and is greatest in the duodenum. Calcium distribution involves calcium entry into and exit from bones and the distribution of different forms of calcium in the plasma. Ionized calcium is the only physiologically active form; additional calcium is bound to protein or ions. Calcium is excreted in urine, feces, and sweat (see *Pathophysiology Illustrated: Calcium Imbalances*).

Parathyroid hormone is the major regulator of the plasma calcium concentration. It increases the plasma calcium concentration by increasing calcium absorption, increasing calcium withdrawal from bones, and decreasing calcium excretion in the urine. The plasma calcium concentration has an important influence on cell membrane permeability and influences the threshold potential of excitable cells. For this reason, calcium imbalances alter neuromuscular irritability.

Developing Cultural Competence Calcium Intake and Osteoporosis

Ingestion and absorption of calcium are important for the growing child to ensure formation of strong bones. Adolescents who ingest more calcium have less risk of osteoporosis in later life. It has been noted that Black women have less bone loss and fewer fractures than White women. Studies with these two groups of women have demonstrated that Blacks absorb more calcium from the diet and lose less in their urine, leading to increased bone density. However, this has led to an underidentification of osteoporosis in Black women who have relative risks of lactose intolerance and low dairy intake. Assess calcium intake for all and suggest appropriate interventions for your population group and individuals (NIH Osteoporosis and Related Bone Diseases National Resource Center, 2011).

Hypercalcemia

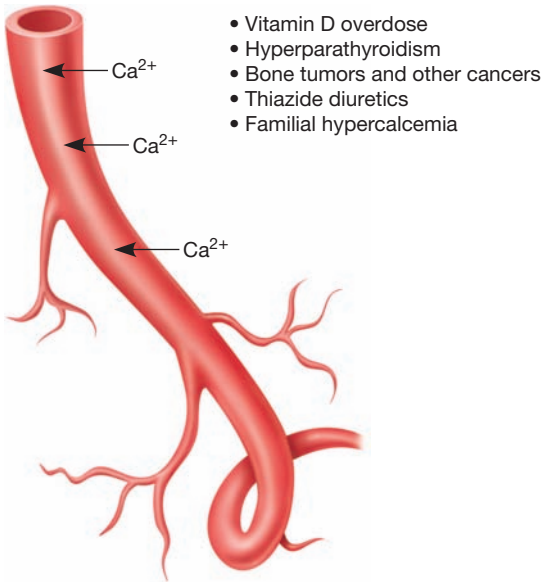
Hypercalcemia refers to a plasma excess of total calcium (above 2.7 mmol/L in infants and children) (see Table 18–9). Because so much calcium is stored in the bones, however, the serum levels of calcium may not reflect body stores.

ETIOLOGY AND PATHOPHYSIOLOGY

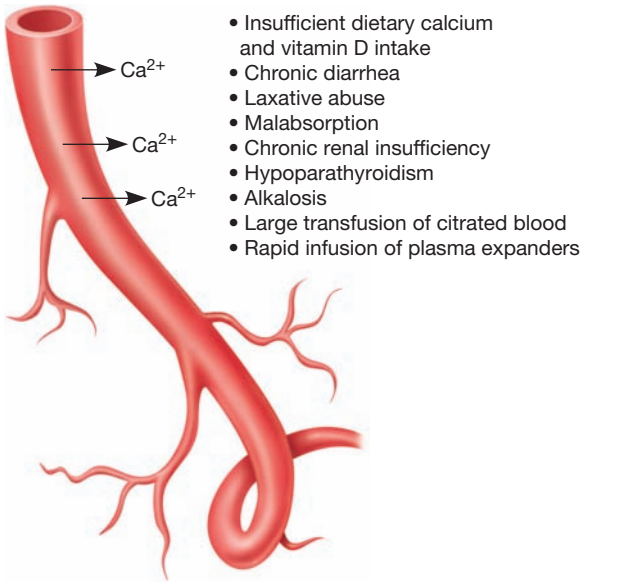
Hypercalcemia is caused by conditions that include increased calcium intake or absorption, shift of calcium from bones into the extracellular fluid, and decreased calcium excretion. Hypercalcemia due to increased calcium intake or absorption may occur if an infant is fed large amounts of chicken liver (source of vitamin A) or is given megadoses of vitamin D or vitamin A, or if a child or adolescent consumes large amounts of calcium-rich foods concurrently with antacids (milk-alkali syndrome). Infants with very low birth weight can develop hypercalcemia if they have inadequate phosphorus intake because bone phosphorus and calcium will be resorbed. Hypercalcemia may also occur when children receiving total parenteral nutrition are given excessive doses of calcium.

Pathophysiology Illustrated: **Calcium Imbalances**

Some causes of excess calcium in the blood (hypercalcemia)



Some causes of decreased calcium in the blood (hypocalcemia)



A variety of conditions can lead to hypercalcemia and hypocalcemia.

Most cases of hypercalcemia in children are due to a shift of calcium from bones into the extracellular fluid. The excessive amounts of parathyroid hormone produced in hyperparathyroidism cause calcium withdrawal from bones. Prolonged immobilization also causes withdrawal of calcium from bones. Often, the excess calcium ions are excreted in the urine. However, if calcium is withdrawn from bones faster than the kidneys can excrete it, hypercalcemia results. Hypercalcemia also occurs with many types of malignancies, such as leukemias. The malignant cells produce substances that circulate in the blood to the bones and cause bone resorption. The calcium from the bones then enters the extracellular fluid, causing hypercalcemia. Bone tumors destroy bone directly, leading to the release of calcium. Familial hypercalcemia and infantile hypercalcemia are rare congenital disorders.

Thiazide diuretics (e.g., thiazide and hydrochlorothiazide) decrease calcium excretion in the urine and may contribute to development of hypercalcemia. Lithium and theophylline can induce hypercalcemia (Ruppe, 2011).

CLINICAL MANIFESTATIONS

Hypercalcemia may have nonspecific symptoms, making diagnosis difficult. Many signs and symptoms of hypercalcemia are manifestations of decreased neuromuscular excitability. Constipation, anorexia, nausea, and vomiting can occur. Fatigue and skeletal muscle weakness dominate. Confusion, lethargy, and decreased attention span are common. Polyuria develops. Severe hypercalcemia may cause cardiac arrhythmias and arrest. Newborns with hypercalcemia have flaccid muscles and exhibit failure to thrive. Hypercalcemia increases sodium and potassium excretion by the kidneys and can lead to polyuria and polydipsia.

CLINICAL THERAPY

Serum calcium is tested although the blood level may not accurately reflect bone stores. Additional laboratory tests include serum albumin, phosphate, magnesium, alkaline phosphate, electrolytes, blood urea nitrogen, creatinine, and parathyroid hormone. Hypercalcemia is treated by increasing fluids and administering the diuretic furosemide (Lasix) to increase excretion of calcium in the urine. Treatment to decrease intestinal absorption of calcium involves effective use of glucocorticoids. Bone resorption can be decreased by administration of glucocorticoids and calcitonin. Phosphate is sometimes given to treat hypercalcemia, but it may cause dangerous precipitation of calcium phosphate salts in body tissues. Dialysis may be used, if necessary. The underlying condition causing the imbalance is treated.

Nursing Management

For the Child With Hypercalcemia

Nursing Assessment and Diagnosis

Nursing assessment of a child with hypercalcemia includes monitoring serum calcium levels, level of consciousness, gastrointestinal function, urine volume, specific gravity, cardiac rhythm, and pH. With chronic hypercalcemia, assessment of activity tolerance and developmental level becomes important.

Many nursing diagnoses are appropriate for children who have hypercalcemia. Diagnoses that address cardiac and neuromuscular manifestation are especially important. The following nursing diagnoses may apply (NANDA-I © 2014):

- ***Activity Intolerance, Risk for,*** related to decreased cardiac output secondary to cardiac arrhythmia
- ***Injury, Risk for,*** related to decreased level of consciousness
- ***Injury, Risk for,*** related to neuromuscular impairment
- ***Injury, Risk for,*** related to possibility of spontaneous fractures
- ***Self-care Deficit: Bathing and Dressing*** related to neuromuscular impairment
- ***Anxiety*** related to change in health status
- ***Constipation*** related to decreased motility
- ***Nutrition, Imbalanced: Less than Body Requirements,*** related to anorexia and nausea
- ***Urinary Elimination, Impaired,*** related to renal calculi

Planning and Intervention

Carefully calculate calcium in total parenteral nutrition and other solutions, administer these solutions with caution, and use cardiac monitoring to prevent hypercalcemia in hospitalized children.

Interventions to increase fluid intake are important for children with hypercalcemia or those who are immobilized. An increased fluid intake, appropriate to the child's age, is necessary to keep the urine dilute and to help reduce constipation (a common symptom of hypercalcemia). An acidic urine helps to keep calcium from forming stones. Because urinary tract infections may cause the urine to be alkaline, institute nursing interventions to prevent urinary tract infection. Thiazide diuretics, which decrease calcium excretion, should not be given to the hypercalcemic child. Provide a high-fiber diet to help reduce constipation.

Increasing mobility through assisted weight bearing helps decrease the withdrawal of calcium from bones that is caused by immobility. If the hypercalcemia is caused by withdrawal of calcium from bones, the child is at risk for fractures with minor trauma and must be handled with special care. See Chapter 29 for further discussion of care following fractures and prolonged casting.

Teach parents to avoid giving calcium-rich foods (such as dairy products) and calcium antacids (e.g., Tums) to children with hypercalcemia. Vitamin D supplements should be avoided as they increase calcium absorption from the gastrointestinal tract.

Evaluation

Expected outcomes include cardiac pump effectiveness, safety, normal bowel excretion, and adequate nutritional status.

Hypocalcemia

Hypocalcemia is a serum deficit of calcium (below 2.1 mmol/L in infants and children). Recall that serum calcium levels may not reflect body stores of this mineral, as most of the body's calcium is stored in bone.

ETIOLOGY AND PATHOPHYSIOLOGY

Hypocalcemia is caused by conditions that include decreased calcium intake or absorption, shift of calcium to a physiologically unavailable form, increased calcium excretion, and loss of calcium by an abnormal route.

Decreased calcium intake or absorption causes hypocalcemia in children with chronic generalized malnutrition or with a diet low in vitamin D and calcium. Female adolescents trying to lose weight or maintain a low weight often decrease foods that contain calcium and may develop chronic hypocalcemia. They may have premature bone loss and inadequate bone. (See Chapter 14 for further discussion of calcium intake during adolescence.) This deficit cannot be made up later in life, increasing the risk of osteoporosis.

Even with a normal calcium intake, hypocalcemia occurs if the mineral is not absorbed. If a child does not have enough vitamin D, calcium is not absorbed efficiently from the duodenum. Sunlight speeds formation of vitamin D in the skin. Children institutionalized without access to sunlight (e.g., severely developmentally delayed children), those with very dark skin, or children kept well covered when outside may become hypocalcemic because of the lack of vitamin D (see Chapter 14). Uremic syndrome is another cause of vitamin D deficiency. It interferes with the kidney's ability to activate vitamin D. High phosphate intake can cause hypocalcemia. Chronic diarrhea and steatorrhea (fatty stools) also reduce calcium absorption from the gastrointestinal tract.

About 40% of calcium is bound to proteins and not available for interactions, 10% is bound to small organic ions such as citrate, and 50% is ionized and physiologically active. Calcium becomes physiologically unavailable when calcium shifts into bone or free ionized calcium in plasma binds to proteins or small organic ions in the plasma. Excessive calcium shifts into bones in various types of hypoparathyroidism, including DiGeorge syndrome (congenital absence of the parathyroid glands). Hypomagnesemia impairs parathyroid hormone function and may cause hypocalcemia. Some types of neonatal hypocalcemia are associated with delayed parathyroid hormone function or hypomagnesemia. Calcium shifts rapidly into bone when rickets is treated. A high plasma phosphate concentration causes plasma calcium to decrease. Ionized hypocalcemia, due to an increased binding of plasma ionized calcium, occurs very rapidly. The ionized hypocalcemia persists until the alkalosis resolves or the citrate is metabolized by the liver. Children who receive liver transplants are hypocalcemic for several days because of impaired citrate metabolism.

Increased calcium excretion occurs in steatorrhea, when calcium secreted into the gastrointestinal fluid binds to the fecal fat in addition to the dietary calcium that is bound in the feces. A similar situation occurs in acute pancreatitis.

Loss of calcium by an abnormal route may contribute to hypocalcemia; calcium is lost through burn or wound drainage or sequestered in acute pancreatitis. Many medications can cause hypocalcemia (see Table 18–12).

CLINICAL MANIFESTATIONS

The signs and symptoms of hypocalcemia are manifestations of increased muscular excitability (tetany). In children, they include twitching and cramping, tingling around the mouth or in the fingers, carpal spasm, and pedal spasm. Laryngospasm, seizures, and cardiac arrhythmias are more severe manifestations of hypocalcemia and may be fatal. Hypocalcemia may cause congestive heart failure, especially in newborns.

Although these symptoms are diagnostic of acute calcium deficiency, a more common state in children and adolescents is chronic low intake of calcium. This may be manifested by spontaneous fractures in infants and in adolescents who exercise excessively.

CLINICAL THERAPY

Laboratory measurement of serum calcium and cardiac monitoring are used for diagnosis. Hypocalcemia is treated by oral or intravenous administration of calcium. The original cause of the imbalance is also treated. If the hypocalcemia is due to hypomagnesemia, the magnesium must be replenished before the calcium replacement can be successful. When the cause is chronic low dietary intake, counseling is needed about high-calcium foods, and perhaps the necessity for vitamin D intake or supplements.

Nursing Management

For the Child With Hypocalcemia

Nursing Assessment and Diagnosis

Carefully assess growth in the young female who is trying to diet. Whenever a female adolescent is very thin, be sure to ask about excessive sports and other activities, and about regularity of menstrual periods. If periods are irregular or not occurring, collect additional dietary information to help determine whether the girl is lacking in intake of calcium, calories, and other nutrients. These assessments are needed even if serum calcium values are normal. Look for signs of inadequate nutrition such as fat and muscle wasting, dry hair, and cold hands and feet. Assess for muscle cramps, stiffness, and clumsiness; grimacing caused by spasms of facial muscles and twitching of arm muscles; and laryngospasm. Increased neuromuscular excitability may be detected by testing for Trousseau sign or Chvostek sign (see Chapter 5). Many healthy newborns have a positive Chvostek sign; however, this assessment should be reserved for children over several months of age. Monitor serum calcium levels and perform cardiac monitoring to observe for cardiac arrhythmias.

Growth and Development

Hypocalcemia in infants is more often seen as tremors, muscle twitches, and brief tonic–clonic seizures. Perform careful neurologic assessments on infants at risk of electrolyte imbalance.

The effects of increased neuromuscular excitability in the child with hypocalcemia are the basis for several nursing diagnoses. These include the following (NANDA-I © 2014):

- ***Injury, Risk for,*** related to potential for fractures
- ***Injury, Risk for,*** related to increased neuromuscular excitability
- ***Breathing Pattern, Ineffective,*** related to laryngospasm
- ***Activity Intolerance*** related to decreased cardiac output secondary to cardiac arrhythmias
- ***Anxiety*** related to change in health status
- ***Nutrition, Imbalanced: Less than Body Requirements,*** related to lack of basic nutritional knowledge of sources and recommended amounts of calcium intake

Planning and Implementation

To correct calcium deficiency in the hospitalized child, give oral or intravenous calcium as prescribed. Monitor for complications of calcium supplementation. Monitor for the side effect of constipation with oral supplements, or for tissue sloughing, elevated serum calcium, or decreased serum phosphate with intravenous supplementation. Verify dosage of calcium gluconate with another nurse, and monitor heart rate and rhythm. Calcium is never given subcutaneously or intramuscularly because it causes tissue necrosis. A 10% calcium gluconate intravenous solution should be readily available for emergency use in severe hypocalcemia.

Take measures to ensure safety for the child who is hospitalized with hypocalcemia. Seizure precautions may be necessary. Explain the cause of muscle cramps to parents and older children.

Counsel the family about dairy products and nondairy foods rich in calcium (see Table 18–13). For the female adolescent whose weight and menstrual patterns show irregularities, total calories and calcium intake should be increased. Teaching may also be needed about proper calcium intake and its importance both to athletic performance and to the prevention of osteoporosis. Encourage three glasses of nonfat milk per day. Teach ways to use milk in the diet. For example, sprinkle nonfat dry milk on cereal and other foods. If the child is lactose intolerant, emphasize nondairy sources of calcium and advise parents to purchase special milk treated with lactase. However, be aware that this milk is more costly, and inadequate family finances may prevent its use. If a child has a health condition leading to chronic diarrhea, encourage increased intake of calcium-rich foods. Calcium supplements in the form of calcium carbonate tablets may be used.

Evaluation

Expected outcomes of nursing care include ingestion of recommended dietary allowances for calcium, absence of discomfort related to calcium imbalance, and freedom from injury.

Magnesium Imbalances

Magnesium is necessary for enzyme function in cells, acetylcholine release, glycolysis, stimulation of ATPases, and bone formation. Since magnesium is a component of chlorophyll, dark green leafy vegetables are a good dietary source of magnesium. Nuts and grains are also good sources of magnesium. Magnesium is absorbed primarily from the terminal ileum. It is distributed among the extracellular fluid (small amounts), the cells (larger amounts), and the bones (large amounts). Magnesium is excreted in urine, feces, and sweat.

Magnesium imbalances are caused by alterations in magnesium intake, distribution, or excretion; by loss of magnesium through an abnormal route; or by a combination of these factors. The plasma magnesium concentration influences the release of acetylcholine at neuromuscular junctions. Thus, magnesium imbalances are characterized by alterations in neuromuscular irritability.

Hypermagnesemia

Hypermagnesemia occurs when the plasma magnesium concentration is too high (above 2.4 mg/dL [0.99 mmol/L]) (see Table 18–9). Keep in mind that the serum levels measured in the laboratory may not reflect body magnesium stores because most magnesium in the body is located in the bones and inside the cells.

Hypermagnesemia is caused by conditions that involve increased magnesium intake and decreased magnesium excretion. Impaired renal function leading to decreased magnesium excretion is the most common cause of hypermagnesemia in children. In both oliguric renal failure and adrenal insufficiency, magnesium ions that cannot be excreted in the urine accumulate in the extracellular fluid.

Less frequently, increased magnesium intake may cause hypermagnesemia. Magnesium sulfate ($MgSO_4$) given to treat eclampsia in the mother before birth causes hypermagnesemia in the newborn. Abnormally high amounts may also be taken in magnesium-containing enemas, laxatives, antacids, and intravenous fluids. Epsom salt is a readily available product that is a nearly pure magnesium sulfate preparation; its use as an enema has caused death in children (see Table 18–12). Aspiration of seawater, as in near-drowning, is an uncommon but potentially serious source of excessive magnesium intake. Children with Addison disease can have abnormally high magnesium levels.

Clinical manifestations of hypermagnesemia include decreased muscle irritability, hypotension, bradycardia, drowsiness, lethargy, and weak or absent deep tendon reflexes. In severe hypermagnesemia, flaccid muscle paralysis, fatal respiratory depression, cardiac arrhythmias, heart block, and cardiac arrest can occur (Crawford & Harris, 2011b).

Hypermagnesemia is managed primarily by increasing the urinary excretion of magnesium. This is usually accomplished by increasing fluid intake (except in oliguric renal failure) and by the administration of diuretics. Dialysis may sometimes be necessary.

Nursing Management

Monitor serum magnesium levels. Take the child's blood pressure (to watch for hypotension), heart rate and rhythm (to monitor for bradycardia and cardiac arrhythmias), respiratory rate and depth (to observe for respiratory depression), and deep tendon reflexes (to assess muscle tone and paralysis or movement). Keep the side rails of the bed raised. Children with hypermagnesemia or oliguria should not be given magnesium-containing medications or sea salt.

Teach parents of children with chronic renal failure that these children should never be given milk of magnesia, antacids that contain magnesium, or other sources of magnesium. When hypermagnesemia is treated with diuretics, monitor potassium levels to watch for hypokalemia.

Expected outcomes of nursing care include maintenance of electrolyte balance, normal neuromuscular tone, safety, and regular heart rate and rhythm.

Hypomagnesemia

Hypomagnesemia refers to a plasma magnesium concentration that is too low (below 1.6 mg/dL [0.66 mmol/L]). Remember that the serum levels of magnesium may not reflect body stores, since most of the magnesium in the body is found in cells and bones.

Hypomagnesemia is caused by conditions that include decreased magnesium intake or absorption, shift of magnesium to a physiologically unavailable form, increased magnesium excretion, and loss of magnesium by an abnormal route.

Decreased magnesium intake or absorption can occur if a child who is not eating has prolonged intravenous therapy without magnesium. Chronic malnutrition is another cause of decreased magnesium intake. Magnesium absorption is decreased in chronic diarrhea, short bowel syndrome, malabsorption syndromes, and steatorrhea.

Magnesium may shift to a physiologically unavailable form after transfusion of many units of citrated blood products; magnesium bound to the citrate is not physiologically active. Such transfusions cause prolonged hypomagnesemia in liver transplant patients, who have impaired citrate metabolism. Magnesium shifts rapidly into bones that have been deprived of adequate stores.

Increased magnesium excretion in the urine occurs with diuretic therapy, the diuretic phase of acute renal failure, diabetic ketoacidosis, and hyperaldosteronism. Chronic alcoholism, occasionally seen in adolescents, increases urinary magnesium excretion. Magnesium contained in gastrointestinal secretions is bound to fat and excreted in the stool.

Clinical Tip

Instruct parents of a child with chronic renal failure to read labels to detect magnesium in antacids and cathartics. Encourage them to check with their pharmacist and other healthcare providers before administering any over-the-counter medication to the child.

Loss of magnesium by an abnormal route occurs with prolonged nasogastric suction and through sequestration of magnesium in acute pancreatitis. Several medications may cause hypomagnesemia (see Table 18–12).

Hypomagnesemia is characterized by increased neuromuscular excitability (tetany). The clinical manifestations are hyperactive reflexes, skeletal muscle cramps, twitching, tremors, and cardiac arrhythmias. Seizures can occur with severe hypomagnesemia.

Hypomagnesemia is managed by administering magnesium and treating the underlying cause of the imbalance.

Nursing Management

In addition to monitoring serum magnesium levels, nursing assessment of hypomagnesemia includes monitoring deep tendon reflexes, testing for Trousseau and Chvostek signs, monitoring cardiac function, and observing for muscle twitching. Children who are able to talk may report muscle cramping. Because magnesium levels are not routinely measured in many settings, request the test for any child who has risk factors and early manifestations of hypomagnesemia. When intramuscular or intravenous magnesium is ordered, administer carefully as directed and monitor vital signs. Electrocardiogram and renal studies may precede drug administration. Have resuscitative drugs and equipment readily available during drug administration.

Teach parents of a child with hypomagnesemia or continuing risk factors such as chronic diarrhea to include magnesium-rich foods in the diet (see Table 18–13). Before administering magnesium supplements, verify that the child's urine output is adequate. Monitor deep tendon reflexes if intravenous magnesium is given, and observe for complications of magnesium supplementation. Oral magnesium may lead to diarrhea, and intravenous magnesium can cause flushing, elevated serum magnesium, cardiac arrhythmias, or decreased deep tendon reflexes.

Expected outcomes of nursing care for the child with an imbalance in magnesium are restoration and maintenance of electrolyte balance.

CLINICAL ASSESSMENT OF FLUID AND ELECTROLYTE IMBALANCE

How can a nurse assess children appropriately for fluid and electrolyte imbalance without thinking through the clinical manifestations of every possible disorder one after the other? First, perform a rapid risk factor assessment on each child to see which factors are present (Tables 18–14 and 18–15).

A risk factor assessment may be performed mentally while providing care. Look for factors that alter the intake, retention, and loss of isotonic fluid and water. Use this information to evaluate which fluid imbalance is most likely to occur in a particular child. Next, look for factors that alter electrolyte intake and absorption, distribution between plasma and other electrolyte pools, excretion, and abnormal routes of electrolyte loss. Use this information to evaluate which electrolyte imbalances are most likely to occur in the child. A review of pathophysiology is important to understand the role of the other electrolytes and substances, such as phosphorus, in the body.

After evaluating possible imbalances for the child, perform a clinical assessment. Assess for fluid imbalances by assessing weight changes, vascular volume, interstitial volume, and cerebral function (Table 18–16). Assess for electrolyte imbalances by assessing serum electrolyte levels, skeletal muscle strength, neuromuscular excitability, gastrointestinal tract function, and cardiac rhythm (Table 18–17). Next, check for other manifestations specific to a particular high-risk imbalance (e.g., polyuria in hypokalemia). Evaluate any serum laboratory values available. This method of risk factor assessment followed by clinical assessment provides a rapid yet thorough approach to assessment for fluid and electrolyte imbalances.

TABLE 18–14 Risk Factor Assessment for Fluid Imbalances

TYPE OF FLUID	FACTORS TO ASSESS
Isotonic fluid (extracellular fluid volume imbalances)	Source of increased intake? Aldosterone secretion increased or decreased? Source of loss from the body?
Water	Source of increased intake? Antidiuretic hormone secretion increased or decreased? Source of unusual loss from the body?

TABLE 18–15 Risk Factor Assessment for Electrolyte Imbalances

POTENTIAL ELECTROLYTE IMBALANCE	ASSESSMENT FINDING
Electrolyte intake and absorption	Increased? Decreased?
Electrolyte shifts	From electrolyte pool to plasma? From plasma to electrolyte pool?
Electrolyte excretion	Increased? Decreased?
Electrolyte loss by abnormal route	Vomiting? Diarrhea? Nasogastric suction? Wound? Burn? Excessive sweating?

TABLE 18–16 Summary of Clinical Assessment of Fluid Imbalances

ASSESSMENT CATEGORY	SPECIFIC ASSESSMENTS	CHANGES WITH FLUID IMBALANCES
Rapid changes in weight	Daily weights	Weight gain—extracellular volume excess
		Weight loss—extracellular volume deficit; clinical dehydration
Vascular volume	Small vein filling time	Increased—extracellular volume deficit; clinical dehydration
	Capillary refill time	Increased—extracellular volume deficit; clinical dehydration
	Character of pulse	Bounding—extracellular volume excess
		Thready—extracellular volume deficit; clinical dehydration
	Postural blood pressure measurements	Postural drop—extracellular volume deficit; clinical dehydration
	Lung sounds in dependent portions	Crackles—extracellular volume excess
	Central venous pressure	Increased—extracellular volume excess
		Decreased—extracellular volume deficit; clinical dehydration
	Tenseness of fontanelle (infants)	Bulging—extracellular volume excess
		Sunken—extracellular volume deficit; clinical dehydration
	Neck vein filling (older children)	Full when upright—extracellular volume excess
		Flat when supine—extracellular volume deficit; clinical dehydration
Interstitial volume	Skin turgor	Skin tents—extracellular volume deficit; clinical dehydration
	Presence or absence of edema	Edema—extracellular volume excess
Cerebral function	Level of consciousness	Decreased—clinical dehydration

TABLE 18–17 Summary of Clinical Assessment of Electrolyte Imbalances

ASSESSMENT CATEGORY	SPECIFIC ASSESSMENTS	CHANGES WITH ELECTROLYTE IMBALANCES
Skeletal muscle function	Muscle strength	Weakness, flaccid paralysis—hyperkalemia; hypokalemia
Neuromuscular excitability	Deep tendon reflexes	Depressed—hypercalcemia; hypermagnesemia
		Hyperactive—hypocalcemia; hypomagnesemia
	Chvostek sign (not seen in infants)	Positive—hypocalcemia; hypomagnesemia
	Trousseau's sign	Positive—hypocalcemia; hypomagnesemia
	Paresthesias	Digital or perioral—hypocalcemia
	Muscle cramping or twitching	Present—hypocalcemia; hypomagnesemia
Gastrointestinal tract function	Bowel sounds	Decreased or absent—hypokalemia
	Elimination pattern	Constipation—hypokalemia; hypercalcemia
		Diarrhea—hyperkalemia
Cardiac rhythm	Arrhythmia	Irregular—hyperkalemia; hypokalemia; hypercalcemia; hypocalcemia; hypermagnesemia; hypomagnesemia
	Electrocardiogram	Abnormal—hyperkalemia; hypokalemia; hypercalcemia; hypocalcemia; hypermagnesemia; hypomagnesemia
Cerebral function	Level of consciousness	Decreased—hyponatremia; hypernatremia

ACID–BASE IMBALANCES

There are four acid–base imbalances. Two are the result of processes that cause too much acid in the body and are referred to as **acidosis**. The other two are the result of processes that cause too little acid in the body and are called **alkalosis**. An acid–base disorder caused by too much or too little carbonic acid is called a *respiratory acid–base imbalance*. A disorder caused by too much or too little metabolic acid is called a *metabolic acid–base imbalance.*

Arterial blood gas measurements (ABGs) provide a laboratory evaluation of a child's current acid–base status. In addition, oxygen saturation, or the percentage of hemoglobin saturated with arterial blood, is normally 95% to 100%. Table 18–18 provides a method that can help interpret the pH, Pco_2, and bicarbonate concentrations, the most important acid–base measures. End-tidal CO_2 can provide a continuous noninvasive measurement. (Remember that Pco_2 reflects carbonic acid status, and bicarbonate concentration reflects the metabolic acid status.)

Clinical Tip

Acidosis: Relatively too much acid in the body

Respiratory acidosis: Relatively too much carbonic acid

Metabolic acidosis: Relatively too much metabolic acid

Alkalosis: Relatively too little acid in the body

Respiratory alkalosis: Relatively too little carbonic acid

Metabolic alkalosis: Relatively too little metabolic acid

TABLE 18–18 Questions to Ask to Interpret Arterial Blood Gas Measurements

QUESTION TO ASK	CONCLUSION
What is the pH?	• If the pH is normal, the child has no imbalance or has compensated for an imbalance. • If the pH is below normal, the child has acidosis. • If the pH is above normal, the child has alkalosis.
What is the Pco_2?	• If the Pco_2 is normal, the child does not have an acid–base imbalance. • If the Pco_2 is above normal, the child has respiratory acidosis. This may be the primary disorder or may be a compensatory response to metabolic alkalosis. Looking at the bicarbonate concentration helps you decide. • If the Pco_2 is below normal, the child has respiratory alkalosis. Again, this can be the primary disorder or may be a compensatory response to metabolic acidosis.
What is the bicarbonate concentration?	• If the bicarbonate concentration is within normal range, the child does not have a metabolic acid–base imbalance. • If the bicarbonate is above normal, the child has metabolic alkalosis. This can be a primary disorder or a compensatory response to respiratory acidosis. • If bicarbonate is below normal, the child has metabolic acidosis, either as a direct disorder or as a compensatory response to respiratory alkalosis.
What do the results together tell you?	• If the pH is abnormal and either the Pco_2 or bicarbonate concentration is normal, there is an uncompensated acid–base disorder. • If all three values are abnormal, the child has a partially compensated disorder and the pH will provide the definitive answer. • If Pco_2, pH, and bicarbonate are all decreased, then partially compensated metabolic acidosis is most likely. • If pH is normal and Pco_2 and bicarbonate are abnormal, there is a fully compensated acid–base disorder.
What are the child's history and clinical signs?	• Does your interpretation fit with what you know about the child's medical condition and with assessments you are making? • This last step helps you to integrate laboratory data with the clinical picture to strengthen your nursing care of the child with an acid–base imbalance.

Respiratory Acidosis

Respiratory acidosis is caused by an accumulation of carbon dioxide in the blood. Since carbon dioxide and water can be combined into carbonic acid, respiratory acidosis is sometimes called carbonic acid excess. The condition can be acute or chronic. It is controlled by the lungs.

ETIOLOGY AND PATHOPHYSIOLOGY

Any factor that interferes with the ability of the lungs to excrete carbon dioxide can cause respiratory acidosis. These factors may interfere with the gaseous exchange within the lungs, may impair the neuromuscular pump that moves air in and out of the lungs, or may depress the respiratory rate (Table 18–19 and Figure 18–10).

As the Pco_2 begins to increase, the pH of the blood begins to decrease. Compensatory mechanisms begin to act in the form of nonbicarbonate buffers, additional hydrogen ion excretion by the kidneys, and formation and decreased bicarbonate excretion by the kidneys. These compensatory mechanisms take several days to become active so the child manifests a changing clinical situation, depending on the underlying cause and the amount of compensation occurring (Table 18–20).

TABLE 18–19 Causes of Respiratory Acidosis

FACTORS AFFECTING THE LUNGS	FACTORS AFFECTING THE NEUROMUSCULAR PUMP	FACTORS AFFECTING CENTRAL CONTROL OF RESPIRATION
Aspiration	Flail chest	Sedative overdose
Spasm of the airways	Pneumothorax or hemothorax	General anesthesia
Laryngeal edema	Mechanical underventilation	Head injury
Epiglottitis	Hypokalemic muscle weakness	Brain tumor
Croup	High cervical spinal cord injury	Central sleep apnea
Pulmonary edema	Botulism	
Atelectasis	Tetanus	
Severe pneumonia	Kyphoscoliosis	
Cystic fibrosis	Poliomyelitis	
Bronchopulmonary dysplasia	Muscular dystrophy	
Pulmonary embolism	Congenital diaphragmatic hernia	
	Guillain-Barré syndrome	

Figure 18–10 **Respiratory acidosis/alkalosis and mechanical ventilation. This child may develop respiratory acidosis or respiratory alkalosis. If the tidal volume is set too low during mechanical ventilation, carbon dioxide (carbonic acid) will accumulate in the body (respiratory acidosis) because it is not being excreted by the lungs. If the tidal volume is set too high, carbon dioxide will be depleted in the body (respiratory alkalosis) because it is being excreted in great quantities.**

CLINICAL MANIFESTATIONS

Acidosis in the brain cells causes central nervous system depression, manifested by confusion, lethargy, headache, increased intracranial pressure, and even coma. Acute respiratory acidosis can lead to tachycardia and cardiac arrhythmias. The child's arterial blood gases always show an increased Pco_2, the laboratory sign of increased carbonic acid. Serum pH can be decreased or normal.

CLINICAL THERAPY

Treatment of respiratory acidosis requires correction of the underlying cause. For example, treatment may include bronchodilators for bronchospasm, mechanical ventilation for neuromuscular defects, decreasing sedative use, or surgery for kyphoscoliosis.

Nursing Management

For the Child With Respiratory Acidosis

Nursing Assessment and Diagnosis

Nursing assessment plays a pivotal role in decisions about interventions for respiratory acidosis. This is especially true in chronic conditions such as cystic fibrosis and kyphoscoliosis. Assess respiratory rate, rhythm, and depth carefully. Take the apical pulse and be alert for tachycardia or arrhythmia. A cardiac monitor may be used. Obtain serial arterial blood gas measurements in acute conditions to evaluate changing status. Assess the level of consciousness and energy. Observe for chronic fatigue, headache, or decreased level of consciousness.

Several nursing diagnoses may apply to the child with respiratory acidosis. The most important addresses the child's ***Injury, Risk for.*** Other nursing diagnoses depend on the specific clinical manifestation and the particular cause of the acidosis. Examples include the following (NANDA-I © 2014):

- ***Injury, Risk for,*** related to decreased level of consciousness

TABLE 18–20 Laboratory Values in Uncompensated and Compensated Respiratory Acidosis

TYPE OF RESPIRATORY ACIDOSIS	HCO_3^-	pH	Pco_2
Uncompensated	Normal	Decreased	Increased
Partially compensated	Increasing	Decreasing but moving toward normal	Increased
Fully compensated	Increased	Normal	Increased

- ***Activity Intolerance*** related to decreased cardiac output secondary to cardiac dysrhythmias
- ***Breathing Pattern, Ineffective (Hypoventilation),*** related to neuromuscular impairment
- ***Pain (Headache)*** related to cerebral vasodilation
- ***Health Management, Family, Ineffective,*** related to complexity of bronchodilator therapy

Planning and Implementation

COMMUNITY-BASED NURSING CARE

Teach children at risk for respiratory acidosis and their parents preventive measures to use at home. For the child with a chronic condition such as cystic fibrosis, muscular dystrophy, or kyphoscoliosis, demonstrate deep breathing and encourage its use several times each day. Teach the family signs of infection—including fever, increased respiratory secretions, and discomfort with breathing—so that these problems can be treated promptly, preventing further respiratory involvement. Position the child to facilitate chest expansion. Teach parents about proper administration of any necessary medications. For example, the child with cystic fibrosis may receive antibiotics to prevent respiratory infections. Teach parents and older children about home respirator use (Figure 18–11).

Figure 18–11 **Home respirator use. This child, who has muscular dystrophy, uses a "turtle" respirator at home to assist with breathing. His parents required instructions from the nurse on use of the respirator. The family has a generator to provide electricity for the respirator during power outages.**

HOSPITAL-BASED NURSING CARE

For the hospitalized child, the focus is on ensuring safety. Keep bed side rails raised, and turn and position the child frequently. Evaluate mental status and document and report any changes in alertness. When laboratory values of blood pH and Pco_2 are available, evaluate them promptly and report any changes or abnormalities. Administer medications as ordered. Carefully monitor the doses of sedatives to avoid further respiratory depression. Provide suctioning and encourage deep breathing.

Evaluation

Expected outcomes of nursing care for the child with respiratory acidosis include maintenance of safety, adequate rate and rhythm of respirations, and management of causative disorders.

Growth and Development

It is usually difficult to get a young child to do deep breathing or to use the "blow bottle" that is often given to older children and adults. To make deep breathing fun, use a pinwheel and have the child turn it during play. Alternatively, give a child a straw to blow bubbles in a glass of water or to blow scraps of paper across the bedside table.

Respiratory Alkalosis

Respiratory alkalosis occurs when the blood contains too little carbon dioxide. This condition is sometimes called *carbonic acid deficit*.

Excess carbon dioxide loss is caused by hyperventilation, in which more air than normal is moved into and out of the lungs. Some common causes of hyperventilation are hypoxia due to severe asthma, salicylate poisoning, and sepsis. Other causes are anxiety, fear, pain, meningitis, septicemia, and mechanical overventilation.

In many cases, respiratory alkalosis lasts for several hours only. Renal compensation does not occur because these compensatory mechanisms take several days to begin action. An example is the hyperventilation that occurs with acute anxiety. However, if the condition persists, the kidneys will begin to retain more acid and excrete more bicarbonate. Hydrogen ions will be released from body buffers to decrease plasma bicarbonate. While the imbalance continues, cellular function is thus protected by returning pH to normal levels (Table 18–21).

Arterial blood gas measurements show a decreased Pco_2 in respiratory alkalosis. Blood pH is generally elevated. The lack of carbon dioxide causes neuromuscular irritability and paresthesias in the extremities and around the mouth. Muscle cramping and carpal or pedal spasms can occur. The child may be dizzy or confused.

TABLE 18–21 Laboratory Values in Uncompensated and Compensated Respiratory Alkalosis

TYPE OF RESPIRATORY ALKALOSIS	HCO_3^-	pH	Pco_2
Uncompensated	Normal	Increased	Decreased
Partially compensated	Decreasing	Increasing but moving toward normal	Decreased
Fully compensated	Decreased	Normal	Decreased

Medical management focuses on correcting the condition that caused the hyperventilation so that the body's compensatory mechanisms can return carbon dioxide levels to normal.

Nursing Management

For the Child With Respiratory Alkalosis

Nursing Assessment and Diagnosis

Assess the child's level of consciousness and ask if the child feels light-headed or has tingling sensations or numbness in the fingers or toes or around the mouth. Assess the rate and depth of respirations. Monitor the hospitalized child's Po_2 with serial arterial blood gas measurements to evaluate changes in status. Make a careful assessment about the cause of hyperventilation. Did an occurrence cause anxiety for the child? Is the child in pain? (See Chapter 15.) Has the child received salicylates in any form? Is the child mechanically ventilated? Is there a central nervous system infection such as meningitis?

Planning and Implementation

Nursing care for the child with respiratory alkalosis centers on teaching stress management techniques, maintaining pain control, promoting respiratory function, ensuring safety, regulating fluid status, and providing health supervision and home care.

SAFETY ALERT!

Check the Po_2 before any therapy for respiratory alkalosis is started because it is dangerous to stop hyperventilation if oxygenation is poor.

TEACH STRESS MANAGEMENT TECHNIQUES

When anxiety is the cause of respiratory alkalosis, instruct the child to breathe slowly; demonstrate the rhythm. Use a calm voice, stuffed toys, and supportive reassurance. Teach stress-control techniques such as relaxation and imagery for situations that cause anxiety.

MAINTAIN PAIN CONTROL

Use medications, imagery, distraction, positioning, massage, and other techniques to decrease pain and maintain pain management. See Chapter 15 for a description of these and other measures to assist with pain control.

PROMOTE RESPIRATORY FUNCTION

Have the child cough, or apply suction as needed. Be certain that mechanical ventilation systems are working properly.

ENSURE SAFETY

Provide a safe environment for the child who has a decreased level of consciousness. Be sure the child is supervised when sitting or standing up. Keep bed rails up.

REGULATE FLUID STATUS

Renal compensation to manage ongoing respiratory alkalosis requires adequate urinary output. Regulate fluid intake to ensure urine output unless fluids are restricted because of a medical condition.

COMMUNITY-BASED NURSING CARE

Teach parents to keep aspirin and other salicylate products out of reach of children, preferably in a locked medicine box. Provide stickers with the number of the Poison Control Center.

Evaluation

Expected outcomes of nursing care for the child with respiratory alkalosis include normal respiratory rate and rhythm, maintenance of safety, and regulation of fluid status.

Metabolic Acidosis

Metabolic acidosis is a condition in which there is an excess of any acid other than carbonic acid. For this reason, it is sometimes called *noncarbonic acid excess*.

ETIOLOGY AND PATHOPHYSIOLOGY

Metabolic acidosis is caused by an imbalance in production and excretion of acid or by excess loss of bicarbonate. Excess accumulation occurs by one of two mechanisms. First, a child can eat or drink acids or substances that are converted to acid in the body. Examples include aspirin, boric acid, and antifreeze. Second, cells can make abnormally high amounts of acid that cannot be excreted. This is the case in ketoacidosis of untreated diabetes mellitus, untreated growth hormone deficiency, bladder construction that uses part of the bowel, or the starvation that can occur in anorexia or bulimia. A disorder of excretion occurs in conditions such as oliguric renal failure (Figure 18–12).

The body can lose bicarbonate through the urine or through excessive loss of intestinal fluid. Diarrhea, fistulas, and ileal drainage are all possible sources. Carbonic anhydrase inhibitors can cause loss of excess bicarbonate in the urine.

Below-normal pH of the blood stimulates the chemoreceptors in the brain and arteries and respiratory compensation begins. The child's rate and depth of breathing increase and carbonic acid is removed from the body. The blood pH shifts to a more normal range even though the cause is not corrected. The underlying condition and the degree of compensation alter the clinical laboratory values observed (Table 18–22).

Figure 18–12 **Disorders of excretion. With any postoperative or immobilized child, it is important to monitor urine output to detect oliguria. If the kidneys do not produce sufficient urine, the metabolic acids accumulate in the body and cause metabolic acidosis. Inadequate fluid intake in the postoperative or immobilized child can lead to oliguria and, potentially, metabolic acidosis.**

TABLE 18–22 Laboratory Values in Uncompensated and Compensated Metabolic Acidosis

TYPE OF METABOLIC ACIDOSIS	HCO_3^-	pH	Pco_2
Uncompensated	Decreased	Decreased	Normal
Partially compensated	Decreased	Decreased but moving toward normal	Decreasing

CLINICAL MANIFESTATIONS

Laboratory values show decreased blood pH and decreased HCO_3^- and Pco_2. An attempt at respiratory compensation causes one of the most important signs of metabolic acidosis, increased rate and depth of respirations (hyperventilation) or **Kussmaul respirations**. Severe acidosis can cause decreased peripheral vascular resistance and resultant cardiac arrhythmias, hypotension, pulmonary edema, and tissue hypoxia. Confusion or drowsiness may result, as well as headache or abdominal pain.

CLINICAL THERAPY

Treatment of metabolic acidosis depends on identification and treatment of the underlying cause. In severe metabolic acidosis, intravenous sodium bicarbonate may be used to increase the pH and to prevent cardiac arrhythmias. This treatment is difficult to manage because renal excretion can cause excess retention of bicarbonate; therefore, intravenous sodium bicarbonate is used only in severe situations, such as prolonged cardiac arrest.

Nursing Management

For the Child With Metabolic Acidosis

Nursing Assessment and Diagnosis

Teach prevention of poisoning at each health promotion visit. For the child admitted with acidosis, assess the rate and depth of respirations. Evaluate the child's level of consciousness frequently. Be alert for signs or complaints of headache and abdominal pain. Serial arterial blood gas measurements will usually be obtained to evaluate changes in status.

Several nursing diagnoses can apply to the child with metabolic acidosis, including the following (NANDA-I © 2014):

- ***Injury, Risk for,*** related to confusion/drowsiness or decreased responsiveness
- ***Cardiac Output, Decreased,*** related to cardiac arrhythmias
- ***Tissue Perfusion: Cerebral, Risk for Ineffective,*** related to tissue hypoxia
- ***Health Management, Family, Ineffective,*** related to complexity of management of diabetes mellitus

Planning and Implementation

Ensure safety, taking into account the child's level of consciousness and alertness. Change the child's position to prevent pressure on the skin. Limit the child's activities to decrease cardiac workload.

Position the child to facilitate chest expansion. Provide oral care during rapid respirations because the mouth may become dry.

Monitor intravenous solutions and laboratory values indicating acid–base balance. Report changes promptly.

Once the child is stabilized, provide teaching to compensate for knowledge deficits. Teach parents of young children to keep medications and acids locked up and out of reach to prevent poisoning (Figure 18–13). This includes medicines with aspirin as well as substances commonly kept in the garage for car maintenance. Teach about home management of diabetes and about early identification and treatment to avoid diabetic ketoacidosis.

Evaluation

Expected outcomes of nursing care relate to prevention of acidosis and restoration of normal body balance during disease processes.

Metabolic Alkalosis

Metabolic alkalosis occurs when there are too few metabolic acids. It is sometimes called *noncarbonic acid deficit*.

A gain in bicarbonate or a loss of metabolic acid can cause metabolic alkalosis. Bicarbonate is gained through excessive intake of bicarbonate antacids or baking soda or through metabolism of bicarbonate precursors such as the citrate contained in blood transfusions. Increased renal absorption of bicarbonate can occur in profound hypokalemia, primary hyperaldosteronism, or extreme deficit in extracellular fluid volume. Use of enhanced water to constitute powdered formula can be a cause of metabolic alkalosis. Acid can be lost through severe vomiting, such as that seen in infants with pyloric stenosis, and through continued removal of gastric contents through suction.

When the chemoreceptors in the brain and arteries detect the rising pH of metabolic alkalosis and respirations decrease, the body retains carbonic acid. This carbonic acid can neutralize the bicarbonate and return pH toward normal.

Blood pH, bicarbonate, and Pco_2 are usually elevated in metabolic alkalosis (Table 18–23). Hypokalemia often occurs simultaneously. Respiratory rate and depth usually decrease.

Figure 18–13 **Prevent metabolic acidosis from poisoning. Teaching parents to use safety latches on cabinets to keep aspirin away from small children can help prevent one cause of metabolic acidosis.**

TABLE 18–23 Laboratory Values in Uncompensated and Compensated Metabolic Alkalosis

TYPE OF METABOLIC ALKALOSIS	HCO_3^-	pH	Pco_2
Acute condition; uncompensated	Increased	Increased	Normal
Partially compensated	Increased	Increased but moving toward normal	Increasing
Fully compensated	The need for oxygen drives respirations and limits full compensation for metabolic alkalosis		

Increased neuromuscular irritability, cramping, paresthesia, tetany, seizures, and excitation can occur. Finally, this state can progress to weakness, confusion, lethargy, and coma.

Clinical therapy is directed at treating the underlying cause of the condition. Increasing the extracellular fluid volume with intravenous normal saline facilitates renal excretion of bicarbonate.

Nursing Management

Assess the child's level of consciousness frequently. Alertness may decrease after an initial period of excitement, so regular assessments are needed. Monitor neuromuscular irritability. Observe for nausea and vomiting. Assess the rate and depth of respirations carefully. Obtain serial arterial blood gas measurements as ordered.

Facilitate ease of respirations. Ensure safety by keeping bed rails elevated and by turning the child frequently. Position the child on the side to avoid aspiration of vomitus.

If antacids or improper formula constitution were the cause of the alkalosis, teach the child and parents about correct use of these medications.

Mixed Acid–Base Imbalances

It is possible for two acid–base imbalances to occur at the same time. For example, a child with cystic fibrosis can develop respiratory acidosis from lung problems and concurrent metabolic alkalosis from vomiting during an illness. Treatment with diuretics may cause concurrent metabolic alkalosis resulting from extracellular volume depletion and hypokalemia in a child with congestive heart failure and chronic respiratory acidosis. In these cases, all underlying causes must be identified and treated. Care of children with mixed acid–base imbalances is often complicated, requiring hospitalization and careful management. On discharge, the nurse can teach parents about signs of imbalance that need to be reported and treated to prevent further complications. Evaluation of care is based on outcomes of adequate respiratory ventilation and metabolic balance.

Chapter Highlights

- Young children are at risk for fluid and electrolyte imbalance due to differences in body fluid compartments and regulation systems.
- Nurses institute health promotion and health maintenance measures to maintain normal body fluids for children who exercise in hot weather and those undergoing surgery.
- Extracellular fluid volume deficit manifests as dehydration.
- Extracellular fluid volume excess is due to an excess of saline in the body. Interstitial fluid volume excess manifests as edema and weight gain. Nurses carefully manage fluid status of young children and teach parents prevention and treatment of fluid imbalances caused by gastroenteritis and other disease states.
- The most common electrolyte imbalances are hypernatremia and hypokalemia, and thus involve sodium and potassium.
- Normal acid–base balance is necessary for proper function of cells in the body.
- The lungs, kidneys, and liver play a role in maintaining acid–base balance.
- Acid–base imbalance can involve alkalosis or acidosis; either can have a respiratory or metabolic origin.

Clinical Reasoning in Action

A 10-month-old named Devin comes to the emergency department by ambulance at 3:00 a.m. for respiratory distress. His parents state that he was experiencing a cough for the past week and developed a fever of over 103.0˚F (39.4˚C) tonight. He woke up crying with a frightening cough and could barely catch his breath; the parents called 9-1-1. Devin's respiratory rate is 50 times per minute with moderate retractions, his temperature is 104.2˚F (40.1˚C), his heart has a regular rhythm with a rate of 150 beats per minute, and he has stridor while breathing. At the hospital, after a breathing treatment with racemic epinephrine, his respiratory rate decreases to 40 and retractions improve. The arterial blood gas measurements show an increased Pco_2, a decreased pH, and a normal HCO_3^-. A diagnosis of croup syndrome and resultant respiratory acidosis is made. Devin is admitted for monitoring.

1. What are some of the other possible causes of respiratory acidosis in children such as Devin?
2. What are some of the signs and symptoms of respiratory distress and the central nervous system problems associated with Devin's particular acid–base imbalance?
3. Devin's heart rate and rhythm are monitored closely in the hospital. What is the reason for these assessments?
4. What is the treatment for Devin's acid–base imbalance?
5. What are some of the measures taken in the hospital to ensure Devin's safety?

Chapter 19
Alterations in Eye, Ear, Nose, and Throat Function

Digital Vision/Getty Images

The early intervention program that Raeanne attended to help her deal with her visual impairment prepared her well for preschool. We learned a lot too about how to help her. We are still really nervous about her starting at preschool and being with a lot of other children. We want it to go well for her.

—Mother of Raeanne, 3 years old

Learning Outcomes

19.1 Identify anatomy, physiology, and pediatric differences in the eye, ear, nose, and throat of children and adolescents.

19.2 Describe abnormalities of the eyes, ears, nose, throat, and mouth in children.

19.3 Carry out screening programs to identify children with vision and hearing abnormalities.

19.4 Plan nursing care for children with vision or hearing impairments.

19.5 Select and apply latest recommendations when implementing care and teaching for children with abnormalities of eyes, ears, nose, throat, and mouth.

19.6 Integrate preventive and treatment principles when implementing health promotion for children related to eyes, ears, nose, and throat.

The eye, ear, nose, and throat are connected, so a malformation, infection, or other condition in one of these structures may affect them all. Intact sensory structures enable children to reach developmental milestones; thus alterations, especially to the eye and ear, may delay a child's development. Most children with eye, ear, nose, and throat disorders are treated at home or in the community rather than in the hospital. How are conditions of the eye, ear, nose, and throat related? Which conditions have the potential to affect a child's growth, development, and behavior? In what settings do children with eye, ear, nose, and throat conditions receive care? How can parents be helped to foster development in their children when they have a visual or hearing disorder?

Disorders of the Eye

Infectious Conjunctivitis

Conjunctivitis is an inflammation of the conjunctiva, the clear membrane that lines the inside of the lid and sclera. Bacteria, viruses, allergies, trauma, or irritants cause the conjunctiva to become swollen and red with a yellow or white discharge (Figure 19–1). Parents commonly refer to all conjunctivitis as "pink eye."

Conjunctivitis in a newborn or infant under 30 days of age is called *ophthalmia neonatorum*. These infections are usually acquired from the mother during vaginal birth as a result

Text continues on page 444

FOCUS ON:
Eyes, Ears, Nose, and Throat

Anatomy and Physiology

Sight, hearing, taste, and smell depend on proper functioning of receptor organs and interpretation by the brain. Thus, certain cranial nerves are also an integral part of the anatomy and physiology of the eye, ear, nose, throat, and mouth. Children are prone to both inborn and acquired sensory alterations, as well as a wide array of infections and injuries that can affect the eye, ear, nose, throat, mouth, and upper respiratory system. Because these body parts are connected anatomically, conditions in one necessarily affect the others. Other conditions of the respiratory system, including obstructive sleep apnea, are discussed in Chapter 20.

Eye

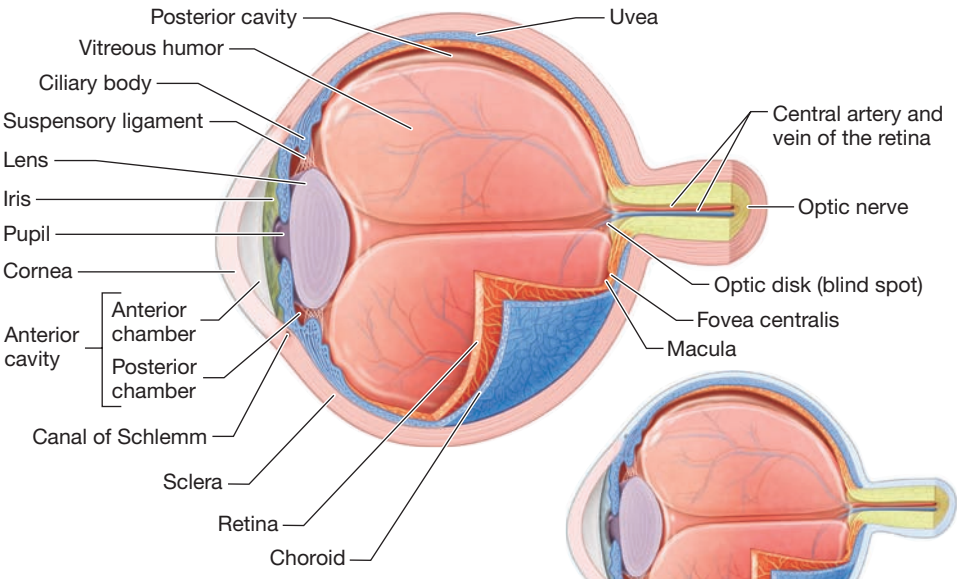
The eye is a complex structure composed of the eyeball and its supporting structures. The *sclera,* or white part of the eye, is the outermost layer. It is transparent in the anterior eye to form the *cornea*, which allows light to enter. The *iris,* or colored part of the eye, is muscular, allowing it to change the size of the *pupil* and regulate the light that enters the eye. The *lens* is located behind the pupil and focuses light onto the retina. The *anterior chamber,* or the space between the cornea and iris, is filled with a fluid called *aqueous humor*. The *posterior chamber* is located behind the lens and is filled with *vitreous humor*. The innermost, posterior section of the eye is the *retina,* which has an inner layer that receives light impulses and an outer neural layer that transports visual images to the brain by the optic nerve (cranial nerve II). The *rods* in the retina perceive vision in dim light and allow for peripheral vision; the *cones* perceive vision in bright light and are responsible for color discernment. See *As Children Grow: The Eye* for normal structures of the child's eye.

The eye has several supporting structures that assist in the sensation of vision. *Eyebrows*, *eyelids*, and *eyelashes* protect the eye and add touch sensation. The *conjunctiva* lines the cornea and the inside of the eyelids, lubricating the eye and keeping it viable. The lacrimal apparatus and ducts bathe the eye and produce tears. A series of six muscles allow the eye to move to all planes and maintain the shape of the eyeball. They are innervated by the oculomotor, trochlear, and abducens nerves (cranial nerves III, IV, and V).

Ear

The ear is responsible for the sensory ability of hearing and it establishes the sense of equilibrium. The *external ear* contains the *auricle,* which is visible outside the body; the *external canal*; and the *tympanic membrane*. These structures collect sound waves and direct them to the middle and inner ear. The *middle ear* lies behind the tympanic membrane and contains three bones necessary for sound vibrations: the *incus*, *malleus*, and *stapes*. Another part of the middle ear, the *eustachian tube*, connects to the nasopharynx and equalizes ear pressure. The *inner ear* contains the bony labyrinth, which in turn houses the *vestibule*, *semicircular canals*, and the *cochlea*. The vestibule and semicircular canals are responsible for the sense of equilibrium. The cochlea contains the *organ of Corti,* which contains sensory hair cells that are innervated by the acoustic nerve (cranial nerve VIII).

As Children Grow: **The Eye**



Eye of Adolescent

Eye of Young Child

The eye is well developed at birth, but there are some variations in the visual acuity of the infant and young child. What influence would the young child's visual acuity have on the types of toys and books that should be made available?

(*continued*)

Nose, Throat, and Mouth

The structures of the nose, throat, and mouth are important to all humans. Mucous membranes bathe these body parts and have a high rate of growth. They help maintain hygiene and protect the body from infectious agents. Salivary apparatus and taste buds are essential parts of the mouth and tongue. The nasal passages contain external nostrils, the sinuses, and the pharynx (or throat). The olfactory, facial, glossopharyngeal, and vagus nerves (cranial nerves I, VII, IX, and X) are responsible for the sense of smell, taste, coordinated swallowing, and the gag reflex, respectively.

Pediatric Differences

Eye

How are the eyes of children different from those of adults? Chapter 5 provides a detailed discussion of the assessment of the eyes and **visual acuity**, the ability to discriminate letters or other objects. The eyes of neonates differ from the eyes of adults in several ways. Visual acuity in neonates ranges between 20/100 and 20/400. The lens is more spherical and cannot accommodate to both near and far objects, which means that the neonate sees best at a distance of about 20 cm (8 in.). Because the optic nerve is not yet completely myelinated, the ability to distinguish color and other details is decreased. If the infant is preterm, especially less than 32 weeks' gestation, retinal vascularization, particularly in the periphery of the retina, may be incomplete (Hou et al., 2011; Wang, Spencer, Leffler, et al., 2012). Pupillary reflex reaction is detected by about 28 to 30 weeks' gestation and so may be sluggish in preterm infants. The rectus muscles that control binocular vision may be somewhat uncoordinated at birth. The eyes should be aligned and movement coordinated by the age of 3 months. Transient nystagmus (involuntary rapid eye movement) and esotropia (momentary turning inward of eyes) are common in neonates but decrease in incidence during the first few months of life. Conjunctival and retinal hemorrhages may be observed in the newborn as a result of the trauma of birth; they usually improve gradually and have no lasting effects. The red reflex is examined in children, because it is a key method for identifying the presence of retinoblastoma (see Chapter 5 for the method to evaluate the red reflex and Chapter 24 for a description of retinoblastoma).

The cornea of the infant and young child occupies a larger portion of the orbit than in the adult; the eyeball is about 3/4 of its adult size. Because the eyeball is relatively unprotected laterally, it is more easily injured. The sclera of the neonate is thin and translucent with a bluish tinge, and the iris is blue or gray. Eye color changes during the first 6 months of life. Infants produce tears to nourish and oxygenate the outer layers of the cornea. However, parents do not see tears when a young infant cries because the infant's lacrimal system drains them efficiently into the nasal cavity.

As infants grow, their eyes mature and their vision improves. The eyeball grows until the third year, when growth slows, until normal adult size is reached by 14 years. By the age of 2 or 3 years, most children have a visual acuity of 20/50, and by the age of 6 or 7 years, it is 20/20. See *As Children Grow: The Eye* for a summary of pediatric differences of the eye. Visual acuity is measured using standardized letter or picture charts (see Chapter 5 and the *Clinical Skills Manual* SKILLS). **Vision** refers to the complex process of acquiring meaning from what is seen, involving the eye, brain, and related neurologic and physiologic structures. Cognitive development interacts with a child's maturing physiologic system to bring increasing meaning to objects in sight (Table 19–1). The first few years of life are considered critical for the formation of normal vision. As acuity improves, the brain learns to interpret messages received from the eyes. Disturbances in vision, even in one eye, can affect the retinal nerve function, muscle function in the eye, or the brain's ability to interpret visual input.

Ear

Why do infants and young children have more ear problems than adults? The eustachian tube, which connects the nasopharynx to the middle ear, is proportionately shorter, wider, and more horizontal in infants than in older children or adults (see *As Children Grow: Eustachian Tube*). During sucking, yawning, and other movements, the tube opens for milliseconds, allowing free passage of air between the nasopharynx and the middle ear. These factors predispose young children to development of otitis media, or middle ear infection.

The fetus can hear at about 20 weeks' gestation. The auditory nerve function is mature at about 5 months of age in the infant. Before 34 weeks' gestation, the external ear is soft with little cartilage apparent. The external ear canal is small at birth, although the internal ear and middle ear are relatively large. As a result, the tympanic membrane is close to the surface and can be easily injured.

Nose, Throat, and Mouth

Up to the age of 6 months, infants are primarily nasal breathers. Edema and nasal discharge may interfere with adequate air intake and feeding. Mucosal swelling and exudate may block the small nasal passages of young children. The immature immune system of young children (see Chapter 22 for further description) and the frequent exposure to other children with illnesses causes a high rate of upper respiratory infections in this population.

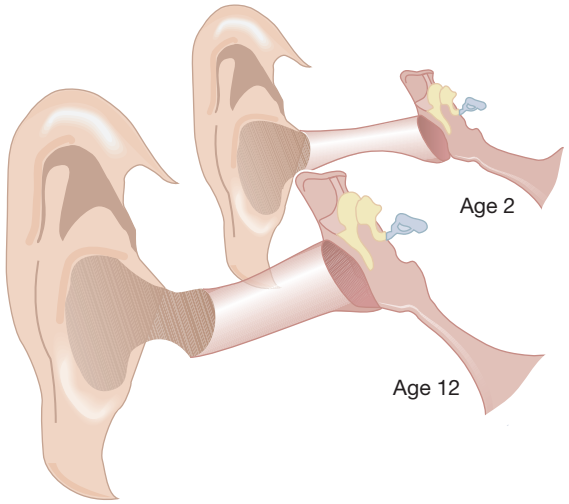
The palatine tonsils, which are visible on oral examination, are located on each side of the oropharynx. The method for examining a child's throat is discussed in Chapter 5. Although tonsils

TABLE 19–1 Visually Related Developmental Milestones

AGE	MILESTONE
Term neonate	Demonstrates alertness to light and visual stimulus presented 20–30 cm (8–12 in.) from eyes.
1 month	Follows an object 60 degrees horizontally and 30 degrees vertically; blinks at an approaching object.
2 months	Follows a person or moving object for 180 degrees from 2 m (6 ft) away; smiles in response to a face; raises head 30 degrees from prone.
3 months	Tracks an object through 180 degrees; regards own hand; begins visual–motor coordination.
4–5 months	Social smile; reaches for a cube 30 cm (12 in.) away; notices a raisin 30 cm (12 in.) away; stares at own hand.
7–8 months	Reaches and grasps an object, picks up a raisin by raking, transfers objects from hand to hand.
8–9 months	Pokes at holes in a peg board; well-developed pincer grasp; crawls; uncovers toy after seeing it hidden.
12–14 months	Stacks blocks; places a peg in a round hole; stands and walks.

Source: Data from Rudolph, C., Rudolph, A., Lister, G., First, L., & Gershon, A. (Eds.). (2011). *Rudolph's pediatrics* (22nd ed.). New York, NY: McGraw-Hill; Kliegman, R. M., Stanton, B. F., St. Geme, J., Schor, N. F., & Behrman, R. E. (Eds.). (2015). *Nelson textbook of pediatrics* (20th ed.). Philadelphia, PA: Saunders.

As Children Grow: **Eustachian Tube**



Position of eustachian tube is at less of an angle in the young child, resulting in decreased drainage (more horizontal).

End of eustachian tube in nasal pharynx opens during sucking.

Eustachian tube equalizes air pressure between the middle ear and the outside environment and allows for drainage of secretions from middle ear mucosa.

Of the three anatomic differences in the eustachian tube between adults and small children (shorter, wider, more horizontal), which do you think could cause more problems for the child and why?

vary in size considerably during childhood, they are normally large, especially in school-age children. The nasopharyngeal tonsils (adenoids) lie in the posterior wall of the nasopharynx, just above the oropharynx. In children, the adenoids may become enlarged, harboring bacteria and interfering with breathing.

The mouth is an important organ for the infant, because strong muscles are needed for sucking and thereby receiving nutrients. Sucking is an important developmental skill that promotes the muscles needed for later speech development. Taste sensation is present before birth, as evidenced by increased swallowing of amniotic fluid that has been sweetened. Taste sensations increase during childhood. By about 6 months of age the first tooth emerges, and by about 2 years the full set of 20 primary teeth is present. Tooth loss of the primary set begins at about 5–6 years, and gradually the secondary teeth (32 total) erupt during childhood. See Chapter 5 for a further description of teeth eruption.

A variety of diagnostic and laboratory tests are used to evaluate the eye, ear, nose, and throat. See Appendices D and E and Chapter 5 for details about audiologic screening, newborn hearing screening, tympanogram, complete blood count (CBC), and culture/sensitivity test. See *Assessment Guide: The Child With an Alteration of the Eye, Ear, Nose, or Throat*.

ASSESSMENT GUIDE | The Child With an Alteration of the Eye, Ear, Nose, or Throat

Assessment Focus	Assessment Guidelines
Eyes	• Describe eye structures and symmetry. • Describe visual acuity using the screening test appropriate for age. • Measure extraocular movements to all quadrants. Evaluate corneal light reflex, cover–uncover test, and visual fields. • Using the ophthalmoscope, elicit and evaluate the red reflex bilaterally. • Observe for and report abnormalities such as eye drainage, cloudiness of lens, or abnormal movement.
Ears	• Describe placement and symmetry of the external ear. • Describe auditory acuity using the screening test appropriate for age. • Using the otoscope, evaluate the ear canal and tympanic membrane. • Ask about pain and discomfort from the ear; observe for drainage.
Nose	• Describe the nose for symmetry and placement. Are the nares bilaterally patent? Are there lesions or drainage? • Can the child identify several smells? • Are signs of sinus infection present, such as facial edema or pain, headache, and tenderness upon palpation over the sinus areas?
Mouth and throat	• Are the oral mucous membranes intact? Is there an odor? • How many primary/secondary/loose teeth are present? Are there visible caries? Are there broken or chipped teeth present? • Evaluate the soft and hard palate for intactness. • Describe the throat and size/appearance of the tonsils. • Palpate cervical lymph nodes, noting size and tenderness.

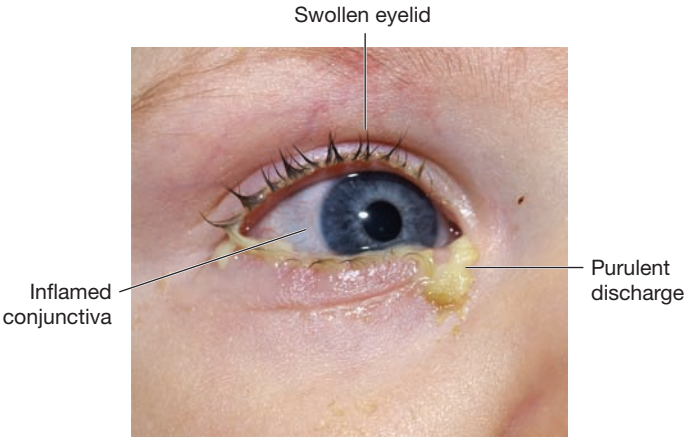


Figure 19–1 Acute conjunctivitis. The major difference between bacterial and viral conjunctivitis is that bacterial conjunctivitis has a purulent discharge that may result in crusting, whereas the discharge from viral conjunctivitis is serous (watery). Allergic conjunctivitis produces watery to thick drainage and is characterized by itching.

SOURCE: Dr. P. Marazzi/Science Source.

of contact with infected vaginal discharge containing organisms such as *Chlamydia trachomatis* and *Neisseria gonorrhoeae*. Newborns occasionally get chemical conjunctivitis in response to prophylactic eye treatment. This may be a cause when the conjunctivitis develops within 24 to 48 hours after instillation of the medication.

Another cause of infection in infants is herpesvirus, which requires prompt and vigorous treatment to prevent eye injury or blindness. Infants with herpesvirus infections of the eye are treated with intravenous acyclovir as well as topical drops.

In infants who have frequent tearing and "mattering" (eyelid discharge that has formed a crust) on awakening, a plugged lacrimal duct may mimic conjunctivitis. Treatment involves massaging the tear duct every 4 hours when the infant is awake. Lacrimal ducts that remain plugged after the age of 1 year may have to be opened surgically.

Bacterial conjunctivitis can occur in children of any age. It is characterized by edema of the eyelid, red conjunctiva, and enlarged preauricular lymph glands. There is usually mucopurulent exudate that causes mattering, making the eyes difficult to open upon awakening. Older children with conjunctivitis complain of itching or burning, mild photophobia, and a feeling of scratching under the lids. Parents may notice increased tearing or a mucoid or mucopurulent discharge, redness and swelling of the conjunctiva, a pink sclera, and crusty eyelids, especially in the morning. There is no change in vision. Common infectious organisms include *Staphylococcus aureus, Haemophilus influenzae, Streptococcus pneumoniae,* and *Moraxella catarrhalis* (Gold, 2011). Most cases are caused by hand-to-eye contact, and the disease can rapidly spread whenever groups of youth spend time together, such as among young children and adolescents in schools and childcare centers, and even among college students in dormitories, sororities, fraternities, and on sports teams. Although bacterial conjunctivitis can be bilateral, it is more commonly unilateral.

Other infections in newborns and children can be caused by viruses. *Viral conjunctivitis* is more often bilateral than unilateral. Adenovirus is a common cause and spreads from respiratory adenovirus infection in hand-to-eye transmission. Signs and symptoms are similar to those of bacterial conjunctivitis, although they are sometimes milder in severity and slower in onset.

Herpes simplex virus (HSV) can also cause infection, either by transfer from a herpes-infected mother to her baby during birth or by contact with an infected person in infants or children of any age. Ophthalmic herpes infection is often accompanied by characteristic vesicular lesions on the skin of the face. A culture of the lesions is performed for diagnosis, and any accompanying conjunctivitis is assumed to be caused by herpesvirus. For the infection caused by HSV, prompt and vigorous treatment is needed to prevent eye injury or blindness, which can occur in children with recurrent herpesvirus infections as a result of antibody reaction to the viral antigen. Herpesvirus infections commonly recur so periodic treatment and sometimes prophylaxis may be needed.

Allergic conjunctivitis is a common cause of eye discomfort (Ortiz, 2013; Steele, 2012). When conjunctivitis is caused by an allergy, the child complains of intense itching. Eyes are red with watery discharge, and the conjunctivae have a "cobblestone" appearance.

In most cases, a diagnosis of the cause of conjunctivitis is made based on the history and symptoms. Cultures can be taken, especially in infants or in cases suspected of being an unusual bacterial illness or herpesvirus infection. A Gram stain of discharge and conjunctival scraping for potential chlamydial infection or herpesvirus infection are performed. Infants and children must be promptly referred to primary healthcare providers or eye specialists for treatment of possible eye infections. When diagnosed in the neonatal intensive care unit, the infant is isolated to prevent spread to other infants.

Antibiotic eye medication is prescribed in droplet or ointment form if a bacterial infection is suspected. Treatment may be started after a laboratory sample is obtained but before the results are known. Fluoroquinolones are now frequently used to treat bacterial conjunctivitis; drops or ointment can be used (O'Brien, 2012). Other drugs used to treat bacterial infections include bacotracom, erythromycin, azithromycin, and aminoglycosides (Granet, 2011; O'Brien, 2012). Newborn gonococcal conjunctivitis is treated with ceftriaxone. Chlamydial infections are treated with oral erythromycin. Careful total evaluation of the newborn with any conjunctivitis is also performed to watch for other signs of infection. Instructions for instilling eye medication are provided in the *Clinical Skills Manual* SKILLS.

Viral conjunctivitis may be treated with comfort measures such as cleaning drainage away with a warm clean cloth and avoiding bright lights and reading to the child. Ophthalmic antibiotics may sometimes be given to prevent bacterial invasion due to frequent rubbing of the eyes. Herpes simplex virus infections of the eye are treated promptly by an ophthalmologist, neonatologist, or others who are trained in this serious disease. Topical drugs are used, and often are combined with a systemic antiviral agent such as acyclovir. Neonatal herpes simplex virus infection is treated vigorously with parenteral acyclovir for 14 days (or longer if central nervous system involvement is found upon lumbar puncture) and with topical ophthalmic medication (trifluridine, iododeoxyuridine, or vidarabine). Recurrent lesions may necessitate suppressive or prophylactic treatment with oral acyclovir, the dosage of which must be adjusted according to the child's age and weight (Liu, Pavan-Langston, & Colby, 2012).

If an allergen is diagnosed as the cause of conjunctivitis, systemic or topical antihistamines may be prescribed. Topical steroids and vasoconstrictors may also be used. Decongestants can be combined with systemic antihistamines for short-term therapy. Mast-cell stabilizers may be used to decrease the activation of mast cells that accompanies allergic reactions; their use is safe in children 3 years of age and older.

Nursing Management

Nurses routinely instill antibiotics into the eyes of newborns after birth. Perform a careful examination so that any cases of ophthalmia neonatorum can be referred promptly to an ophthalmologist. Women infected with gonococcus or chlamydia should be identified so their babies can receive attention and medication at birth to prevent infection. Babies born at home should have ocular examinations soon after birth.

In suspected conjunctivitis, gentle pressure for several seconds with a gloved index finger placed next to the inner corner of the eye may cause a discharge of mucopurulent drainage. Refer for care and report the findings. Since infectious conjunctivitis is extremely contagious, tell parents that children should not return to child care or school until they have been taking an antibiotic for 24 hours. Teach parents the importance of careful hand hygiene and the avoidance of shared towels. Tell parents that children should not rub their eyes. Mittens may help prevent infants from rubbing their eyes. Toddlers may be distracted by activities that keep their hands busy. Teach parents the proper techniques for instilling eye medications. For children with allergies, alert parents to signs of infection so if the child gets an eye infection, they will seek prompt treatment.

Periorbital Cellulitis

Periorbital cellulitis is a bacterial infection of the eyelid and surrounding tissues that is usually caused by *Streptococcus* or *Staphylococcus*. Children present with swollen, tender, red or purple eyelids; restricted, painful movement of the area around the eye; and fever. Periorbital cellulitis should be treated promptly to prevent the spread of the infection to the posterior orbit. Orbital cellulitis is a serious outcome that can lead to bacterial meningitis. Management includes hospitalization for intravenous antibiotics and the application of hot packs. Children usually respond favorably within 48 to 72 hours (Cohen, 2011; Seltz, Smith, Durairaj, et al., 2011).

Visual Disorders

Vision, the complex process of acquiring meaning from what is seen, depends on many factors. The eyes must move quickly and in a coordinated manner. (See Chapter 5 for discussion of eye movement assessment.) They must function together for clear, single vision to occur. If this ability, called **binocularity**, is not present (perhaps because of strabismus or amblyopia), the child may have double vision and the brain cannot make sense of the images it receives. Normally, perceptions of objects seen are integrated with other senses through eye–hand coordination, and with the brain through visual imagery and discrimination of objects seen. Although visual acuity is essential, the child's movements, mental processes, and other senses all interact to give meaning to objects that are viewed. Vision therefore influences learning and school performance (Davidson & Quinn, 2011).

Visual disturbances must be diagnosed and treated promptly to prevent impairment or loss of vision. Most children undergo a simple test for visual acuity during healthcare visits as soon as they can cooperate with the examiner. Once in school, children's visual acuity is screened every 2 to 3 years during the elementary years. Nurses often organize vision screening programs for children. Table 19–2 provides a series of questions that can be used to identify visual disturbances in children. A child who does not pass vision screening is referred to an ophthalmologist or optometrist for more detailed examination of near and far vision, eye structure and movement, and color discrimination.

Families Want to Know

Instilling Eye Medications in Children

It can be challenging to safely instill medication into young children's eyes. Give parents the following suggestions:

- Wash your hands well.
- Be sure the medicine is warmed at least to room temperature.
- Remove any drainage from the eye with a clean or sterile, moist, warm cloth or gauze.
- Wash your hands again.
- Have the child lie on the back with eyes closed.
- Gently pull the lower lid down to form a small pocket.
- Apply a thin string (for ointment) or drops of the medicine.
- Allow the eyelid to return to normal position.
- Have the child keep the eye closed for several seconds.
- Help prevent spread of the infection by keeping the child's hands clean.
- Enhance comfort by keeping the head elevated to decrease swelling and avoid exposure to bright light.

TABLE 19–2 Assessment Questions for Identifying Visual Disturbances in Children

YOUNG CHILD
Ask the parents:
Do your child's eyes follow you as you come into a room?
Are other objects followed with ease?
Do both eyes work together or does one seem to wander off?
At what age did your baby sit, stand, walk?
Does your child have any difficulty picking up objects?
SCHOOL-AGE CHILD
Ask the parents:
Does your child like to look at pictures and read?
Does your child hold toys or books close or sit very close to the television?
Does your child squint or rub the eyes?
Is your child at grade level in all subjects?
Has your child demonstrated any learning difficulties?
Does your child use a computer, watch television, or play computer games?
Does your child play sports and games at the same level of ability as peers?

Some of the common visual disorders in children are:

- *Hyperopia (farsightedness):* Light rays focus posterior to the retina, resulting in an inability to focus on nearby objects. All children have some degree of hyperopia until 9 to 10 years of age. However, their eyes can accommodate sufficiently to enable them to see near objects clearly. Blurring of vision occurs only in children with excessive hyperopia, or a difference in accommodation between the two eyes. *Amblyopia*, or a weakening of the poorer eye, can occur in these children if treatment is not obtained.
- *Myopia (nearsightedness):* Light rays focus anterior to the retina, resulting in an inability to see far-off objects. Although children of any age can manifest myopia, it most commonly develops at about 8 years of age. The child may complain of headaches and often squints to improve distance vision.
- *Astigmatism:* Light rays are refracted differently depending on their place of entry to the eye. The curvature of the cornea or lens is not uniformly spherical, causing blurred images. The child with astigmatism often holds pages very close to the face to obtain the best visual image.

For the description and management of four disorders that can significantly affect vision—strabismus, amblyopia, cataracts, and glaucoma—see Table 19–3.

Compensatory lenses are prescribed for most visual disorders. A significant difference in visual acuity between the eyes is often a result of amblyopia or strabismus, and further treatment may be needed. The visual acuity of a child with compensatory lenses should be reevaluated every 1 to 2 years. More frequent visits to an eye specialist are needed when a child is being treated for amblyopia or strabismus.

Nursing Management

The nurse plays an important role in identifying visual disorders in children and performing careful eye examinations of newborns and children. Observe for symmetry of placement and movement, ability to follow objects with each eye, and any abnormalities in appearance. The light reflex, cover–uncover test, and visual acuity testing are essential tests for every child. See Chapter 5 for a description of eye examination and the *Clinical Skills Manual* for visual acuity tests SKILLS.

Nurses in preschools and schools plan and carry out visual acuity screening on children. Generally, certain grades (such as kindergarten, 2, 4, 6, and 8) are screened annually along with any children new to a district. The nurse performs and records the screening results and informs the school and families of any children with abnormal results, who are then referred to an eye specialist for care. An important part of the screening process is following up on referrals to be certain that children receive the diagnostic care they need.

Healthy People 2020

(V-1) Increase the proportion of preschool children aged 5 years and under who receive vision screening

- Currently, only 40% of preschool children receive vision screening, while the goal is for 44% to have such screening by 2020. Clearly, nurses can play a role in increasing the number of young children who have vision screening.

When abnormalities are found on screening, nurses refer families to the care of an eye specialist. When prescriptive lenses are used, the nurse instructs the parent and child on correct wear practices and care. If surgery is required, surgical and postoperative follow-up are needed. This will include pain control, observing for signs of infection (ophthalmic or systemic), and administering needed eye medications. Sterile technique is used postoperatively to provide eye care. Promptly report deviations from normal such as increased pain, redness, discharge, or edema of the eye; increased temperature or pulse, which may indicate infection; increased sensitivity to light; or other abnormalities. Children are usually discharged home with instructions to minimize certain vigorous activities for a certain period of time. Perform postoperative and discharge teaching and emphasize the importance of follow-up visits.

Color Blindness

Color blindness is an X-linked recessive disorder found in 10% of males and very rarely in females; it is more common in White than Black males. The most common form affects the ability to distinguish between the colors red and green; blue-yellow discrimination and other colors can also be involved. Preschool boys are tested for color blindness in some clinics to identify those with the disorder (Adams, Verdon, & Spivey, 2012). Color blindness is not treatable, and management focuses on issues of safety (e.g., problems in distinguishing between red and green traffic signals) and techniques to improve discrimination of colors in the affected color groups.

TABLE 19–3 Clinical Manifestations of Visual Disorders

ETIOLOGY	CLINICAL MANIFESTATIONS	CLINICAL THERAPY
STRABISMUS		
Can be congenital or acquired. Seen in up to 4% of all children; 30%–50% of children with strabismus develop amblyopia. Most common types: **Esotropia:** inward deviation of eyes ("crossed eyes") **Exotropia:** outward deviation of eyes ("wall-eyes") Strabismus. Source: Biophoto Associates/Science Source/Photo Researchers, Inc.	Eyes appear misaligned to observer. May occur only when child is tired. Symptoms include squinting and frowning when reading; closing one eye to see; having trouble picking up objects; dizziness and headache. Corneal light reflex and cover–uncover tests confirm diagnosis. Child may have no other abnormalities but certain conditions such as cerebral palsy, hydrocephalus, Down syndrome, and seizure disorder are more commonly accompanied by strabismus.	Occlusion therapy (patching the fixating or good eye for 1–2 hr daily to force use of the weak eye) Compensatory lenses Surgery of the rectus muscles to correct muscle imbalance Eye drops to cause blurring of the good eye Prisms Vision therapy (eye exercises) If treatment is begun before 24 months of age, amblyopia (reduced vision in one or both eyes) may be prevented.
AMBLYOPIA (LAZY EYE)		
Reduced vision in one or both eyes; affects up to 4% of children and is the leading cause of vision loss in children. Amblyopia can result from anything that causes visual deprivation to one eye. The most common causes are untreated strabismus, with the child "tuning out" the image in deviating eye, congenital cataract, or uncorrected refractive errors causing visual differences between eyes.	Symptoms are the same as for strabismus. Vision testing can be used to diagnose condition.	Compensatory lenses Occlusion therapy for 2–6 hr daily through patching the eye or eye glass Occasionally, vision therapy (eye exercises) is used in an attempt to improve the weaker eye. Atropine 1% 1 drop/day in unaffected eye. Treatment is discontinued when visual acuity no longer improves; 20/20 acuity rarely attained. Treatment is most successful if received by 5–6 years of age.
CATARACTS		
Occurs when all or part of lens of eye becomes opaque, which prevents refraction of light rays onto retina. Seen in 1–2/10,000 newborns.  Congenital cataract. Source: Sue Ford/Science Source/Photo Researchers, Inc.	Can affect one or both eyes and may be congenital or acquired. Examples include a variety of genetic syndromes and maternally transmitted intrauterine infections. Clouding of lens indicates presence of cataract; however, cataracts are not always visible to naked eye. Symptoms include distorted red reflex, symptoms of vision loss (see strabismus), white pupil. May be present alone but sometimes associated with other conditions such as fetal alcohol syndrome, Down syndrome, and Turner syndrome.	Must be diagnosed at a young age for successful treatment; many cases are missed. When diagnosed, a thorough examination is warranted because of genetic systemic disorders that are sometimes associated with pediatric cataracts. Specific treatment depends on whether one or both eyes are affected, extent of clouding, and presence of other ocular abnormalities. Surgical removal of lens and corrective lenses; contact lenses frequently used; results of surgery are good; surgery before the age of 2 months is associated with the best results; visual acuity in 55% of children is 20/40 or better. Lens implant may be used. Eye protectors and restraints are used postoperatively to prevent injury; antibiotic or steroid drops may be used for several weeks; treatment for amblyopia may be necessary.

TABLE 19–3 Clinical Manifestations of Visual Disorders (*continued*)

ETIOLOGY	CLINICAL MANIFESTATIONS	CLINICAL THERAPY
GLAUCOMA		
Increased intraocular pressure damages eye and impairs visual function; ciliary body of eye produces aqueous fluid that flows between iris and lens into anterior chamber; if enough fluid accumulates, blindness results; about 1 in 10,000 newborns have glaucoma. May be congenital (occurring in first 3 years of life) or juvenile (occurring from 3–30 years) and affect one or both eyes. Acquired cases can be related to conditions such as eye trauma or neoplasm. Primary glaucoma (50% of cases) is an isolated anomaly of drainage; secondary glaucoma (50% of cases) is associated with other ocular or systemic abnormalities.	Symptoms of congenital glaucoma include tearing, blinking, corneal clouding, eyelid spasms, and progressive enlargement of eye; photophobia (extreme sensitivity to light). Symptoms of juvenile glaucoma include constant bumping into objects in child's periphery (painless visual field loss); seeing halos around objects. Diagnosis is made using a tonometer, which measures intraocular pressure.	Surgery to reduce intraocular pressure is treatment of choice, since medications used to combat glaucoma in adults are not as effective in children. Compensatory lenses are used following surgery. Treatment is not always successful, especially if the child has congenital glaucoma, so parents' feelings regarding care of a child with a visual impairment should be explored.

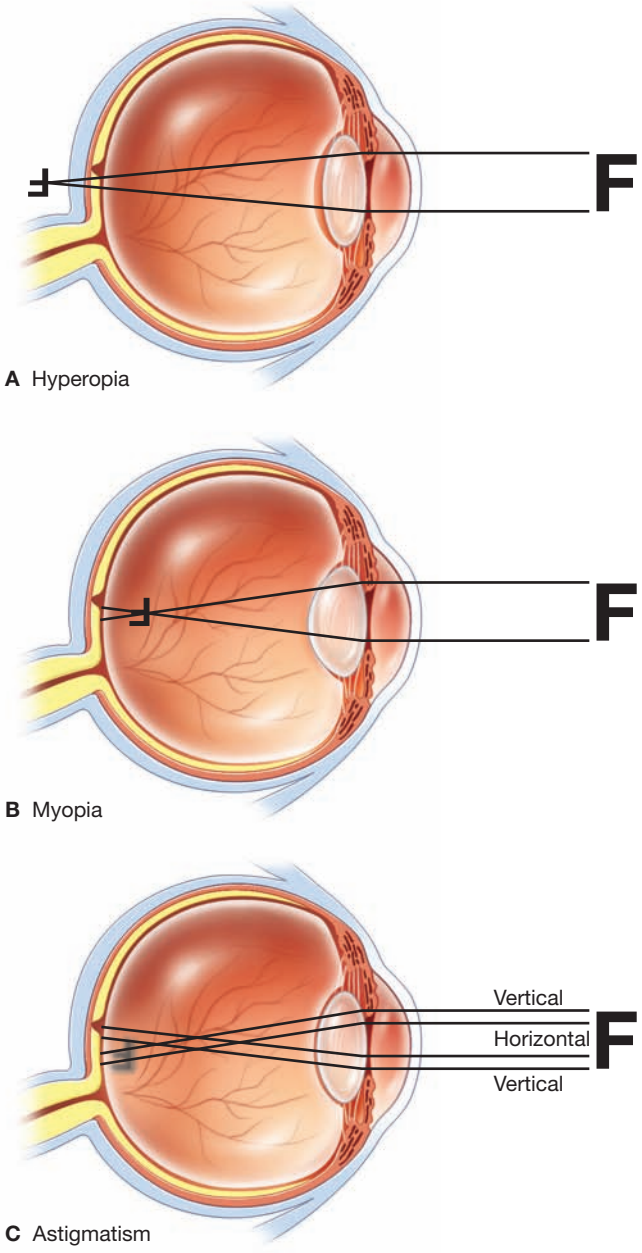
Retinopathy of Prematurity

Retinopathy of prematurity (ROP) occurs when immature blood vessels in the retina constrict and become necrotic. This condition, which may occur in infants of low birth weight or of short gestation, can heal completely or lead to mild myopia or retinal detachment and blindness.

ETIOLOGY AND PATHOPHYSIOLOGY

Retinopathy of prematurity results from injury to the developing capillaries of the retina. Oxygen therapy is associated with the development of ROP (Figure 19–2), but other factors such as respiratory distress, artificial ventilation, apnea, cerebral palsy, bradycardia, heart disease, multiple blood transfusions, infection, hypoxia, hypercarbia, acidosis, shock, and sepsis have also been linked with the disorder. It is most common in male infants born before 28 weeks of gestation and weighing under 1600 g (3 lb, 8 oz) at birth. A genetic link may be present because White infants are more commonly affected than those of African heritage, and Alaskan Natives have a high rate of the disorder. In developed countries, ROP is the second most common cause of blindness, with increasing prevalence in infants of lesser gestational age (Hartnett et al., 2014; National Eye Institute, 2014).

Pathophysiology Illustrated: **Visual Abnormalities**



A, In hyperopia, light rays focus behind the retina, making it difficult to focus on objects at close range. *B,* In myopia, light rays focus in front of the retina, making it difficult to focus on objects that are far away. *C,* In astigmatism, light rays do not uniformly focus on the eye because of abnormal curvature of cornea or lens.

Figure 19–2 **Artificial ventilation and risk for retinopathy of prematurity. This premature infant in the neonatal intensive care unit is receiving artificial ventilation—a risk factor for retinopathy of prematurity. The infant will need careful management of oxygen exposure and periodic eye examinations.**

The retina is normally vascularized by about 8 months' gestation. However, for the premature infant, this process must continue after birth, and the environmental and other conditions listed in the preceding paragraph appear to affect its course. Arteriole constriction, followed by vascular proliferation of abnormal vessels, occurs. In most cases, the abnormal vessels gradually regress and normal vascularization occurs. Sometimes, however, the abnormal vascularization continues into the vitreous cavity, causing abnormalities of the retina, optic disc, and macula. It is not known why the disease progresses in some cases, but progression is directly linked to lower birth weight, greater prematurity, and duration (not necessarily concentration) of oxygen therapy. Raeanne, the child described in the scenario at the beginning of this chapter, developed retinopathy of prematurity after receiving oxygen therapy to aid her underdeveloped lungs.

Although the developing capillaries are lost, in many cases, some degree of revascularization occurs later (National Eye Institute, 2014). The degree of visual loss, varying from slight to total, is determined by the degree of revascularization.

CLINICAL MANIFESTATIONS

Retinopathy of prematurity is characterized by progressive changes in the retinal blood vessels, and in severe disease, by retinal detachment. Premature and low–birth-weight infants at risk for the disease are given frequent ocular examinations to ensure early detection of these changes. For infants who do not receive ophthalmologic examinations, resulting visual impairment may be detected only later in infancy when the child progresses slowly in meeting developmental milestones, fails to reach for objects, and does not follow objects or faces

with the eyes. When visual impairment is present, the child usually manifests myopia. Total loss of vision can occur in the child who suffers a retinal detachment.

CLINICAL THERAPY

Diagnosis is made by ophthalmologic examination. A classification system that includes zone (area of retina with abnormal vasculature), stage (severity of disease), and plus disease (vascular dilation and tortuosity in posterior pole near optic nerve) is used to describe the location, extent, and severity of the disease (International Committee for the Classification of Retinopathy of Prematurity, 2005; National Institutes of Health, 2013). All infants at risk—namely, those born before 32 weeks of gestation and under 1500 g (3 lb, 7 oz) or those born after 32 weeks' gestation with birth weight from 1500 to 2000 g (3 lb, 7 oz to 4 lb, 3 oz)—are assessed frequently, using binocular ophthalmoscopy, by an ophthalmologist experienced with the condition. The disease is not manifested before 4 to 6 weeks after birth, so it is important that the infant receive regular eye examinations until the risk is discounted. Eye examinations continue every 1 to 3 weeks, with the frequency being determined by the location of disease, progress of disease, and the infant's degree of immature vascularization. Involvement of blood vessels in the periphery of the retina rarely leads to visual impairment. With involvement in other areas of the retina, risk of visual problems is more common.

Treatment of infants with retinopathy of prematurity may include laser therapy or cryotherapy to stop progression of the disease process. New therapies such as injections are being explored in research protocols. Surgical procedures such as a scleral buckle procedure and vitrectomy have been used in retinal detachments. Prompt treatment of accompanying problems such as strabismus, amblyopia, and myopia can promote maximal development.

Nursing Management

For the Child With Retinopathy of Prematurity

Nursing Assessment and Diagnosis

Assessment of the infant at risk for retinopathy of prematurity begins at birth by identifying infants who may require oxygen therapy or assisted ventilation. Look for risk factors such as prematurity and low birth weight. Assess the infant's breathing efforts and report any changes. Be certain the ventilation equipment is properly set to deliver the correct ventilatory pressure and amount of oxygen, evaluated by pulse oximetry saturation (see the *Clinical Skills Manual* SKILLS). Note the cumulative risks in a particular case and suggest the need for a referral to an ophthalmologist, as necessary.

The following *Nursing Care Plan: The Child With a Visual Impairment Secondary to Retinopathy of Prematurity* outlines several nursing diagnoses. Other nursing diagnoses may be appropriate for an infant with the potential to develop retinopathy of prematurity or a child with resulting visual impairment. They include the following (NANDA-I © 2014):

- ***Gas Exchange, Impaired,*** related to ventilation-perfusion imbalance
- ***Development: Delayed, Risk for,*** related to effects of visual impairment
- ***Family Processes, Interrupted,*** related to a child with a visual impairment

Planning and Implementation

The nurse plays an important role in preventing retinopathy of prematurity. Encourage early and regular prenatal care to prevent unnecessary premature births. Administer oxygen only to newborns who need it, and in the amount specified by the physician to maintain prescribed oxygen saturation. Ensure that the proper ventilatory settings are used. Shield newborns from excessive exposure to light, since that may decrease susceptibility to retinopathy of prematurity. Be alert for infants with multiple risk factors and refer them, when appropriate, for ophthalmologic examination. Parents of infants at risk for retinopathy of prematurity require information about the disorder, as well as support, because the long-term effects on the child's vision are often identified only after subsequent examinations as the child grows.

The accompanying *Nursing Care Plan* summarizes care for the child with a visual impairment resulting from retinopathy of prematurity. The nurse is instrumental in case management for such children. Reinforce to parents the importance of follow-up eye examinations. Teach methods of stimulating development for a child with a visual impairment (refer to the next section).

Clinical Reasoning The Child With ROP

Raeanne, 3 years old, has a severe visual impairment. Born prematurely at 25 weeks of gestation, she received oxygen therapy, which damaged her retinal blood vessels. As a result, Raeanne developed retinopathy of prematurity (ROP). While in the hospital, Raeanne was given frequent ophthalmoscopic examinations. She received cryotherapy to the retinal vessels—a treatment designed to prevent detached retinae and the resulting total vision loss. Although this treatment halted progression of the disorder, Raeanne was left severely myopic (nearsighted).

For the first 3 years of life, Raeanne and her mother attended an early-intervention program, which provided stimulation for Raeanne and helped teach her mother techniques for enhancing her developmental progress. Raeanne will soon begin attending preschool. Her speech is well developed for a 3-year-old; she is socially mature, converses readily, and shows no developmental delays. However, she has had little contact with other children.

As the nurse in the preschool Raeanne will be attending, how will you assist both her parents and the preschool staff in helping Raeanne adapt to the preschool experience?

Nursing Care Plan: The Child With a Visual Impairment Secondary to Retinopathy of Prematurity

1. Nursing Diagnosis: *Communication, Readiness for Enhanced,* related to altered reception, transmission, and integration resulting of visual images (NANDA-I © 2014)

GOAL: The child will receive adequate sensory input.

INTERVENTION	RATIONALE
• Provide kinesthetic, tactile, and auditory stimulation during play and in daily care (e.g., talking and playing). Provide music while bathing an infant, using bells and other noises on each side of infant. Verbally describe to a child all actions being carried out by adult.	• Because visual sensory input is not present, the child needs input from all other senses to compensate and provide adequate sensory stimulation.

EXPECTED OUTCOME: Child will demonstrate minimal signs of sensory deprivation.

2. Nursing Diagnosis: *Injury, Risk for,* related to impaired vision (NANDA-I © 2014)

GOAL: The child will be protected from safety hazards that can lead to injury.

INTERVENTION	RATIONALE
• Evaluate environment for potential safety hazards based on age of child and degree of impairment. Be particularly alert to objects that give visual cues to their dangers (e.g., stairs, stoves, fireplaces, candles). Eliminate safety hazards and protect the child from exposure. Take the child on a tour of new rooms, explaining safety hazards (e.g., schools, hotel room, hospital room).	• The child may be at risk for injury related both to developmental stage and to inability to visualize hazards.

EXPECTED OUTCOME: Child will experience no injuries.

3. Nursing Diagnosis: *Development: Delayed, Risk for,* related to impaired vision (NANDA-I © 2014)

GOAL: The child has experiences necessary to foster normal growth and development.

INTERVENTION	RATIONALE
• Help parents plan early, regular social activities with other children.	• The child with a visual impairment benefits developmentally from contact with other children.
• Provide opportunities and encourage self-feeding activities.	• To obtain adequate nutrients, the child needs to feel comfortable feeding self.
• Provide an environment rich in sensory input.	• Sensory input is needed for normal development to occur.
• Assess growth and development during regular examinations to identify the child's strengths and needs.	• Regular examinations aid in early identification of growth problems or developmental delays, so that appropriate interventions can be planned.

EXPECTED OUTCOME: Child will demonstrate normal growth and development milestones.

4. Nursing Diagnosis: *Family Processes, Interrupted,* related to child's prolonged disability from sensory impairment (NANDA-I © 2014)

GOAL: The family will identify methods for coping with their child with a visual impairment.

INTERVENTION	RATIONALE
• Provide explanation of visual impairment as appropriate.	• The parents may feel guilt about the child's visual impairment, which can be allayed by knowledge of the cause.
• Refer parents to organizations, early intervention programs, and other parents of children with visual impairments.	• The parents will receive needed information and support from others.
• Assist parents to plan for meeting the developmental, educational, and safety needs of their child with a visual impairment. Offer resources for changing home environment to assist child.	• The child may require an enhanced environment in order to foster developmental progress.

EXPECTED OUTCOME: Family will successfully cope with the experience of having a child with a visual impairment.

Evaluation

Expected outcomes of nursing care for the child with retinopathy of prematurity include the following:

- Visual impairment is identified early in life.
- The child achieves normal developmental milestones.
- The family effectively manages the child's visual condition.

Visual Impairment

Visual impairment related to refractive errors, amblyopia, strabismus, and astigmatism occurs in 5% to 10% of young children (Granet & Khayali, 2011). About 500,000 children in the United States have visual impairment and about 60,000 are legally blind (vision 20/200 or worse) (American Foundation for the Blind, 2011).

Many conditions discussed earlier in this chapter lead to temporary or permanent visual impairment. Infants who are premature; whose mothers were infected prenatally with rubella, toxoplasmosis, or other viruses; and who have certain congenital and hereditary conditions have a high risk of visual problems (Table 19–4). Fetal alcohol syndrome (FAS) is a major cause of visual disturbance; 90% of children with FAS have eye abnormalities. See Chapter 28 for further description of FAS.

The signs of visual impairment depend on the cause and degree of the problem and the age of the child (Table 19–5). The child's eyes may appear crossed or watery, and the lids may be crusty. Verbal children may complain of itching, dizziness, headache, or blurred, double, or poor vision.

Diagnostic tests include vision screening, followed by referral to an eye specialist for full examination. Tests that are commonly performed include responses to visual stimuli, symmetry of eye movements, location of corneal light reflex, cover–uncover testing, visual field testing, and funduscopic examination of the retina. The U.S. Preventive Services Task Force (2011) recommends screening to detect amblyopia, strabismus, and defects in visual acuity in children at least once between 3 and 5 years of age. The American Academy of Pediatrics (2011) recommends age-appropriate eye evaluations at health visits from birth through 4 years and age-appropriate visual acuity testing and ophthalmoscopy in children 5 years and older.

Clinical therapy depends on the child's condition and may include surgery, medication, and supportive aids. In the case of a disorder that results in permanent visual impairment, a collaborative care team of specialists works with the child and family. Nurses have an important role in this team to ensure developmental progression for the child and ongoing support for the family.

TABLE 19–4 Common Causes of Visual Impairment in Children

CONGENITAL OR HEREDITARY	ACQUIRED
Cataracts	Injury to eye or head
Glaucoma	Infections
Tay-Sachs disease	Rubella
Marfan syndrome	Measles
Down syndrome	Chickenpox
Fetal alcohol syndrome	Brain tumor
Prenatal infections (maternal infection):	Retinopathy of prematurity
Rubella	Cerebral palsy
Toxoplasmosis	
Herpes simplex	
Zika virus	
Retinoblastoma	

TABLE 19–5 Signs of Visual Impairment

INFANTS	TODDLERS AND OLDER CHILDREN
May be unable to follow lights or objects	May rub, shut, or cover eyes
Do not make eye contact	Tilt or thrust head forward
Have a dull, vacant stare	Blink frequently
Do not imitate facial expressions	Hold objects close
	Bump into objects
	Squint

Growth and Development

Infants with visual impairment use kinesthesia, touch, and language to socialize. They appreciate and use touch more than other children and respond to verbal explanations when others use nonverbal communication. Vision affects both fine and gross motor skills, so skills such as hand-to-mouth coordination and walking may be delayed in children who have visual impairments.

Nursing Management

For the Child With Visual Impairment

Nursing Assessment and Diagnosis

Prevent visual deficits by teaching safety in activities that can injure the eye, engage in activities for early identification of the condition, and enhance the development of children with low vision. Vision screening facilitates early detection and treatment of conditions that can lead to vision loss. Visual testing can be done at any age, including immediately after birth. Developmental milestones that require vision, such as following bright lights, reaching for objects, or looking at pictures in a book, can be used to assess vision. For children over the age of 3 years, visual acuity is most frequently measured by means of an age-appropriate acuity test (see the *Clinical Skills Manual* SKILLS). Vision screening should begin at 3 years of age and take place during annual healthcare visits. See *Evidence-Based Practice: Nursing Role in Vision Screening and Follow-Up.* Most states mandate school screening of vision (see Chapter 5). The photo screener, a device that can be used to take a photo of the child's eyes, is useful for infants, toddlers, and preschoolers. The photo can be used to diagnose refraction errors, eye opacities, and misalignment. Visual fields and the ability to discriminate colors are tested at school age, when children can cooperate.

Children who have a visual impairment may lag in development of cognitive and other skills. Sighted children learn the word *cup* using four senses—sight, touch, hearing, and taste—to obtain the information necessary to connect words with the objects they represent. In contrast, children with visual impairments rely on only three senses—touch, hearing, and taste. They learn concepts through differences in sounds, textures, and shapes.

Many visual disorders are linked with conditions that influence development. Thus a child with cerebral palsy or fetal alcohol syndrome should be assessed frequently to identify a visual disorder, as well as to evaluate normal developmental milestones.

EVIDENCE-BASED PRACTICE | Nursing Role in Vision Screening and Follow-Up

Clinical Question

Screening for visual ability is important to identify children with impairments. The American Academy of Pediatrics recommends that children be screened at every well-child visit, beginning in the newborn period. Screenings should include vision history, vision assessment, external inspection of the eyes and lids, eye movement assessment, pupil examination, and elicitation of red reflex. Once the child can cooperate, usually by about age 3 years, a vision test such as HOTV or tumbling E, along with ophthalmoscopic examination, should be added to the examination (Chou, Dana, & Bougatsos, 2011; U.S. Preventive Services Task Force, 2011). Worldwide, 13 million children are visually impaired because of uncorrected refractive errors, so vision screening is critical as the first step in providing corrective lenses (Sharma, Congdon, Patel, et al., 2012). How can nurses integrate into their practice the completion of vision examinations, provision of training for other screeners, evaluation of results, referral to specialists when abnormalities are found, and provision of follow-up care after diagnosis and treatment?

The Evidence

A study of the outcomes of school vision screening of 2726 children in North Carolina found that 3 children in 100 were identified upon follow-up with a vision problem, such as myopia, hyperopia, and astigmatism (Kemper, Helfrich, Talbot, et al., 2012). This study also found that no follow-up information was obtained on the outcome of referral for a full eye examination for 35% of the children with potential problems. School nurse staffing issues have made vision screening for children in schools a challenge, but innovative programs for training and supervising screeners such as volunteer parents, nursing students, and others have been successful. Key components of programs are to ensure that the nurse is present during screening for monitoring accuracy and consistency checks, performs the questionable results found by screeners, performs referrals, and conducts follow-up of vision referral results (National Association of School Nurses [NASN], 2012; Sides & Sigmon, 2013).

Best Practice

Nurses play a vital role in ensuring that children receive early, periodic, and regular visual and eye screening. Evidence that suggests the most accurate methods should be closely examined. While identification of problems is important, the nursing roles of training screeners, referral for care, identifying barriers to care, and ensuring that follow-up care has been received are also integral to vision care.

Clinical Reasoning

What vision screening methods are available in the offices, clinics, and schools in your community? How could you perform vision screening in the hospital setting if a child did not demonstrate expected visual ability for age? Design a program to train and supervise nursing students to perform vision screening. What are the essential components of a follow-up program for a school that screens all kindergartners and first graders for visual acuity? What questions will you ask parents during a well-child visit for a 2-year-old to determine if vision is normal? How will you combine your knowledge of developmental milestones with screening for vision?

Nursing diagnoses for the child with impaired vision might include the following (NANDA-I © 2014):

- ***Mobility: Physical, Impaired,*** related to altered sensory perception
- ***Injury, Risk for,*** related to poor vision
- ***Development: Delayed, Risk for,*** related to visual impairment
- ***Family Processes, Interrupted,*** related to demands of a child with a sensory impairment

Planning and Implementation

Promote safety in sports and other activities to prevent visual impairment when possible. Nursing care for a child with a visual impairment focuses on encouraging the child's use of all senses, promoting socialization, helping parents to meet the child's developmental and educational needs, and providing emotional support to parents. Refer the parents to an early intervention program as soon as the diagnosis is made. Nearly all care occurs in community and home settings.

ENCOURAGE USE OF ALL SENSES

Children who are partially sighted or blind use other senses to a great extent. Encouraging the use of the eyes as much as possible is important even if a child has poor vision (Figure 19–3).

Figure 19–3 Encouraging use of the senses. This child needs ongoing developmental assessment and a comprehensive individualized education plan. Since she has impaired vision, the nurse uses touch and speaks with her throughout procedures to ensure sensory input.

PROMOTE SOCIALIZATION

The child's interactions and socializations should be as normal as possible (similar to those of sighted children of the same age and development).

- Stroke, rock, and hug infants and children who have a visual impairment. Sing and talk to them. These infants do not make eye contact and have rather blank expressions.
- Call the child's name and speak before touching the child. Tell the child when the nurse and others are leaving the room. Describe locations of foods on the plate and tray to orient the child.
- Teach parents to read body language and vocalization as expressions of emotion. Facial expressions give a great deal of information, but infants and children with poor vision do not have the ability to learn by visual imitation. Show parents how to use tactile means to teach appropriate facial expressions. For example, a touch on the arm can be soft and stroking to indicate a smile, but firmer to indicate dismay or frown.
- Describe procedures such as blood pressure, ear examination, or cast application so the child knows what they will feel like. Let the child touch the equipment.
- Explain to parents that discipline and rewards for children with poor vision should be the same as those for other children in the family. The child should be given age-appropriate tasks.
- Encourage contact with peers as the child grows older. Teach children to look directly at persons who are talking to them. Play, sports, and other activities can be modified to give the child with a visual impairment the same social experiences as a sighted child.

COMMUNITY-BASED NURSING CARE

Public laws require that each state provide educational and related services for children with disabilities (see Chapter 1). Parents and healthcare providers should develop an individualized education plan (as discussed in Chapter 12) that maximizes the child's learning ability. If possible, the child with a vision problem should attend child care and preschool with children who have normal visual acuity. What nursing actions are needed to help a child with a visual impairment adjust to child care or school?

- Provide parents with information about educational options before their child reaches school age. Education should take place in a setting that allows the child to have contact with other children and to participate in social activities.
- The child may be mainstreamed with a tutor, be partially mainstreamed in a resource room, attend special classes, or be tutored at home. If the child is to attend public school, suggest to parents that they contact the school well before enrollment to ensure that school personnel understand the child's disability.
- Make sure that equipment such as large-print books, Braille materials, audio equipment, or an Optacon (described in *Families Want to Know: Enhancing Development of the Child With a Visual Impairment*) is available. Ensure that frequent eye examinations are performed and assist with proper use and care of prescribed glasses or contact lenses as necessary. Clean glasses daily with warm water and dry with a clean, soft cloth. Follow the directions that the family provides, which describe the methods they use for cleaning contact lenses.
- Familiarize the child with the new environment.

Growth and Development

Children with visual impairment may take longer to master self-help skills such as feeding and dressing. Perform regular developmental assessments and suggest adaptive ways that parents can help the child learn these skills.

Families Want to Know

Enhancing Development of the Child With a Visual Impairment

- Encourage a toddler or preschooler who has a visual impairment to look at pictures in well-lit settings. Have a school-age child read large-print books. Computers designed for people with visual impairments are also available. The Optacon (a device that raises print so it can be felt by the child) and View Scan (which magnifies print) improve reading capability.
- Expose the infant and child to everyday sounds.
- Encourage the infant to use the sense of touch to explore people and objects. Have the parents purchase toys with sound and texture in mind. Directional concepts can be taught using games. Responding to the infant's and child's vocalizations encourages the use of speech.
- Teach specific techniques for toileting, dressing, bathing, eating, and safety.
- When the child becomes mobile, furniture and other objects in the environment should be kept in the same positions so the child can safely move around independently. Extra care must be taken to prevent injuries when a child does not see.
- Emphasize the child's abilities. Adolescents can use seeing-eye dogs or a white cane to function independently.
- Encourage the child to function independently within normal developmental parameters.
- If the child goes to a hospital or another strange environment, orient the child to the placement of objects and do not rearrange them.
- Teach those around the child to:
  - Announce their presence to the child when approaching.
  - Walk slightly ahead of the child so the child can sense the movement of the accompanying person.
  - Let the child hold the seeing person's arm rather than the reverse.
  - Identify the contents of meals and encourage the child to feed self.

PROVIDE EMOTIONAL SUPPORT

The family often needs help to understand the child's abilities and disabilities. Support them as they learn about their child's visual problems, tell friends and family, and then adjust to supporting the child.

- Encourage habilitation as soon as realistically possible. Make the adjustment easier by providing information about the child's specific type of visual impairment, available community services, and groups or associations for children with similar vision conditions.
- Suggest resources to families of children with visual disorders.
- Be supportive and listen to the family's concerns about the child's visual deficit.
- Make sure the parents meet their own physical and emotional needs so they are better able to care for and provide support to their child.

Evaluation

Expected outcomes of nursing care for the child with a visual impairment include the following:

- The child is protected from injury.
- The child manifests growth and development to maximum potential.
- The child establishes a successful individualized education plan.

Injuries of the Eye

In the United States, eye injuries are common in children of all ages, especially from 11 to 14 years, and particularly in boys. Sports, darts, fireworks, air-powered BB guns, blunt and sharp objects, chemical and thermal burns, physical irritants, and abuse are causes of eye trauma. Sports injuries are most common, with 100,000 occurring annually; they are a common cause of blindness in children (National Eye Institute, n.d.).

Prevention is an important part of health promotion. Protective eyewear should be used by participants in all sports with a risk of eye injury, with extreme caution in those with diminished vision or only one functional eye. Common injuries occur in baseball, basketball, swimming, bicycling, and football so preventive measures should be taken such as proper training and use of protective gear. Chemicals and objects such as scissors and knives should be placed out of reach.

Some injuries can be treated at home but many require emergency care or hospitalization. The nurse will document the history of the injury, perform an assessment of the eye, and measure the visual acuity. If a tetanus booster has not been given in the last 5 years, the child is reimmunized. Table 19–6 summarizes emergency treatment of common eye injuries.

Disorders of the Ear

Otitis Media

Otitis media, or inflammation of the middle ear, is sometimes accompanied by infection. This condition is one of the most common childhood illnesses, with a majority of infants having at least one case of acute otitis media by 3 years of age (Qureishi, Lee, Belfield, et al., 2014). Otitis media occurs more frequently among boys and in children who attend childcare centers, in those with allergies, in children exposed to tobacco smoke, and in those who use pacifiers several hours daily. It is most common during the winter months. Children with conditions such as cleft lip and palate or Down syndrome more often experience otitis media. Breastfeeding appears to be protective against otitis media. In the past decade, an increased number of cases have been observed, and recent changes have been made in recommendations for treatment.

TABLE 19–6 Emergency Treatment of Eye Injuries

INJURY	TREATMENT
Subconjunctival hemorrhage (caused by coughing, mild trauma, or increased physical activity)	Usually heals spontaneously; child should see ophthalmologist if most of sclera is covered or if condition does not clear up in 1–2 weeks.
Periorbital ecchymosis ("black eye")	Apply ice to eye area (both eyes) for 5–15 min every hour for the first 1–2 days after injury (even if only one eye is affected, both eyes may discolor); then apply warm compresses.
Foreign body on conjunctiva	Do not let child rub eye; remove material on surface of eye by closing upper lid over lower lid, irrigating or everting upper lid, visualizing material, and removing it with slightly damp handkerchief; patch eye and transport child to emergency department if foreign body cannot be removed.
Corneal abrasion	Superficial corneal abrasions are diagnosed by touching sterile fluorescein strip to lower conjunctiva; dye remains where corneal epithelial cells are disrupted; most corneal abrasions heal spontaneously, although antibiotic ointment may be prescribed and eyes may be patched in some children.
Burns (alkaline burns readily penetrate cornea and are more serious than acid burns)	For child with chemical burn, irrigate eye for 15–30 min; transport child to emergency department where irrigation should continue (see the *Clinical Skills Manual* SKILLS); pupils are dilated to reduce pain and prevent adhesions; after irrigation is complete, eyes are patched and antibiotics are prescribed.
Penetrating and perforating injuries	Obtain medical assistance immediately; never try to remove an object that has penetrated the child's eye; such objects should be removed by an ophthalmologist; prevent the child from rubbing injured eye; cover both eyes with shield before transportation to emergency department.
Eye injuries caused by severe blows to head and eye (blunt trauma can seriously injure all eye structures, including orbit, which can be fractured)	Transport immediately to ophthalmologist's office or emergency department for evaluation and treatment; retinal hemorrhage is a common presentation of the type of child abuse called "shaken child syndrome."

Growth and Development

Fluid accumulation in the middle ear prevents the efficient transmission of sound and can result in hearing loss over time, potentially delaying speech and language development. These delays may manifest as cognitive deficits or behavior problems. Motor development has been found to be impaired in children with chronic ear infections.

ETIOLOGY AND PATHOPHYSIOLOGY

The specific cause of otitis media is unknown, but it appears to be related to eustachian tube dysfunction. Often, an upper respiratory infection precedes otitis media. This infection causes the mucous membranes of the eustachian tube to become edematous. As a result, air that normally flows to the middle ear is blocked, and the air in the middle ear is reabsorbed into the bloodstream. Fluid is pulled from the mucosal lining into the former air space, providing a medium for the rapid growth of pathogens. The tympanic membrane and fluid behind it become infected. The most common causative organisms are *Streptococcus pneumoniae, Haemophilus influenzae,* and *Moraxella catarrhalis* (Harmes et al., 2013).

Conditions such as enlarged adenoids or edema from allergic rhinitis can also obstruct the eustachian tube and lead to otitis media. Pacifier use raises the soft palate and may alter dynamics in the eustachian tube, providing for entry of microorganisms from the nasopharynx. Recurrent otitis media has an increased frequency in children of parents who smoke. Children with multiple siblings and those who attend childcare centers have increased rates of recurrent acute otitis media. Ethnicity appears to be a factor (see *Developing Cultural Competence: Otitis Media*).

Developing Cultural Competence Otitis Media

American Indian, Alaskan Native, and Black children have high rates of otitis media. Recent research is identifying genetic links in this disease, since it is more common in certain families (Rye, Blackwell, & Jamieson, 2012). However, major risk factors for frequent otitis media, such as crowding, exposure to tobacco smoke, and lack of breastfeeding for infants, are the same regardless of ethnicity. Be alert for frequent recurrent otitis media, plan prevention programs, and ensure prompt care and teaching about treatments for families of children affected. What prevention measures would you emphasize with families that have high rates of otitis media among children? See the following *Nursing Management* section for suggestions of preventive approaches.

CLINICAL MANIFESTATIONS

Otitis media is the general term for inflammation of the middle ear. *Acute otitis media (AOM)* is diagnosed when the child has acute onset of ear pain, bulging of the tympanic membrane upon otoscopy, and middle ear effusion (Figure 19–4). *Recurrent acute otitis media* is defined as three or more separate AOM episodes in 6 months, or four or more episodes in 12 months with at least one episode in the past 6 months (Lieberthal et al., 2013). *Otitis media with effusion (OME)* is evidence of fluid in the middle ear without inflammation (Figure 19–5). Sometimes OME becomes chronic in nature (continuing more than 3 months) and is more commonly associated with hearing loss (Williamson, 2011).

Figure 19–4 Acute otitis media is characterized by pain and a red, bulging, nonmobile tympanic membrane.

SOURCE: Courtesy of Kevin Kavanagh, MD, FACS/Cumberland Otolaryngology Consultants.

Figure 19–5 Otitis media with effusion is noted on otoscopy by fluid line or air bubbles.

SOURCE: Courtesy of Kevin Kavanagh, MD, FACS/Cumberland Otolaryngology Consultants.

Infants and young children have characteristic behaviors that indicate otitis media may be present. Pulling at the ear is a sign of ear pain (Figure 19–6). Diarrhea, vomiting, and fever are typical of otitis media. Irritability and "acting out" may be signs of a related hearing impairment. The child with otitis media often has night awakenings with crying due to increased pressure when prone or supine. Some children with otitis media are asymptomatic; therefore, an ear examination should be performed at every healthcare visit (see Chapter 5). See Table 19–7.

Figure 19–6 **This young child is pulling at the ear, an important sign of otitis media. Ask the parents about fussiness, presence of fever, and night awakenings; these are additional signs that are often observed in children with this condition.**

CLINICAL THERAPY

Otoscopic examination includes visualization and pneumatic otoscopy. The trained clinician can perform pneumatic otoscopy in which positive air pressure in the external canal is used to measure the movement of the tympanic membrane. Special gradient acoustic reflectometry (SGAR) measures the condition of the middle ear by introducing a sound and measuring the tympanic membrane response. A "flat" tympanogram is also suggestive of otitis media. (The tympanogram is described in a later section on hearing impairment.)

Since otitis media with effusion may only involve fluid in the middle ear, it is best diagnosed by pneumatic otoscopy and tympanometry. Since this type of otitis media is most commonly associated with hearing loss, audiologic testing should be performed in the pediatric healthcare home (medical home) (see Chapter 5) if the effusion persists for 3 months or longer.

Concern has developed about the increasing appearance of drug-resistant microbials as causative agents in otitis media. These organisms may explain the increase in otitis media observed in the past decade. Based on current knowledge, the American Academy of Pediatrics (AAP) established recommendations for diagnosis and management of otitis media in 2004, which were updated in 2013 (Lieberthal et al., 2013). Consistent with current guidelines, for children from 6 months to 23 months with nonsevere unilateral disease, the healthcare provider and parent should consult about whether antibiotic use or observation for 48 to 72 hours is best. If nonsevere bilateral AOM is present or if severe AOM is present (temperature of 39.0°C [102.2°F] with pain for 48 hours) the young child should be treated with antibiotic. For children 24 months and older, nonsevere AOM can be treated with antibiotic or by observation for 48 to 72 ours (Lieberthal et al., 2013). In all cases where 48- to 72-hour observation is implemented, a method for follow-up is needed to ensure that the child has improved. When not improved during the period of watchful waiting, acute otitis media is treated with antibiotic therapy for 10 days in children under 6 years, and 5 to 7 days for children 6 years and over (Hoberman et al., 2011).

When prescribed, the choice of antibiotic depends on the probable organism, ease of administration, cost, previous effectiveness, and any history of allergies. First-line therapy

TABLE 19–7 Clinical Manifestations of Acute Otitis Media and Otitis Media With Effusion

ETIOLOGY	CLINICAL MANIFESTATIONS	CLINICAL THERAPY
Acute otitis media—bacterial infection in the middle ear from pathogens transferred from the nasopharynx; most common infectious agents are *S. pneumoniae, H. influenzae, M. catarrhalis*	*Behavioral*—ear pain, pulling at ear, rapid onset, irritability, malaise, poor feeding *Examination*—bulging tympanic membrane, air or fluid bubbles present behind tympanic membrane; immobile or poorly mobile tympanic membrane, red (or other color change such as white, gray, or yellow as long as bulging is present) tympanic membrane, reduced visibility of tympanic membrane landmarks with displaced light reflex	Treat ear pain with anesthetic ear drops, herbal pain products instilled into the auditory canal, or systemic acetaminophen or ibuprofen. Verify that the tympanic membrane is intact before inserting ear drops. In cases of nonsevere unilateral disease, consult with parents of children under 2 years to decide together on observation or antibiotic treatment. For child 2 years and above with nonsevere disease, observe the child's condition for 48–72 hr and, if not improved, treat with course of antibiotics. Severe and bilateral disease is always treated with antibiotic.
Otitis media with effusion—collection of fluid in the middle ear behind the tympanic membrane, which is not infected with bacteria	*Behavioral*—difficulty hearing or responding as expected to sounds *Examination*—signs of acute inflammation are NOT present; tympanic membrane is retracted or neutral; immobile or partly mobile tympanic membrane; yellow or gray tympanic membrane; opaque or thickened tympanic membrane with visibility of landmarks reduced	Symptomatic treatment and pain relief Careful assessment of hearing acuity over several months Speech assessment if loss of hearing acuity occurs Developmental assessment

Professionalism in Practice **Clinical Guidelines**

In recent years, the American Academy of Pediatrics and other bodies have established new guidelines for treatment of conditions such as acute otitis media and sinusitis (described later in this chapter). Parents often expect antibiotics for any illness their child may have and do not understand the rationale for guidelines that recommend watchful waiting for a limited time to see if the child improves. Nurses should be familiar with recommendations and guidelines for preventive care (e.g., vision and hearing screening) and treatments (e.g., acute otitis media and sinusitis) so that they can explain the rationale for these approaches to parents. Such explanations can often allay concern and worry, and help build confidence in healthcare providers as partners with parents in care for their children.

is amoxicillin, unless it has been given to the child in the previous 30 days. Amoxicillin with clavulanate and cefuroxime are second-line drugs. If an intramuscular drug is preferred, cefdinir at 14 mg/kg/day, cefpodoxime at 10 mg/kg/day, or cefuroxime at 30 mg/kg/day can be prescribed (Tschudy & Arcara, 2012).

OME is not treated with antibiotics but is evaluated periodically to be sure there is not an additional AOM that needs treatment. Children with OME generally improve within 3 months. Because this type of otitis is more commonly associated with hearing loss and cochlear damage, follow-up with audiology is essential. If hearing is abnormal, speech testing should be performed (Farboud, Skinner, & Pratap, 2011; Williamson, 2011).

Neither decongestants nor antihistamines have been shown to be effective in the treatment of otitis media with or without effusion. If infection recurs in spite of antibiotic treatment, **myringotomy** (surgical incision of the tympanic membrane) may be performed and **tympanostomy tubes** (pressure equalizing tubes) inserted to drain fluid from the middle ear. (See *Families Want to Know: Care of the Child With Tympanostomy Tubes*.)

Nursing Management

For the Child With Otitis Media

Nursing Assessment and Diagnosis

Assess the tympanic membrane for color, transparency, mobility, presence of landmarks, and light reflex. Ask the parents whether the child has had a fever, been fussy, or been pulling at the ears. Observe for signs of impaired hearing.

Inquire about what the family has done at home to treat the ear infection and its associated pain. Some home remedies, such as rocking and singing to the child, are safe. Some other practices may be harmful.

Several nursing diagnoses that may apply are included in *Nursing Care Plan: The Child With Otitis Media*. Additional nursing diagnoses might include the following (NANDA-I © 2014):

- ***Body Temperature: Imbalanced, Risk for,*** related to infectious process
- ***Fatigue (Child and Parent)*** related to sleep deprivation
- ***Health Maintenance, Ineffective,*** related to chronic ear infections and altered sensory reception

Planning and Implementation

Most children with otitis media are not hospitalized; therefore, nursing management centers on care of the child in the home. The child having tympanostomy tubes inserted is generally treated in a day surgery setting. Occasionally, children admitted to the hospital for other problems have a concurrent ear infection. The accompanying *Nursing Care Plan* summarizes nursing care for the child with otitis media.

Emphasize preventive measures. Exposure to secondhand smoke in the home increases the incidence of otitis media in children, so encourage parents who smoke to avoid smoking near the child or in the home. Wood-burning stoves should also be avoided when possible. If young children are in child care with fewer than 10 children, incidence decreases. Breastfeeding provides some protection from the disease. Placing infants or toddlers to sleep with a pacifier may increase incidence and should be avoided in the infant with prior infections. Many cases of otitis

Families Want to Know

Care of the Child With Tympanostomy Tubes

After Surgery

- Encourage the child to drink generous amounts of fluids.
- Reestablish a regular diet as tolerated.
- Give pain medication (acetaminophen) as ordered for discomfort and at bedtime.
- Place drops in child's ears if prescribed.
- Restrict the child to quiet activities.

Following Postoperative Period

- Follow the care provider's instructions regarding swimming and water (some practitioners caution against swimming and other activities that might get water in ears; others do not).
- Ear plugs can be used to prevent water from getting into ears.
- Be alert for tubes becoming dislodged and falling out and alert healthcare provider (they usually fall out within 1 year).
- Report purulent discharge from the ear, which may indicate a new ear infection. Contact the healthcare provider.

Nursing Care Plan: The Child With Otitis Media

1. Nursing Diagnosis: *Pain, Acute,* related to inflammation and pressure on tympanic membrane (NANDA-I © 2014)

GOAL: The child or parent will indicate absence of pain.

INTERVENTION	RATIONALE
• Give analgesic such as acetaminophen. Use analgesic ear drops.	• Analgesics alter perception or response to pain.
• Have the child sit up, raise head on pillows, or lie on unaffected ear.	• Elevation decreases pressure from fluid.
• Apply warmth to the ear.	• Heat increases blood supply and reduces discomfort.
• Have the child blow a pinwheel to relieve pressure in ear.	• Attempts to open the eustachian tube may help aerate the middle ear.

EXPECTED OUTCOME: Verbal child will state that pain is relieved. Nonverbal child will exhibit improved disposition and comfort.

2. Nursing Diagnosis: *Infection, Risk for,* related to presence of pathogens (NANDA-I © 2014)

GOAL: The child will be free of infection.

INTERVENTION	RATIONALE
• Encourage breastfeeding of infants.	• Breastfeeding affords natural immunity to infectious agents.
• Instruct the parents to administer antibiotics exactly as directed and to complete prescribed course of medication.	• Taking antibiotics as prescribed minimizes chance for overgrowth of pathogens.
• Telephone the parents 2 or 3 days after initial examination.	• If symptoms have not improved in 36 hours, treatment should be evaluated.
• Examine ear 3 or 4 days after completion of antibiotic treatment, or if symptoms worsen in child on symptomatic treatment.	• Checkup determines whether treatment is effective.

EXPECTED OUTCOME: Child's temperature will be normal, symptoms will disappear, and tympanic membrane will show no signs of infection.

3. Nursing Diagnosis: *Development: Delayed, Risk for,* related to hearing loss (NANDA-I © 2014)

GOAL: The child will have normal hearing.

INTERVENTION	RATIONALE
• Assess hearing ability frequently.	• Monitoring detects hearing loss early.

EXPECTED OUTCOME: Child's general health and hearing will improve, and incidence of the condition will decrease.

GOAL: The child will have normal motor and language development.

INTERVENTION	RATIONALE
• Assess motor and language development at each healthcare visit.	• Early detection of developmental delays can lead to appropriate intervention.

EXPECTED OUTCOME: Child will have language and motor development within norms for age group.

media are related to microbials such as *H. influenzae* and *Pneumococcus pneumoniae,* so immunization against these pathogens (see Chapter 16) can be effective preventive measures.

Help parents understand why there is a waiting period before prescriptions are given for antibiotics. When antibiotics are prescribed, review administration techniques, side effects, and the need for a repeat appointment when the medication is completed.

Chronic otitis media can create problems for the family. The child's waking at night with ear pain results in lack of sleep and parental fatigue. Since many children with otitis media experience ear pain that can disrupt their sleep and that of family members, anesthetic ear drops have been used for their analgesic effect on the tympanic membrane, and some families might prefer use of natural remedies for ear pain. Herbal extract ear drops (a naturopathic herbal extract of *Allium sativum, Verbascum thapsus, Calendula flores, Hypericum perforatum,* lavender, and vitamin E) with a local anesthetic of amethocaine and phenazone have been used. Parents often become frustrated and disillusioned by the healthcare system's inability to cure the child and may fear a permanent hearing impairment. Reassure parents that as the child grows older, the recurrent infections eventually cease.

Teach them that asking for courses of antibiotics for every infection may not be the best treatment.

Provide pain relief techniques such as teaching correct administration of ear drops, oral administration of acetaminophen, and positioning the baby with the head slightly elevated.

Provide hearing and language examinations at regular intervals, inform parents of results, and refer to an audiology specialist if hearing problems are identified. Make sure parents of children with tympanostomy tubes know how to care for the child and what symptoms to report. For the child with some hearing loss due to otitis media with effusion, a home environment that fosters cognitive skills can overcome the effects of lowered hearing during the time of infection. Focus interventions on helping parents to read and talk with children frequently who have otitis media with effusion.

Evaluation

Expected outcomes of nursing care for the child with otitis media include the following:

- The child returns to normal sleep and feeding patterns.
- The child maintains normal hearing and speech development.
- Pain and temperature are effectively managed.
- Parents demonstrate understanding of the treatment regimen.

Otitis Externa

Otitis externa is an inflammation of the skin and surrounding soft tissue of the ear canal. It is sometimes called "swimmer's ear" because it is common in children who swim frequently, especially during hot and muggy weather. The ear canal can also be injured by use of cotton-tipped applicators, foreign objects, or sprays used near the face. If the tympanic membrane is not intact because of tympanostomy tubes or breakage of the membrane, drainage may be visible in the canal; this drainage may irritate the canal and lead to otitis externa. Any irritation of the canal can become infected with bacteria, virus, or fungi; sometimes it represents an allergic reaction. The child usually complains of pain and itching, and may have intense pain when the examiner presses on the tragus, or skin tab in front of the ear. Sometimes the ear appears swollen, and redness or drainage of the canal may be seen upon otoscopic examination.

Treatment of otitis externa requires removing the dried and flaking epithelium and cerumen. Burrow solutions or normal saline is used to irrigate and clean the canal if the tympanic membrane is intact. Steroid ear drops are used to decrease inflammation, and antibiotic drops are also used if a bacterial infection is suspected. If the child has tympanostomy tubes or a perforated tympanic membrane, nonototoxic ear antibiotic such as quinolone antibiotic ear drops are used. Ibuprofen or acetaminophen may be helpful for pain control. The ear canal should then be kept dry by using ear plugs or a swim cap for swimming and gently blow-drying the canal after bathing. The child should not return to swimming for about 5 days. Cotton-tipped applicators or other objects should not be placed in the ear canal so that the skin in the canal can heal. If hair sprays or other solutions are irritating, they should not be used by the child or adolescent.

Nurses should be aware of the signs of otitis externa such as a painful ear, drainage, and irritated canal. Verify that the tympanic membrane is intact during otoscopic examination. Teach families to avoid the irritants identified such as cotton-tipped applicators, sprays, and frequent swimming. Demonstrate proper instillation of drops (see the *Clinical Skills Manual* SKILLS) and give instructions for use of acetaminophen for pain relief in the acute period.

Hearing Impairment

About 1.6% of newborns do not pass the newborn hearing examination (Centers for Disease Control and Prevention [CDC], 2012). Additional children receive a diagnosis after the newborn period, and approximately 1 million children (2–3 of every 100 births) in the United States have some form of hearing impairment (National Institute of Deafness and Other Communication Disorders, [NIDCD], 2014). Hearing impairment is expressed in terms of **decibels (dB)**, which are units of loudness, and rated according to severity (Table 19–8). Children who have a mild hearing loss (35 to 40 dB) may miss 50% of everyday conversation and are considered at high risk for school failure. Children with a hearing loss of more than 80 dB are considered legally deaf.

Hearing disorders can be classified according to the location of the deficit. **Conductive hearing loss** occurs when conditions in the external auditory canal or tympanic membrane prevent sound from reaching the middle ear. **Sensorineural hearing loss** occurs when the hair cells in the cochlea or along the vestibulocochlear (acoustic) nerve (cranial nerve VIII) are damaged. This leads to permanent hearing loss. A **mixed hearing loss** indicates a hearing loss having a combination of conductive and sensorineural causes.

ETIOLOGY AND PATHOPHYSIOLOGY

About 50% of hearing loss is genetically caused, generally in a recessive inheritance pattern with *GJB2* gene abnormalities (American Speech-Language-Hearing Association [ASLHA], 2011). Another 25% is due to environmental causes around the time of birth. Acquired causes are due to injury or disease later in life such as frequent ear infections, infectious diseases, ototoxic drugs, head injury, and noise exposure (ASLHA, 2011). This type of loss is increasing; hearing loss among all populations has doubled in the past 30 years, and now approximately 14.9% of U.S. children have low-frequency or high-frequency hearing loss of at least 16-dB hearing level in one or both ears (ASLHA, 2014). Infants at risk for hearing loss include those with:

- Family history of congenital hearing loss
- Positive titer for TORCH infections (toxoplasmosis, rubella, cytomegalovirus, syphilis, herpes)

TABLE 19–8 Severity of Hearing Loss

TYPE OF LOSS	HEARING ABILITY
Slight/mild (20–40 dB)	Some speech sounds are difficult to perceive, particularly unvoiced consonant sounds.
Moderate (41–60 dB)	Most normal conversational speech sounds are missed.
Severe (61–80 dB)	Speech sounds cannot be heard at a normal conversational level.
Profound (81–90 dB)	No speech sounds can be heard; considered legally deaf.
Deaf (over 90 dB)	No sound at all can be heard.

Source: Data from American Speech-Language-Hearing Association. (2011). *Type, degree, and configuration of hearing loss*. Retrieved from http://www.asha.org/public/hearing/disorders/types.htm

- Craniofacial abnormalities
- Very low birth weight (less than 1500 g [3.3 lb])
- Stay in neonatal intensive care unit of over 5 days, or need for extracorporeal membrane oxygenation (ECMO), assisted ventilation, administration of ototoxic medications (e.g., gentamicin, tobramycin) or loop diuretics (e.g., furosemide), or hyperbilirubinemia that requires exchange transfusion
- Chemotherapy, particularly with aminoglycoside medications over 5 days
- Low Apgar score at 1 or 5 minutes
- Bacterial or viral meningitis
- Head trauma, especially basal skull/temporal bone fractures requiring hospitalization
- Mechanical ventilation for more than 5 days
- Caregiver concern regarding speech, language, hearing, developmental delay
- Presence of syndromes associated with hearing loss (Down syndrome, Pierre Robin syndrome, Arnold-Chiari malformation, neurofibromatosis, osteopetrosis, Hunter syndrome) (Joint Committee on Infant Hearing, 2007, 2008)

Common causes of conductive hearing loss include impacted cerumen, the most frequent reason for conductive loss; outer ear infection ("swimmer's ear"); trauma; or a foreign body. Conductive loss also occurs if the tympanic membrane does not fully vibrate, as in otitis media. In these cases, hearing loss may be restored after the infection clears. Chronic and untreated ear infections may lead to structural changes in the ear and permanent hearing impairment. The loss of acuity may be gradual or rapid and results in diminished hearing in all ranges.

Conditions leading to sensorineural hearing loss may be congenital (maternal rubella), genetic (Tay-Sachs disease), or acquired (such as from ototoxic drugs, bacterial meningitis, or loud noise). In sensorineural hearing loss, high-frequency sounds are most affected. Such hearing loss may be preceded by **tinnitus** or ringing in the ears. Teenagers who use earphones at high volumes or attend many rock concerts are at risk for hearing loss (Figure 19–7). Other noise hazards include firecrackers, guns, and power and farm equipment.

Figure 19–7 **Listening to loud music with headphones or at rock concerts is a frequent cause of hearing loss among teenagers and young adults. This adolescent needs to be informed about the possible outcomes of this activity.**

CLINICAL MANIFESTATIONS

Hearing is both an innate and a learned behavior. Infants and children who have hearing impairments exhibit a range of behaviors, depending on their age and the severity of the deficit. Infants who hear normally respond to sound in both obvious and subtle ways that do not occur in those who have hearing impairments (Table 19–9). As children mature, their hearing impairments affect their language skills. Hearing loss is often manifested as a cognitive deficit, a behavioral problem, or both.

TABLE 19–9 Behaviors Suggestive of Hearing Impairment

AGE	BEHAVIOR
Infant	Has a diminished or absent startle reflex to loud sound. Does not awaken when environment is very noisy. Awakens only to touch. Does not turn head to sound at 3–4 months. Does not localize sound at 6–10 months. Babbles little or not at all.
Toddler and preschooler	Speaks unintelligibly, in a monotone, or not at all. Communicates needs through gestures. Appears developmentally delayed. Appears emotionally immature, yells inappropriately. Does not respond to doorbell or telephone. Appears more interested in objects than people and prefers to play alone. Focuses on facial expressions rather than verbal communications.
School-age child and adolescent	Asks to have statements repeated. Answers questions inappropriately, except when able to view speaker's face. Daydreams and is inattentive. Performs poorly at school or is truant. Has speech abnormalities or speaks in a monotone. Sits close to or turns television or radio up loudly. Prefers to play alone.

Figure 19–8 **Newborn hearing screening is an effective tool in diagnosing some causes of hearing impairment very early in life.**

CLINICAL THERAPY

Early identification of hearing loss is a key element in successful treatment (see *Growth and Development*). Detection of hearing loss in infants is important to ensure optimal development. Universal screening of all infants is recommended before 1 month of age, with diagnostic audiologic evaluation before 3 months, and beginning of early intervention programs by 6 months of age for those with hearing impairment. State laws now mandate screening of newborns, and national data are maintained on outcomes. Observations of response to noise in all newborns should be accompanied by more sophisticated testing such as auditory brain stem response or transient evoked otoacoustic emissions, especially in those at high risk of deficits (Figure 19–8). All children should be evaluated for communication development beginning at 2 months of age during all well-child visits (American Academy of Pediatrics Committee on Practice and Ambulatory and Bright Futures Periodicity Schedule Work Group, 2014). See Table 19–10.

Growth and Development

Children with hearing loss can easily fall behind their peers in language milestones because they cannot hear and speak in the same manner as other children. Without interventions to enable them to learn language, they can also fail to develop reading and other literacy skills, related cognitive processes, and social-emotional development (Joint Committee on Infant Hearing, 2007). Carefully evaluate hearing and all developmental milestones during each regularly scheduled healthcare visit. Refer infants and children with abnormalities for further evaluation. When hearing loss is identified as a cause of delayed development, interventions guided by healthcare providers with expertise in hearing loss are needed.

An otoscopic examination with a tympanogram can be performed on an older infant to determine conductive hearing loss. The **tympanogram** is a test that provides a graph of the ability of the middle ear to transmit sound. An airtight probe is inserted into the external ear canal and a tone is emitted. The probe measures the pressure, which is plotted on a graph. A "flat" tympanogram suggests conductive hearing loss. **Audiography** can be used with cooperative children over 3 years of age. Sounds of various frequencies and intensities are presented to the child through earphones, and the child is instructed to raise a hand when the sound is heard. Audiography cannot detect hearing loss caused by middle ear effusion but can indicate sensorineural loss.

The hearing of preschool and school-age children is tested by asking them to repeat whispered words. Hearing of school-age children and adolescents also is assessed with the Weber and Rinne tests (see Chapter 5).

If a hearing loss is uncorrectable, a collaborative care team composed of pediatrician, audiologist, otolaryngologist, speech–language pathologist, nurse, teacher, and social worker should help the child and family adapt to the disability. If the deficit is due to recurrent ear infections, tympanostomy tube insertion may improve hearing.

A hearing aid may be prescribed for a conductive loss. A sensorineural loss is more difficult to treat, but cochlear implants and bone conduction hearing aids have been used in some children. A cochlear implant is a small electronic device that helps to provide sound for those who are deaf or profoundly hard of hearing. It consists of the following:

1. A microphone to pick up sound that is located outside of the body; worn as a headpiece behind the ear
2. A speech processor that organizes sound from the microphone; worn behind the ear or on a belt
3. A transmitter that transfers the sound into electrical impulses; part of the headpiece behind the ear
4. Electrodes that send the signals to the brain; this receiver is implanted in the skin behind the ear with a wire leading to the cochlear fluid in the middle ear

TABLE 19–10 Screening Tests for Newborn Hearing

TEST	MECHANISM OF ACTION
Otoacoustic emission (OAE) (either transient-evoked [TEOAE] or distortion-product [DPOAE])	A measure of low-intensity sounds from the cochlear hair cells in response to clicks from a probe placed in the ear canal Sensitive in frequency range above 1500 Hz May show false negative for loss below 1000–1500 Hz Detects inner ear hearing loss by evaluating cochlear and hair cell function Does not detect neural damage to cranial nerve VIII Can be sensitive to outer ear canal obstruction or middle ear effusion, leading to false positive result
Auditory brainstem response (ABR)	Electrical response to auditory stimuli from three surface scalp electrodes Reflects activity of cochlea, cranial nerve VIII, and auditory brainstem pathways Detect hearing loss from 1000–8000 Hz May show false-negative results for losses in the 500- to 2000-Hz levels Will give a positive result if there is damage to cranial nerve VIII or brainstem pathways even if cochlear loss is not present

TABLE 19–11 Communication Techniques for Children Who Have a Hearing Impairment

TECHNIQUE	DESCRIPTION
Cued speech	Supplement to lipreading; eight hand shapes represent groups of consonant sounds and four positions about the face represent groups of vowel sounds; based on the sounds the letters make, not the letters themselves; child can "see-hear" every spoken syllable a hearing person hears
Oral approach	Uses only spoken language for face-to-face communication; avoids use of formal signs; uses hearing aids and residual hearing
Total communication	Uses speech and sign, fingerspelling, lipreading, and residual hearing simultaneously; child selects communication technique depending on the situation

For children with uncorrectable hearing loss, several approaches are used to enhance communication (Table 19–11). Children with hearing impairments may receive speech therapy and instructions in lipreading, sign language, cuing, and fingerspelling.

Growth and Development

Infants and young children respond automatically with a blink or the startle reflex to unexpected or loud noises. As they mature, they localize the sound source, then understand speech, and then communicate verbally.

Nursing Management

For the Child With a Hearing Impairment

Nursing Assessment and Diagnosis

Nurses conduct newborn hearing tests soon after birth and make observations of the infant's responses to sound. As the child grows, assess hearing at every well-child visit. The best judges of hearing are parents; ask them if they have any concerns about their child's hearing. An infant's reaction to rattles, bells, or handclapping (about 30 cm [12 in.] from the ear) is an important observation. Evaluate language milestones when examining the older infant and child. Language development is a major area of focus in deaf children. Deaf infants begin to babble at about 5 to 6 months of age, the same age as hearing infants. However, this babbling ceases several months later in the child who has a hearing impairment.

School nurses use audiometers to evaluate hearing during screening programs in schools, and refer children who do not pass the screening test (see the *Clinical Skills Manual* SKILLS). Measures to promote speech and communication development as well as safety are implemented.

Common nursing diagnoses for the child with impaired hearing include the following (NANDA-I © 2014):

- ***Communication: Verbal, Impaired,*** related to abnormal sound transmission
- ***Development: Delayed, Risk for,*** related to communication impairment
- ***Coping: Family, Readiness for Enhanced,*** related to caring for a child with a hearing impairment

Planning and Implementation

Nurses can encourage prevention of hearing loss from exposure to loud noises such as loud music and power and farm equipment. Music should be turned down and ear protection worn for other activities. School nurses should be active in hearing conservation education programs in school. Several programs are available to assist the school nurse in teaching children at targeted ages about noise-induced hearing loss. The nurse should develop and deliver hearing conservation curricula to children at elementary, middle, and high school levels; inform teachers and other professionals about noise-induced hearing loss; and train volunteers to assist with school programs.

Newborn screening, developmental assessment, and childhood hearing screening facilitate identification of hearing loss in newborns, infants, and children. Newborns and infants should be tested for hearing loss by 1 month of age. In cases of loss, intervention should begin before 6 months of age (Joint Committee on Infant Hearing, 2007).

Nursing care of the child with a hearing impairment focuses on facilitating the child's ability to receive spoken language and to send information, helping parents meet the child's schooling needs, and providing emotional support to parents. Refer the parents to an early intervention program as soon as the diagnosis of hearing impairment is made, in order to foster the child's development. If a cochlear implant is planned, the child needs surgical care and follow-up to monitor results and integrate sound gradually into the child's life. Pneumococcal and meningococcal vaccines and ongoing speech therapy are needed.

FACILITATE ABILITY TO RECEIVE SPOKEN LANGUAGE

Be aware of how the child compensates for hearing loss and use these strategies in communication:

- If hearing loss is mild or temporary or if the child reads lips, first obtain the child's visual attention by lightly touching the child or saying the child's name.
- Position your face 1 to 2 m (3 to 6 ft) from the child's face and make sure that the child's eyes are focused on your face and lips. Make sure the room is well lit, with no backlighting. Speak at a normal rate and tone, and use facial expressions that show caring or concern. If the child does not understand, rephrase the information in shorter, simpler sentences. Use specific, concrete explanations, and give the child time to comprehend. Watch for subtle signs of misinterpretations and give consistent and immediate feedback since only 30% of the English language is visible on the lips.
- Be familiar with the different types of hearing aids. Hearing aids, which are microphones that amplify all sounds, can be worn in or behind the ear, in the frame of glasses, or on the body with a wire attached to the ear. Place the hearing aid in the ear with the volume off, then slowly turn up to half volume. Adjust as needed. When talking to a child with a hearing aid, speak slowly within 15 to 45 cm (6 to 18 in.) of the microphone using a normal conversational tone. Talk to the child even if the child is not looking at you. Make sure the batteries are fresh for the best reception. Since all sound is amplified, reduce background noise as much as possible. Clean the hearing aid daily with a damp cloth. Change the batteries as needed, usually about once a week. The child's growth necessitates a new fitting, usually about once annually.

Health Promotion The Child With a Hearing Impairment

Growth and Developmental Surveillance

- Ensure that the child receives all immunizations at scheduled times. All children with cochlear implants should have pneumococcal vaccine (PCV7 for under 5 years of age or PPV23 for over 5 years). The immunization should be completed 2 weeks before surgery for cochlear implant. Children should be up-to-date on all immunizations, but rubella, mumps, and measles are especially important since infections with the diseases could cause further hearing loss.
- Complete developmental assessment, including receptive and expressive verbal skills at each visit.
- Teach about safety precautions for those with hearing impairment, such as inability to hear announcements at school, fire alarms at home, or sirens when traveling. Assist the family to install visual stimuli for fire alarms and other safety needs.

Communication

- Review the type of communication used by the child and the family's satisfaction.
- Ask about relationships with other children, both those with hearing impairments and those without.
- Review discipline techniques used by the parents and consistency of limit setting.

Nutrition and Physical Activity

- Complete 24-hour diet recall and be sure the child receives adequate nutrition appropriate in energy for activities.
- Review the child's exercise patterns since some children with hearing impairment may avoid interactions with other children in sports.
- Refer the family to community activity programs as needed.

Mental Health

- Determine stressors parents may feel.
- Locate community resources for early intervention and ongoing programs.
- Assist the youth and family to plan for moves to new schools and communities, and for plans related to transition to young adulthood, including college, trade schools, or work in the community.

Disease Prevention Strategies

- Be sure signs of ear infection such as fever, irritability, disturbed sleep, rubbing ear, or ear drainage are promptly evaluated in the pediatric healthcare home.
- Teach parents to administer antibiotics for ear infections exactly as prescribed.
- Encourage breastfeeding of infants and avoiding smoking to minimize incidence of ear infections.
- Be sure the child has all recommended immunizations.

Injury Prevention Strategies

- Encourage family to preserve any hearing the child may have by avoiding exposure to loud sounds; when children are old enough to understand, be sure they safeguard against exposure to loud music, guns, and other risks.
- Teach the child and family to plan for safety when crossing streets, driving cars, escaping house fires, and other situations that normally rely on hearing.

Acoustic feedback, an audible whistling sound that cannot always be heard by the child, is one of the most common problems with hearing aids. To eliminate this sound, readjust the hearing aid to make sure that it is inserted properly and that no hair or ear wax is caught between the ear mold and canal. Turning down the volume may also help. (See *Health Promotion: The Child With a Hearing Impairment*.)

A remote microphone system is another type of device designed to improve hearing. This is often used in the classroom situation because it eliminates background noise. The speaker wears a transmitter that picks up the voice and transmits it to a receiver worn by the child.

FACILITATE ABILITY TO SEND INFORMATION

Maintain the child's hearing aid in proper condition. Many children with impaired hearing communicate using speech, which is enhanced through speech therapy. In addition, they are taught to sign, fingerspell, or use cued speech (Figure 19–9). Articulation may be difficult, and understanding what the child is trying to say may be frustrating for both the nurse and the child. Taking time to listen carefully is important.

Take measures to promote speech and communication development as well as safety. Ask the parents to explain the child's communication techniques and to help interpret words. Have younger children point to pictures. Use assisted technologies such as a computer or picture board as well as drawings or gestures if necessary. This is especially helpful for communicating feelings of pain and hunger during hospitalization. If the child signs or fingerspells, make sure that you understand the signs for important functions. Give older children a pad of paper and pencil to write requests. People other than parents should be able to understand what the child is trying to communicate. Have an interpreter available if the child uses American Sign Language. Learn some common signs to communicate simple

Figure 19–9 This child with a hearing impairment and tracheostomy is communicating by means of American Sign Language (ASL).

words or phrases. Orient the child carefully to new settings such as the hospital room or a new school.

HELP PARENTS MEET CHILD'S EDUCATIONAL NEEDS

Public laws apply to the education of children who have a hearing impairment (see Chapter 1). After diagnosis, the parents and healthcare professionals together agree on an individualized education plan (see discussion in Chapter 12). Day care and preschool are recommended for children with hearing problems.

- Give parents information about adjustments that may have to be made for a child with a hearing impairment who attends public school. By sitting at the front of the classroom, the child may be able to hear and see more clearly. The teacher should always face the child when speaking, and background noise should be reduced.
- Tell parents that children who have hearing impairments have the same intelligence quotient (IQ) distribution as children without a hearing impairment. However, communication and learning can be difficult, and extra support is needed.
- Children with a hearing impairment should reach their intellectual potential, although development in certain areas may take place more slowly than it does in children without a hearing impairment.

PROVIDE EMOTIONAL SUPPORT

By recognizing the effects of the diagnosis on the family, the nurse can help the family deal with their reaction to the child's hearing loss. Supporting healthy coping is an important intervention to help the parents carry on with their lives.

- Help the parents understand the child's disability and its effect on speech and language development. Provide accurate information about their concerns. Work jointly with other healthcare professionals and social service workers if necessary.
- Tell the family about the community services available for medical, nursing, psychologic, and financial assistance.

Evaluation

Expected outcomes of nursing care for a child with a hearing impairment include the following:

- The child is assisted in establishment of communication method.
- The child manifests growth and development to maximum potential.
- A successful individualized education plan is established.
- The family demonstrates positive coping and healthcare management.

Injuries of the Ear

Ear injuries of many types commonly occur in children. Lacerations, infections, and hematomas may occur in the external ear structures, especially the pinna. Children may place foreign objects in the ear, and insects may enter the ear canal. Rupture of the tympanic membrane may result from head injuries, blows to the ear, or insertion of objects into the ear canal. Caution children and parents not to place anything into the ear, including cotton swabs for cleaning.

See Table 19–12 for information on the emergency treatment of ear injuries. Any injury resulting in earache, decreased hearing, persistent bleeding, or other discharge should be seen by a healthcare provider.

Disorders of the Nose and Throat

Epistaxis

Epistaxis, or nosebleed, is common in school-age children, especially boys. The Kiesselbach plexus, an area of plentiful veins located in the anterior nares, is the most common source of bleeding. The most common cause is irritation from nosepicking, foreign bodies, or low humidity. Other causes include forceful coughing, allergies, or infections resulting in congestion of the nasal mucosa. Posterior nosebleeds have a variety of causes, some of which may indicate systemic disease (i.e., bleeding disorder) or injury. Bleeding from the posterior septum is more serious and may be life threatening. Hospitalization may be necessary.

Nursing Management

Children with nosebleeds are sometimes brought to the emergency department by a parent who has been unable to stop the flow of blood within a few minutes. Both parent and child may be frightened. Ask the parent briefly about any history of nosebleeds and other contributing factors, including medications. Take the child's pulse and blood pressure to assess for excessive blood loss. Carefully examine the nasal mucosa by asking the child to blow any clots out gently, if possible. Suctioning may be necessary.

Observing the flow may help determine whether the blood is coming from an anterior or a posterior location. A nosebleed confined to one side of the nose is almost always anterior, but posterior bleeding can flow on one or both sides. If blood cannot be seen, the child may be swallowing it and may become nauseated. Suspect posterior bleeding in children who have sustained blunt trauma to the head.

TABLE 19–12 Emergency Treatment of Ear Injuries

INJURY	TREATMENT
PINNA	
Minor cuts or abrasions	Wash thoroughly with soap and water and rinse well; leave exposed to air if possible or apply adhesive bandage; monitor for infection.
Hematomas	Needle aspiration should be performed and pressure dressing applied; undrained hematomas may become fibrotic; "cauliflower ear" deformity may develop.
Cellulitis or abscesses	Apply moist heat intermittently; make sure that prescribed antibiotic is taken; minor surgery may be performed for an abscess.
Deep lacerations	Apply pressure to stop bleeding; transport to healthcare provider's office or emergency department for suturing.
EAR CANAL	
Foreign bodies	Have child lie on back and turn head over edge of bed, with affected side down; wiggle earlobe and have child shake head; foreign object may fall out as result of gravity; if object remains in ear, call healthcare provider; do not try to remove foreign body with tweezers since this may push the object further into the ear.
Insects	Shine flashlights into ear to try to attract insect; instilling a few drops of mineral oil, olive oil, or alcohol kills insect, and irrigating ear canal gently may remove dead insect. See the *Clinical Skills Manual* SKILLS.
TYMPANIC MEMBRANE	
Ruptures	Call healthcare provider if child has persistent ear pain after blow, blast injury, or insertion of foreign object; cover external ear loosely with piece of sterile cotton or gauze; if tympanic membrane has been ruptured, systemic antibiotics are prescribed.

The child with anterior bleeding should sit upright quietly. The head should be tilted forward to prevent blood from trickling down the throat, which can lead to vomiting. The nares should be squeezed just below the nasal bone and held for 10 to 15 minutes while the child breathes through the mouth. If the bleeding does not stop, a cotton ball or swab soaked with Neo-Synephrine, epinephrine, thrombin, or lidocaine may be inserted into the affected nostril to promote topical vasoconstriction or anesthesia. Once the bleeding has stopped, the nostril may have to be cauterized with silver nitrate or electrocautery. If the bleeding cannot be stopped, absorbable packing may be used.

Posterior bleeding must also be stopped by packing, and the child must be monitored carefully. Arterial ligation is occasionally needed. Repeated or severe nosebleeds need further evaluation (Montague, Whymark, Howatson, et al., 2011).

Assess the child's hematocrit or hemoglobin if significant bleeding has occurred. Take a complete history and do a physical examination of children with frequent epistaxis to rule out systemic disease. (See *Families Want to Know: Prevention and Home Management of Epistaxis*.)

After the nosebleed has stopped, the child is more vulnerable to recurrent bleeding and should avoid bending over, stooping, strenuous exercise, hot drinks, and hot baths or showers for the next 3 to 4 days. Sleeping with the head elevated on two or three pillows and humidifying the air with a vaporizer may also prevent a recurrence. Give parents suggestions for prevention and home management of epistaxis.

Families Want to Know

Prevention and Home Management of Epistaxis

Prevention

- Humidify the child's room, especially during the winter.
- Discourage the child from picking or rubbing the nose or inserting foreign objects in the nose.
- Instruct the child to blow the nose gently and release sneezes through the mouth.

Home Management

- Keep the child calm.
- Sit the child upright with head tilted slightly forward so blood does not run down the nasopharynx.
- Press a roll of cotton under the upper lip to compress the labial artery.
- Apply steady pressure to both nostrils just below the nasal bone with the thumb and forefinger for 15 to 20 minutes. Time by the clock.
- Apply an ice pack or cold compress to the bridge of the nose or the back of the neck.
- Call healthcare provider if the bleeding does not stop.
- Avoid vigorous exercise and aspirin or other noncoagulant drugs during the first few days after an episode of epistaxis.

Source: Adapted from Melia, L., & McGarry, G. W. (2011). Epistaxis: Update on management. Current Opinion in Otolaryngology & Head and Neck Surgery, 19, 30–35.

Nasopharyngitis

Nasopharyngitis, also known as upper respiratory infection (URI) or the "common cold," causes inflammation and infection of the nose and throat and is a common illness of infancy and childhood. More than 200 viruses and numerous bacteria can cause this condition. The most common viruses include rhinovirus and coronavirus, and the most frequently occurring bacterium is group A *Streptococcus*. See Chapter 20 for a discussion of respiratory syncytial virus (RSV), a common cause of both upper and lower respiratory illness. The organisms incubate in 1 to 3 days, and the infection is communicable several hours before symptoms develop and for 1 to 2 days after they begin. Symptoms may last 4 to 10 days or longer. The pathogens spread when the infected person touches the hand of an uninfected person, who then touches the mouth or nose, resulting in self-inoculation with infected droplets.

A red nasal mucosa with clear nasal discharge and an infected throat with enlarged tonsils may be apparent in children with nasopharyngitis. Vesicles may be present on the soft palate and in the pharynx. Accompanying symptoms may vary, depending on the child's age (Table 19–13).

Between episodes of nasopharyngitis, the child should be asymptomatic. If a child continues to have upper respiratory infections, an underlying condition such as allergy, asthma, or polyps should be ruled out.

TABLE 19–13 Manifestations of Nasopharyngitis

INFANTS YOUNGER THAN 3 MONTHS OF AGE	
Lethargy	Feeding poorly
Irritability	Fever (may be absent)
INFANTS 3 MONTHS OF AGE OR OLDER	
Fever	Anorexia
Vomiting	Irritability
Diarrhea	Restlessness
Sneezing	
OLDER CHILDREN	
Dry, irritated nose and throat	Anorexia
Chills, fever	Thin nasal discharge, which may later become thick and purulent
Generalized muscle aches	
Headache	Sneezing
Malaise	

Nursing Management

For infants who cannot breathe through the mouth, normal saline nose drops can be administered every 3 to 4 hours, especially before feeding, and followed by bulb suctioning if needed (see the *Clinical Skills Manual* SKILLS). For infants over 9 months of age, nasal stuffiness can be treated with normal saline. Children over 6 years of age can use nasal sprays.

Decongestant nose drops and sprays should not be used for more than 4 or 5 days or more often than recommended. Antihistamines may be helpful for children with allergic rhinitis or profuse nasal drainage. Long-acting nasal sprays and medications with several ingredients are not recommended. (See *Families Want to Know: Over-the-Counter Cough and Cold Medications*.)

Families Want to Know

Over-the-Counter Cough and Cold Medications

Parents may try to treat children who have upper respiratory infections with the same medications they are accustomed to taking for a cold. Work with parents during a health promotion visit and help them plan for how to handle medications for the child. Guidelines are as follows:

- Do NOT use cough and cold products in children under 2 years of age unless given specific directions to do so by a healthcare provider.
- Read the label to be sure the medication is recommended for the child's age and condition. Give only the dose recommended for the age and weight of the child. Do NOT use products packaged for adults.
- Be sure you know how to measure the medication. Tablespoon and teaspoon are not the same, and using household spoons may lead to incorrect dosing. Use only the measuring device that is provided with liquid medications to ensure accuracy. If one is not provided, purchase one at the pharmacy that is precisely labeled. Use only a measuring device with the precise marking to match the dose you need to give.
- Consult the pharmacist, nurse, or other healthcare provider if you have questions, if the child is taking other medicines, if the medication is not recommended for the age of the child, if the child's condition does not improve, or if other symptoms appear.
- Use the child-resistant cap after each opening of the bottle. Store the medication out of reach of all children, preferably in a locked location.
- Inspect containers and do not buy those that may have tears, imperfections, or tampering. Review all of the information in the "Drug Facts" box on the package label.
- If you use home remedies or other herbal products to treat colds, be sure to check on their safety with your healthcare provider first.
- If the child becomes more ill or does not improve, stop the medicine and contact the healthcare provider. If you do not understand instructions on the package contact a healthcare provider before using it.

Room humidification may help prevent drying of nasal secretions. Antipyretics such as acetaminophen reduce fever and make the child more comfortable. Aspirin is not recommended because of its association with Reye syndrome (refer to Chapter 27).

Children should avoid strenuous physical activity and engage in quiet play such as reading, listening to music or stories, or watching television or videotapes. Children should not be forced to eat. Encourage the intake of favorite fluids to liquefy secretions. Tell parents that no medicine or vaccine can prevent the common cold, but eliminating contact with infected persons can reduce the spread of infection. Proper hand hygiene and disposal of tissues helps to decrease the spread of the infection. Cleaning counters, toys, door knobs, and other surfaces on a daily basis can decrease the spread of infections. Discourage sharing of food, dishes, and utensils at meals.

Developing Cultural Competence Hot and Cold Disease Theory

Many Hispanic and Asian cultural groups believe in the "hot and cold theory" of disease, in which health problems are viewed as the result of imbalance. For example, some Mexican Americans traditionally treat a "cold disease" such as an earache or common cold with "hot" substances. Ask families if they prefer to eat certain foods or use complementary treatments during an illness. Incorporating such preferences may help the child and increase the confidence of the family in healthcare providers.

Sinusitis

Sinusitis is an inflammation of one or more of the paranasal sinuses. These sinuses, which have respiratory epithelium and are continuous with the respiratory tract, include the maxillary, ethmoid, frontal, and sphenoid sinuses. The sinuses may become infected with bacteria following a viral upper respiratory infection or allergic inflammation, and therefore sinusitis is a common occurrence in children (Wald et al., 2013).

Sinusitis can be viral or bacterial. Signs and symptoms of sinusitis in children are sometimes nonspecific. A history of recent upper respiratory infection is common, persistent cough from postnasal drip can occur, and nasal discharge or swelling can be apparent. Malodorous breath, fever, mouth breathing, hyponasal speech, and cervical lymphadenopathy may be present. Young children may be anorexic or have difficulty feeding, and older children may complain of headache.

Diagnosis of sinusitis is usually based on history and physical examination findings. Acute bacterial sinusitis is diagnosed when a child with upper respiratory infection (URI) presents persistently (10 days or more) with nasal discharge and or daytime cough, worsening course, or severe onset with temperature 39.0°C (102.2°F) or above and purulent nasal discharge for 3 days or more (Wald et al., 2013). Percussion and illumination of sinuses, computed tomography (CT), magnetic resonance imaging (MRI), and ultrasound are not generally useful in diagnosing sinusitis in children. CT or MRI may be used when orbital or central nervous system complications are suspected. For the child with repeated sinusitis or who appears toxic, aspiration of sinus aspirate may be performed for culture by an otolaryngologist.

Antibiotics are prescribed if there is severe onset or worsening course of illness, and often when there is persistent illness (Wald et al., 2013). Amoxicillin is the first choice for therapy; amoxicillin/clavulanate, cefuroxime, cefdinir, azithromycin, and clarithromycin are also sometimes used. Children with recurrent sinusitis should be referred for further care by an otolaryngologist and allergy specialist. Efficacy of decongestants, antihistamines, and nasal irrigation has not been demonstrated (Shaikh & Wald, 2014).

Parents whose child has persistent and purulent nasal drainage should be told to see a healthcare provider, particularly if the drainage is accompanied by facial pain, headache, and fever. Nurses should teach parents to correctly administer antibiotics (e.g., to take medications for the full course) if prescribed, and to use saline nose drops if needed for comfort. Infants may need their noses cleared with nose drops and a bulb syringe prior to feedings. (Refer to the *Clinical Skills Manual* SKILLS for correct use of a bulb syringe.) Antipyretics can be given for fever and to relieve pain.

Pharyngitis

Acute pharyngitis is an infection that primarily affects the pharynx, including the tonsils. It is seen most frequently in children 4 to 7 years of age and is rare in children less than 1 year of age. Approximately 80% of these infections are caused by viruses; the rest are caused by bacteria. Bacterial pharyngitis is commonly known as "strep throat," since in many cases it is caused by group A beta-hemolytic streptococcus (GABHS) (Ebell, 2014).

The major complaint is a sore throat. Children with symptoms of strep throat who have minimal throat redness and pain, exudate, mild lymphadenopathy, and a low-grade fever, and who have been exposed to someone who has strep pharyngitis should have a throat culture. The classic signs of purulent drainage and white patches are not present in all cases of strep throat.

A child who finds swallowing difficult or extremely painful, who drools, or who exhibits signs of dehydration or respiratory distress should be seen by a healthcare professional immediately. These signs could be indicators of serious conditions such as peritonsillar or retropharyngeal abscess, epiglottitis (Chapter 20), or diphtheria (Chapter 16).

Peritonsillar abscess (a tonsil infection that spreads into surrounding tissues and causes cellulitis) or retropharyngeal abscess (an infection of the lymph nodes that drain the adenoids, nasopharynx, and paranasal sinuses) are serious conditions. These conditions may have additional symptoms such as decreased neck movement, neck edema or pain, and respiratory distress. CT scan or MRI may be helpful in diagnosis of abscess. See Table 19–14 for manifestations of viral pharyngitis, strep throat, peritonsillar abscess, and retropharyngeal abscess.

The diagnosis of strep throat is made by throat culture, using the rapid or traditional strep tests (see the *Clinical Skills Manual* SKILLS). Results of the rapid strep test may be available within minutes; those for the traditional test are available in 24 to 48 hours. A negative rapid test is followed by a traditional test in order to verify results.

Streptococcal pharyngitis is treated with oral penicillin for 10 days or with long-acting penicillin given in one injection. If the child is allergic to penicillin, erythromycin, azithromycin, or clarithromycin is given. Acute symptoms should resolve within 24 hours of therapy, at which time, the child is no longer contagious. For viral pharyngitis, symptomatic treatment alone is used.

Clinical Tip

Throat cultures must be properly performed for accurate diagnosis. Swab a sterile cotton-tip applicator across the tonsils, posterior edge of the soft palate, and uvula. Ask cooperative children to put their hands under their buttocks, open their mouth, and laugh or pant like a dog. Quickly swab the throat. You can place uncooperative and young children on their backs with their hands next to their heads and have a parent or an assistant hold them. Depress the tongue gently with a tongue blade and swab the throat and both tonsils.

TABLE 19–14 Clinical Manifestations of Viral Pharyngitis, Strep Throat (Group A Beta-Hemolytic Streptococcus [GABHS]), Peritonsillar Abscess, and Retropharyngeal Abscess

VIRAL PHARYNGITIS	STREP THROAT	PERITONSILLAR ABSCESS	RETROPHARYNGEAL ABSCESS
Nasal congestion	Abrupt onset	Fever	Fever
Mild sore throat	Tonsillar exudate	Malaise	Sore throat
Conjunctivitis	Painful cervical lymphadenopathy	Sore throat, more severe on one side	Inability to eat
Cough	Anorexia, nausea, vomiting, abdominal pain	Marked erythema and edema, especially of one side of throat, tonsil, and soft palate, sometimes with deviated uvula	Neck pain and edema
Hoarseness	Severe sore throat	Mouth odor	Pharyngitis
Mild pharyngeal redness	Headache, malaise	Difficulty speaking	Respiratory distress and stridor
Minimal tonsillar exudate	Fever > 38.3°C (101.0°F)	Difficulty opening mouth wide	
Mildly tender anterior cervical lymphadenopathy	Petechial mottling of soft palate	Cervical lymphadenitis	
Fever < 38.3°C (101.0°F)		Ear pain	

Note: Children 6 months to 3 years of age may have streptococcal pharyngitis with symptoms that resemble those of viral pharyngitis. Children with scarlet fever have the symptoms of strep throat plus a sandpaper-textured erythematous generalized rash and pallor around the lips.

Source: Data from Hsiao, H. J., Huang, Y. C., Hsia, S. H., Wu, C. T., & Lin, J. J. (2012). Clinical features of peritonsillar abscess in children. *Pediatric Neonatology, 53*, 366–370; Hoffman, C., Pierrot, L., Contencin, P., Morisseau-Durand, M. P., Manach, Y., & Couloigner, V. (2011). Retropharyngeal infections in children: Treatment strategies and outcomes. *International Journal of Pediatric Otorhinolaryngology, 75*, 1099–1103.

Peritonsillar abscess is treated by draining the abscess, providing antibiotics effective in treating the fluid cultured from the abscess, and hydration. Commonly administered antibiotics include ampicillin/sulbactam, penicillin G, and clindamycin. Once treatment has resolved the infection, the child is evaluated for possible tonsillectomy (Hsaio, Huang, Hsia, et al., 2012). Retropharyngeal abscess is also frequently treated by drainage of the abscess, although intravenous antibiotics alone are effective in some cases. Ampicillin/sulbactam, clindamycin, cephalosporin, and penicillin are common antibiotics. Respiratory management may be needed.

Nursing Management

Nursing care focuses on symptomatic relief. Acetaminophen reduces throat pain and generalized fever. Cool, nonacidic fluids and soft foods, ice chips, or frozen juice pops given frequently in small amounts facilitate swallowing and prevent dehydration. Humidification and gargling with warm salt water (5 g [1 teaspoon] salt to 250 mL [8 oz] water) soothe an irritated throat. Alternatively, the salt water can be placed in a spray bottle and sprayed gently toward the throat. Commercial throat sprays or throat lozenges are not generally more effective than these home remedies. Encourage the child to rest to conserve energy and promote recovery.

Teach parents the importance of completing the 10-day course of antibiotics if prescribed for bacterial pharyngitis. Reinforce to parents the importance of treating streptococcal infections because untreated infections may lead to rheumatic fever, cervical adenitis, sinusitis, glomerulonephritis, or meningitis.

Tonsillitis and Adenoiditis

Tonsillitis is an infection or inflammation (hypertrophy) of the palatine tonsils. Although most children with pharyngitis may have infected tonsils, they do not necessarily have tonsillitis. The adenoids are lymphatic tissue located on the posterior pharyngeal wall and are sometimes called the pharyngeal tonsils; they can manifest with acute or chronic infection.

ETIOLOGY AND PATHOPHYSIOLOGY

Like pharyngitis, tonsillitis and adenoiditis may be caused by a virus or bacterium. The primary site of infection is the tonsils.

CLINICAL MANIFESTATIONS

Symptoms suggestive of tonsillitis include frequent throat infections with breathing and swallowing difficulties, persistent redness of the anterior pillars, and enlargement of the cervical lymph nodes. If children breathe through their mouths continuously, the mucous membranes may become dry and irritated. Adenoiditis is characterized by nasal stuffiness, discharge, and postnasal drip, which result in coughing or excessive clearing of the throat.

CLINICAL THERAPY

Diagnosis is made on the basis of visual inspection and clinical manifestations. Tonsils appear large and inflamed. Enlarged adenoids are diagnosed by radiologic studies.

Symptomatic treatment for tonsillitis is the same as for pharyngitis. Recent guidelines provide clear recommendations for surgery involving repeated infections and sleep-disordered breathing. Watchful waiting is recommended in most cases. Tonsillectomy can be considered when there are at least seven episodes of tonsillitis in the previous year, at least five episodes per year for 2 years, or at least three episodes annually for 3 years. In these cases, tonsillitis diagnosis requires a sore throat and at least one of the following symptoms: temperature above 38.3°C (101.0°F), cervical adenopathy, tonsillar exudate, and positive group A beta-hemolytic streptococcal infection (Giordano et al., 2011). Sleep-disordered breathing that exists with tonsillar hypertrophy and a condition such as growth abnormality, poor school performance, enuresis, or behavioral problem is also appropriate reason for surgical tonsillectomy (Mitka, 2011). One intraoperative dose of intravenous dexamethasone is recommended, but routine operative antibiotics are not needed.

Nursing Management

For the Child With Tonsillitis and Adenoiditis

Nursing Assessment and Diagnosis

Assess the throat carefully during each physical examination. Observe for tonsils that are simply large (a common finding in childhood) and those that are inflamed. Look for the degree of redness and presence of any exudate. Ask if the child has pain or difficulty swallowing. Ask about the history of past tonsillar infections and the length of time of the present discomfort.

If surgery is indicated, take a complete history of the child preoperatively. Monitor vital signs and observe for respiratory distress, hemorrhage, and dehydration postoperatively.

Several nursing diagnoses may apply to the child with tonsillitis. They include the following (NANDA-I © 2014):

- ***Pain, Acute,*** related to inflammation of the pharynx
- ***Fluid Volume: Deficient, Risk for,*** related to inadequate intake
- ***Breathing Pattern, Ineffective,*** related to obstruction by enlarged tonsils
- ***Swallowing, Impaired,*** related to inflammation and pain
- ***Knowledge, Readiness for Enhanced,*** related to home care following discharge

Planning and Implementation

The nurse provides general supportive care and, if medication is prescribed, encourages completion of the full course of treatment. The nursing management of children with tonsillitis is similar to that of children with pharyngitis (see earlier discussion).

If surgery is indicated, help the parents prepare their child for a short-term surgical procedure with a possible overnight stay in the hospital (see Chapter 11). Children should be free of sore throat, fever, or upper respiratory infection for at least 1 week before surgery. They should not be given aspirin or ibuprofen for 2 weeks before surgery since these medications can increase postoperative bleeding. Check if any herbal medications are taken and report them to the surgeon and anesthesiologist since some may interfere with anesthetic drugs used in surgery.

DISCHARGE PLANNING AND HOME CARE TEACHING

Discharge planning includes teaching parents about pain management, fluid and nutrition intake, activity restrictions, and possible complications in the postoperative period. Most children have a sore throat for 7 to 10 days after tonsillectomy. Advise parents how to relieve the child's throat pain. (See *Families Want to Know: Care After Tonsillectomy.*)

Families Want to Know

Care After Tonsillectomy

After tonsillectomy, the parent can take the following measures to increase the child's comfort:

- Have the child drink adequate cool fluids to reduce spasms in the muscles surrounding the throat.
- Ensure that the child drinks recommended amount of fluid to avoid dehydration.
- Apply an ice collar around the child's neck.
- Give acetaminophen elixir or other analgesic as prescribed.
- Have the child gargle with a solution of 2.5 g (1/2 teaspoon) each of baking soda and salt in a glass of water.
- If ordered by the healthcare provider, have the child rinse the mouth well with viscous lidocaine or other local anesthetic.

Families Want to Know

Complications of Tonsillectomy and Adenoidectomy

Bleeding

- To prevent bleeding, aspirin or ibuprofen should not be given for pain for the first postoperative week. Use acetaminophen instead.
- Bleeding is most likely to occur within the first 24 hours or 7 to 10 days after the tonsillectomy, when the scar is forming. Report any trickle of bright red blood or increased swallowing to the healthcare provider immediately.

Infection

- The back of the throat will look white and have an odor for the first 7 to 8 days after the surgery. The child may also have a low-grade fever. These are not signs of infection.
- For temperatures over 38.3°C (101.0°F), acetaminophen may be used.
- Call the healthcare provider if the child develops a fever above 38.8°C (102.0°F).

Pain

- Administer acetaminophen as ordered.
- Offer frequent small amounts of cool liquids. Avoid citrus juice.
- Provide for rest and quiet activities for several days.

Families Want to Know

Care of a Tooth Avulsion

When a tooth is removed during an injury, prompt treatment may improve the chance that it can be reimplanted. If the child's condition is stable, try to reimplant the tooth and then transfer to an emergency dental facility.

- Handle the tooth only by the crown (its top) rather than the root to avoid further damage.
- Gently rinse the tooth with a stream of sterile saline. Do NOT place it under running water.
- Insert into the socket.
- Have the child provide gentle pressure by biting a piece of gauze or a moistened tea bag. If the child is unstable or has other injuries, enlist emergency medical transportation (call 9-1-1). In this case, the tooth is transported with the child.
- If a dental aid kit is available, it may contain a transport liquid such as ViaSpan or Hank's Balanced Salt Solution. If these are not available, alternatives include cold milk, saline, saliva, or water. Place the tooth in one of these transfer liquids to keep it moist and send it with the child to the healthcare facility.

Source: Adapted from American Association of Endodontists. (2013). *The treatment of traumatic dental injuries*. Retrieved from http://www.nxtbook.com/nxtbooks/aae/traumaguidelines/index.php#/0

Children may experience ear pain, especially when swallowing, between 4 and 8 days after tonsillectomy. Advise parents that this pain is referred from the tonsillar area and does not indicate an ear infection.

Emphasize to parents the importance of adequate fluid intake. Children should be given any liquid they prefer for the first week, except citrus juices, which may produce a burning sensation in the throat. Soft foods such as gelatin, applesauce, frozen juice pops, and mashed potatoes can be added as tolerated.

Children do not need to be confined to bed, but they should avoid vigorous exercise for the first week after surgery. Advise parents that the child may return to school approximately 10 days after tonsillectomy.

Any surgery carries the risk of postoperative complications. Teach parents the normal signs of healing in the postoperative period, as well as signs of complications. (See *Families Want to Know: Complications of Tonsillectomy and Adenoidectomy*.)

Evaluation

Expected outcomes of nursing care for the child with tonsillitis include the following:

- The child has adequate intake of food and fluids.
- Pain and fever are effectively managed.
- There is an absence of postoperative complications such as bleeding, hemorrhage, and dehydration.
- Healing occurs without impairment following tonsillectomy.

Disorders of the Mouth

The mouth is an important structure that is directly linked to both the gastrointestinal and respiratory systems. Structural problems can occur in the mouth, often in conjunction with other defects such as tracheoesophageal fistula or cleft lip and palate (see Chapter 25). A second type of mouth disorder in children is ulceration. Children sometimes have changes in the mucous membranes of the mouth, associated with illnesses, infections, or as a side effect of drug treatments. Trauma is a third cause for mouth disorders in children. Accidents can cause fractures of the jaw, dental emergencies, or other trauma.

Nursing Management

Most mouth ulcers are treated symptomatically. Since the oral mucosa is fast growing, the cells can rapidly heal. Keeping the mouth clean and administering systemic or topical analgesics can assist with comfort. Foods should be mild and nonirritating. Acyclovir may be administered for treatment of herpes infections. Antibiotics are needed for bacterial infection of oral lesions. Stevens-Johnson syndrome necessitates removing the drug that causes the reaction, and treating the child with oral antihistamines and supportive therapy.

Nurses inform parents of proper treatment for injuries and may provide emergency treatment in schools and other community settings. Injury prevention is encouraged through use of protective gear during sports. Mouth guards can be helpful to prevent dental damage. See Chapter 17 for a discussion of protective sporting gear and of body piercing that may involve the oral cavity. Because the mouth has a profuse blood supply, bleeding may be extensive for even minor injuries. It is best to use clean cloths to absorb the blood and prevent choking on it, and get the child to an emergency facility to have the lesion examined.

Dental injuries may involve fracture of a tooth, luxation (partial extrusion), or avulsion (complete removal). The periodontal ligament holds the tooth in the socket but its attachment is torn during a tooth avulsion. When avulsion has occurred, fast care improves the chance that a permanent tooth can be reimplanted and kept alive. When reimplanted within 30 minutes, the chances of survival of the tooth are best (American Association of Endodontists, 2013). The nurse or family provides immediate care and the child should be transported immediately to an emergency facility. (See *Families Want to Know: Care of a Tooth Avulsion*.)

Chapter Highlights

- Health conditions affecting the eyes and ears are common in childhood, partially because of anatomic differences in structure, and can lead to developmental and communication disorders.
- Conjunctivitis can occur in the newborn and throughout childhood.
- Children manifest a wide array of visual disorders, such as hyperopia, myopia, and astigmatism.
- Strabismus, amblyopia, cataracts, glaucoma, and retinopathy of prematurity are serious conditions that can affect vision.
- Nurses commonly screen vision of children in schools and healthcare facilities to identify those with visual impairment.
- Otitis media is a common childhood health condition, with monitoring and antibiotics as potential treatments.
- Newborns should be screened for response to sounds, and those at high risk of hearing impairment should be carefully monitored in early childhood.
- Hearing loss may be conductive, sensorineural, or mixed.
- Nursing interventions for the child with vision or auditory impairment should focus on maximizing development and communication.
- Common disorders of the nose, throat, and mouth include epistaxis, nasopharyngitis, pharyngitis, tonsillitis, and oral ulcers.
- Nurses are influential in providing preventive teaching and emergency care when trauma occurs to the eyes, ears, and mouth.

Clinical Reasoning in Action

You are working at a local children's urgent care facility when a couple comes in carrying their screaming 9-month-old child, Becky. The parents are worried, as Becky has been crying steadily for the past 2 hours. You ask about recent illnesses or injuries and they tell you that she has had only two colds in her life and the most recent was about a week ago.

You assess Becky's vital signs as follows: weight 19 lb (8.6 kg), temperature 101°F, respirations 60 breaths per minute without retractions, and heart rate 120 beats per minute. She does not have any rashes or evidence of injuries, and upon examination, she appears well nourished but clearly in distress. Her heart rate is regular and rhythmic, and breath sounds are equal bilaterally and clear to auscultation. Both tympanic membranes are red and bulging. Her abdomen is soft and without organomegaly. The healthcare provider diagnoses bilateral acute otitis media and administers analgesic ear drops and ibuprofen in the office. Within 15 minutes, Becky has settled down, stopped crying, and is resting in her father's arms. The family is sent home with instructions to administer analgesics and return within 48 hours for further assessment.

1. What are the three main organisms that may have caused Becky's otitis media?
2. What are some of the guidelines you can give Becky's parents about otitis media treatment?
3. The mother says she has family members who have had tubes placed in their ears because of ear infections and wants to know if this is something that Becky will need to have done. How will you answer the mother's question?
4. What are some methods parents can use to prevent future otitis media episodes?

Chapter 20
Alterations in Respiratory Function

Ron Chapple/Getty Images

Emily gets sick so much faster than my other children. I guess the chronic lung disease and her tracheostomy make her more susceptible to infections. I really get concerned because she struggles so hard to breathe when she gets an infection. I have learned to suction and change her tracheostomy, but I'm afraid that one day her tracheostomy tube will get completely blocked. I just hope I remember all the things I've learned if that happens, and that the emergency medical personnel come quickly.

—Father of Emily, 8 months old

Learning Outcomes

20.1 Describe unique characteristics of the pediatric respiratory system anatomy and physiology and apply that information to the care of children with respiratory conditions.

20.2 Contrast the different respiratory medical conditions that can cause respiratory distress in infants and children.

20.3 Explain the visual and auditory observations made to assess a child's respiratory effort or work of breathing.

20.4 Assess the child's respiratory status and analyze the need for oxygen supplementation.

20.5 Distinguish between conditions of the lower respiratory tract that cause illness in children.

20.6 Create a nursing care plan for a child with a common acute respiratory condition.

20.7 Develop a school-based nursing care plan for the child with asthma.

20.8 Develop a home nursing care plan for the child with cystic fibrosis.

20.9 Contrast the signs of different injuries to the respiratory system.

Respiratory conditions are the most common cause of hospitalization in children between 1 and 17 years of age when numbers for pneumonia and asthma are combined (Pfuntner, Wier, & Stocks, 2013). Some respiratory conditions are chronic and have a significant impact on the child's growth and development. However, most respiratory problems in children produce mild symptoms, last a short time, and can be managed at home.

Respiratory Distress and Respiratory Failure

Many respiratory conditions associated with breathing difficulty can progress to respiratory distress. If the condition is not managed effectively, it can progress to respiratory failure. Foreign-body aspiration is a common cause of airway obstruction and respiratory distress.

Text continues on page 478

FOCUS ON:
The Respiratory System

Anatomy and Physiology

The respiratory system is composed of both the upper and lower airways. The upper airway, containing the nasopharynx and oropharynx, serves as the pathway for gases exchanged during ventilation, the movement of oxygen into the lungs and carbon dioxide out of the lungs. The larynx divides the upper and lower airways. The lower airways (trachea, bronchi, and bronchioles) serve as the pathway of gases to and from the alveoli in the lungs. The left lung is divided into two lobes, and the right lung is divided into three lobes. Alveolar sacs surrounded by capillaries are located at the end of the airways and are the site of gas exchange, where oxygen diffuses across the alveolocapillary membrane. Surfactant secreted by alveolar cells coats the inner surface of the alveolus to allow expansion during inspiration. The lung tissue surrounding the airways keeps them from collapsing as the oxygen moves in and carbon dioxide moves out during ventilation. The lungs are positioned in the thoracic cavity, where the ribs and muscles protect the lungs from injury.

The intercostal muscles work with the diaphragm to perform the work of breathing. The diaphragm is a muscle that separates the abdominal and thoracic cavity contents. When the diaphragm contracts, it creates negative pressure that increases the thoracic volume and pulls air into the lungs. The lungs and chest wall have the ability to expand during inspiration (compliance) and then to recoil or return to the resting state with expiration. The work of breathing is tied to the muscular effort required for ventilation, which can be increased in cases of airway obstruction or disorders that increase the stiffness of the lungs.

The respiratory center in the brain controls respiration, sending impulses to the respiratory muscles to contract and relax. Breathing is usually automatic as the nervous system adjusts the ventilatory rate and volume to maintain normal gas exchange (Brashers, 2014). Chemoreceptors monitor the pH, $PaCO_2$, and PaO_2 in the arterial blood and send signals to the respiratory center to increase ventilation in cases of arterial hypoxemia. Effective gas exchange requires a near even distribution of ventilation and perfusion (oxygenated blood flow to all portions of the lungs). As oxygen diffuses across the alveolocapillary membrane, it dissolves in the plasma and the resulting increased partial pressure of oxygen (PaO_2) helps bind the oxygen to the hemoglobin molecules for transport to the cells for metabolism. Carbon dioxide produced by cellular metabolism is dissolved in the plasma (PCO_2) and/or as bicarbonate and travels back to the lungs where it diffuses across the alveolocapillary membrane (Brashers, 2014).

Pediatric Differences

The child's respiratory tract constantly grows and changes until about 12 years of age. The young child's neck is shorter than an adult's, resulting in airway structures that are closer together.

Upper Airway Differences

The child's airway is shorter and narrower than an adult's. These differences create a greater potential for obstruction (see *As Children Grow: Airway Development*). The infant's airway diameter is approximately 4 mm (0.16 in.), about the width of a drinking straw, in contrast to the adult's airway diameter of 20 mm (0.8 in.). The child's little finger is a good estimate for the child's tracheal diameter and can be used for a quick assessment of airway size. The trachea primarily increases in length rather than diameter during the first 5 years of life.

The tracheal division of the right and left bronchi is higher in a child's airway and at a different angle than the adult's (see *As Children Grow: Trachea Position*). The cartilage that supports the trachea is more flexible, and the airway may be compressed when the head and neck are flexed toward the chest. The child's narrower airway causes a greater increase in **airway resistance** (the effort or force needed to move oxygen through the trachea to the lungs) in any condition causing airway inflammation or edema (see *Pathophysiology Illustrated: Airway Diameter*).

Newborns are obligatory nose breathers. The only time newborns breathe through the mouth is when they are crying. The coordination of mouth breathing is controlled by maturing neurologic pathways, and infants up to 2 to 3 months of age do not automatically open the mouth to breathe when the nose is obstructed. It is important to keep the newborn's nose patent for breathing and eating.

Lower Airway Differences

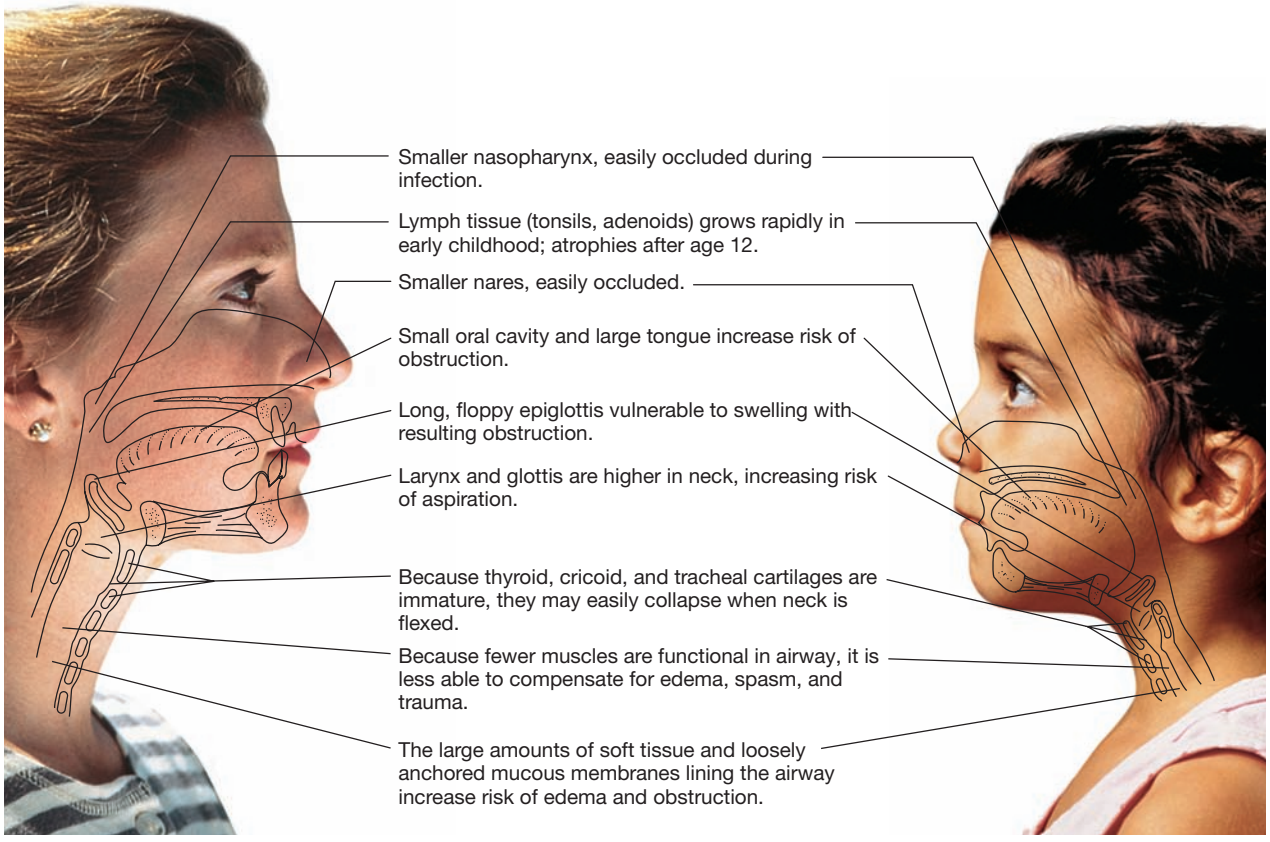
The tracheobronchial tree is complete in the full-term newborn, but the child's lower airway is constantly growing. Beginning at 24 weeks' gestation, the lung sacs begin forming to support future gas exchange. The lung sacs begin differentiating into alveoli at 36 weeks' gestation (Rozance & Rosenberg, 2012). Alveoli continue developing and increasing in number for the first 5 to 8 years of age, followed by further development in size and complexity (Brashers & Huether, 2014). The bronchi and bronchioles are lined with smooth muscle that develops after birth.

Children under 6 years of age use the diaphragm to breathe because the intercostal muscles are immature. By 6 years of age the child uses the intercostal muscles more effectively. The ribs are primarily cartilage and very flexible. In cases of respiratory distress, the negative pressure caused by the diaphragm movement causes the chest wall to be drawn inward, causing **retractions** (see *Pathophysiology Illustrated: Retraction Sites*).

Children consume more oxygen than adults because of their higher metabolic rate. This rate of oxygen consumption increases when the child is in respiratory distress. The child also has fewer muscle glycogen reserves, leading to more rapid muscle fatigue when accessory muscles must be used for breathing (Brashers & Huether, 2014).

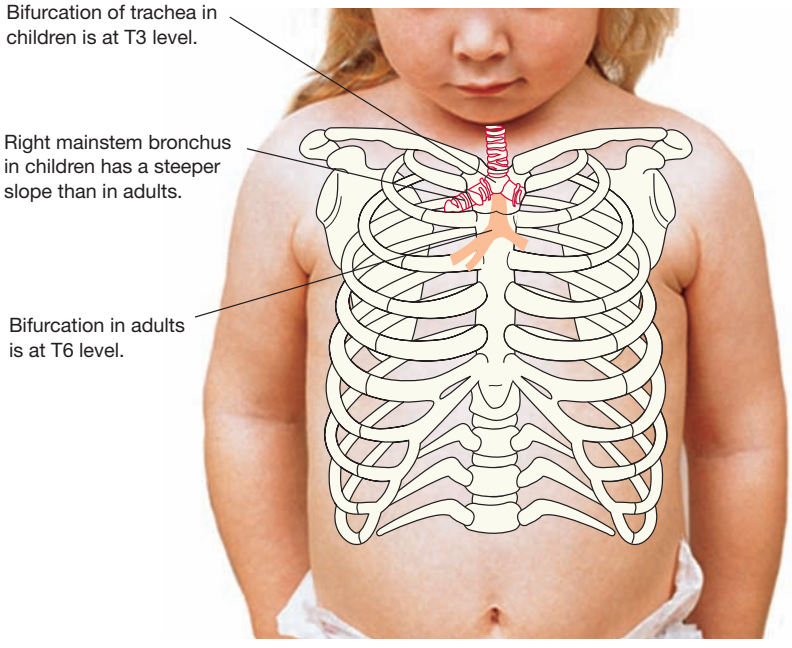
Use *Assessment Guide: The Child in Respiratory Distress* to perform a nursing assessment of the respiratory system. See Table 20–1 for a list of diagnostic and laboratory tests used to evaluate respiratory conditions. See Appendix D for expected laboratory values and Appendix E for information about diagnostic procedures.

As Children Grow: **Airway Development**



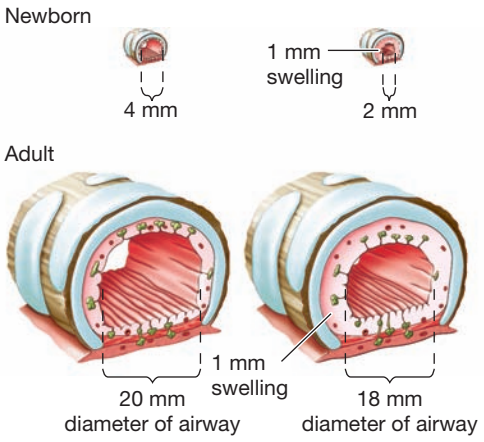
It is easy to see that a child's airway is smaller and less developed than an adult's airway, but why is this important? An upper respiratory tract infection, allergic reaction, positioning of the head and neck during sleep, and the small objects children play with can have serious consequences in the child.

As Children Grow: **Trachea Position**



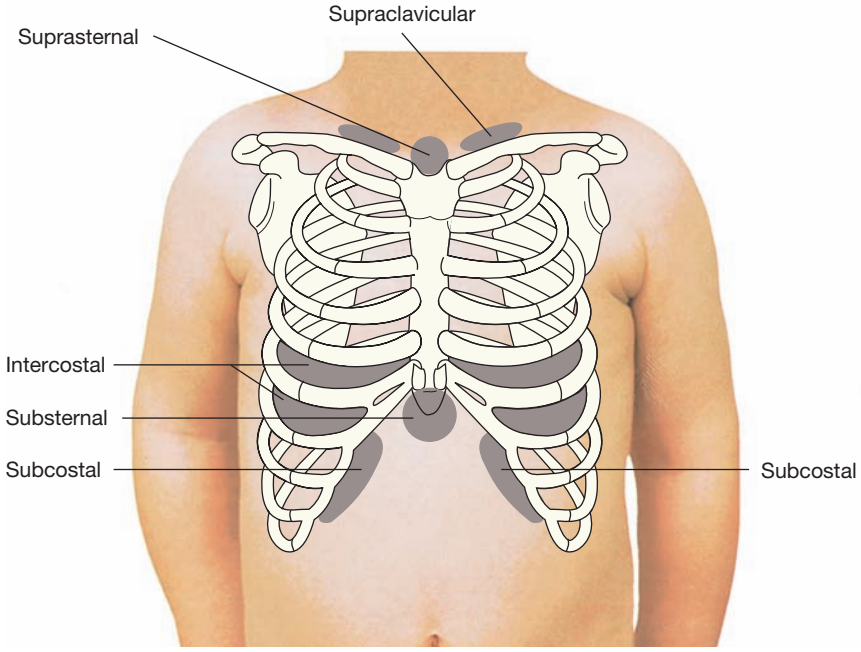
In children, the trachea is shorter and the angle of the right bronchus at bifurcation is more acute than in the adult. When you are resuscitating or suctioning, you must allow for these differences. Do you think that the angle of the right bronchus is significant in foreign-body aspiration? Why?

Pathophysiology Illustrated: **Airway Diameter**



An infant's airway diameter is approximately 4 mm (0.16 in.), in contrast to the adult's 20–mm (0.8-in.) airway diameter. An inflammatory process in the airway causes swelling that narrows the airway, and airway resistance increases. Note that swelling of 1 mm (0.04 in.) reduces the infant's airway diameter to 2 mm (0.08 in.), but the adult's airway diameter is only narrowed to 18 mm (0.7 in.). Air must move more quickly in the infant's narrowed airway to get the needed amount of air into the lungs. The friction of the quickly moving air against the side of the airway increases airway resistance. The infant must use more effort to breathe and must breathe faster to get adequate oxygen.

Pathophysiology Illustrated: **Retraction Sites**



Infants and young children have immature chest muscles and ribs of cartilage, making the chest wall very flexible. The negative pressure created by the downward movement of the diaphragm is increased in cases of respiratory distress, and the chest wall is pulled inward, causing retractions. Intercostal retractions are seen in mild respiratory distress. As respiratory distress severity increases, substernal and subcostal retractions are seen. In cases of severe distress, supraclavicular and suprasternal retractions occur as the accessory muscles (sternocleidomastoid and trapezius muscles) are used.

TABLE 20–1 Diagnostic and Laboratory Procedures/Tests for the Respiratory System*

DIAGNOSTIC PROCEDURES	LABORATORY TESTS
Bronchoscopy	Arterial blood gas analysis
Chest radiograph	Cultures
Polysomnography (sleep study)	Neonatal screening for cystic fibrosis
Pulse oximetry	Protein-purified derivative (PPD), the Mantoux test
Spirometry (pulmonary function tests)	
Sweat chloride test	

* See Appendices D and E for information about these diagnostic procedures and tests.

Pediatric respiratory conditions may occur as a primary problem or as a complication of nonrespiratory conditions. Respiratory problems may result from structural problems, functional problems, or a combination of both. Structural problems involve alterations in the size and shape of parts of the respiratory tract. Functional problems involve alterations in gas exchange and threats to the process of ventilation due to irritation by large particles and chemicals or infection. Alterations in other organ systems, especially the immune and neurologic systems, may also threaten respiratory function. See Chapter 19 for upper respiratory conditions such as otitis media, sinusitis, and pharyngitis.

ASSESSMENT GUIDE | The Child in Respiratory Distress*

Assessment Focus	Assessment Guideline
Position of comfort	• Is the child comfortable lying down? • Does the child prefer to sit up or in the **tripod position** (sitting forward with arms on knees for support and extending the neck)?
Vital signs	• Assess the rate and depth of respirations. See Table 5–9 for age-related respiratory rates. Is **tachypnea** (abnormally rapid respiratory rate) present? • Assess the pulse for rate and rhythm. See Table 5–11 for age-related heart rates.
Lung auscultation	• Are breath sounds bilateral, diminished, or absent? • Are **adventitious sounds** (wheezes, crackles, or rhonchi) present?
Respiratory effort (work of breathing)	• Is **stridor** (audible crow-like inspiratory and expiratory breath sounds) or wheezing present? Is grunting heard on expiration? • Is breathing easy or labored? • Are retractions present or are accessory muscles used to breathe? • Is nasal flaring present? • Can the child say a full sentence or is a breath needed every few words? Is the cry strong or weak? • Do the chest and abdomen rise simultaneously with inspiration or is **paradoxical breathing** present in which the chest and abdomen do not rise simultaneously?
Color	• What is the color of the mucous membranes, nail beds, or skin (pink, pale, cyanotic, or mottled)? • Does crying improve or worsen the color?
Cough	• Is the cough dry (nonproductive), wet (productive, mucousy), brassy (noisy, musical), or croupy (barking, seal-like)? • Is the coughing effort forceful or weak?
Behavior change	• Is irritability, restlessness, or change in level of responsiveness present?

** Refer to Chapter 5 for the assessment techniques mentioned in this table.*

Foreign-Body Aspiration

Foreign-body aspiration is the inhalation of any object (solid or liquid, food or nonfood) into the respiratory tract. It is a major health threat for infants and young toddlers because of their increasing mobility and tendency to put objects into their mouths. Aspiration occurs most often during feeding and reaching activities, while crawling, or during playtime. However, aspiration may occur in children of any age. Approximately 100,000 cases occur each year, most often in children between 1 and 3 years old (Brashers & Huether, 2014). Some children die as a result of complete airway obstruction.

ETIOLOGY AND PATHOPHYSIOLOGY

In infants over 6 months of age and young children, any number of small objects that enter the child's mouth may cause aspiration. Foods such as nuts, popcorn, or small pieces of raw vegetables or hot dog and small objects such as toy parts, beads, safety pins, coins, buttons, or latex balloon pieces are frequent causes of airway obstruction. Partial and sometimes complete airway obstruction can occur.

The severity of the obstruction depends on the size and composition of the object or substance and its location within the respiratory tract. Most aspirated foreign bodies (AFBs) usually cause bronchial, not tracheal, obstruction. An object lodged high in the airway above the vocal cords is more easily removed by coughing or by back blows and chest thrusts.

The right lung is the most common site of the AFB because of the angle of its mainstem bronchus. Objects may migrate from higher to lower airway locations. An object may also move back up to the trachea, creating extreme respiratory difficulty. If the AFB is lodged in the trachea, it becomes life threatening.

CLINICAL MANIFESTATIONS

In many cases, the aspiration is unobserved. The child may have a sudden onset of choking, spasmodic coughing, shortness of breath, or **dysphonia** (muffled, hoarse, or absent voice sounds). These signs may be brief or may persist for several hours if the object drops below the trachea into a mainstem bronchus. Some children become asymptomatic after coughing for 15 to 30 minutes. The child may develop increased respiratory effort such as **dyspnea** (difficulty breathing), tachypnea, nasal flaring, and retractions. As respiratory distress progresses, the child may have a concentrated focus on breathing, an anxious expression, and an upright position with the neck extended. As **hypoxia** (lower than normal oxygen in the tissues) increases, behavior changes such as irritability and decreased responsiveness are seen.

If the AFB drops into the right bronchus and lower airway and is not removed, the child may present weeks later with a chronic cough, persistent or recurrent pneumonia, or a lung abscess.

CLINICAL THERAPY

Clinical therapy focuses on taking a careful history to determine whether aspiration could have occurred. Witnessed coughing, gagging, or choking associated with feeding or crawling on the floor may confirm the aspiration. Decreased breath sounds, stridor, and respiratory distress increase suspicion in the child without a witnessed aspiration. Many aspirated objects are organic, such as food, and cannot be seen on a radiograph. See Figure 20–1. A special radiograph, called a forced expiratory film, may show local hyperinflation (air trapping) and a mediastinal shift away from the affected side, abnormalities that an AFB may cause.

An object lodged in the trachea is life threatening. Back blows and chest thrusts or abdominal thrusts are used to remove an object from an obstructed airway. (See the *Clinical Skills Manual* SKILLS.) Fluoroscopy and fiberoptic bronchoscopy may be used to identify, locate, and extract the AFB. The child may develop pneumonia if an AFB is not recognized as a cause of respiratory distress. See the section on pneumonia later in the chapter.

Nursing Management

For the Child With Foreign-Body Aspiration

Nursing Assessment and Diagnosis

PHYSIOLOGIC ASSESSMENT

Perform the respiratory assessment following the guidelines given in *Assessment Guide: The Child in Respiratory Distress*. The child with an acute AFB will be in respiratory distress and must be constantly monitored. If the object remains lodged, observe the child for signs of increasing respiratory distress, especially vital signs, altered mental status, and audible wheezing on auscultation. Note changes in breath sounds, from noisy to decreasing to absent, on the affected side. This can indicate that the object is moving and blocking a mainstem bronchus. Document any subtle changes in the child's respiratory status and report promptly.

Attach the child to a cardiorespiratory monitor and pulse oximeter (a transcutaneous assessment method to detect the amount of hemoglobin saturated with oxygen [SpO_2]) to assess the child for subtle signs of increasing hypoxia. A pulse oximetry reading (SpO_2) of less than 95% indicates **hypoxemia** (lower than normal oxygen level in the blood).

PSYCHOSOCIAL ASSESSMENT

The unexpected and acute nature of the event creates anxiety for both parents and child. The child will be fearful because of difficulty breathing. Assess the family's level of distress and coping ability.

DEVELOPMENTAL ASSESSMENT

As the child's condition stabilizes, observe how well the child's abilities match the parents' understanding of age-appropriate behaviors. See Chapter 4.

Common nursing diagnoses for a child with an AFB include the following (NANDA-I © 2014):

- ***Airway Clearance, Ineffective,*** related to obstruction by a foreign body
- ***Ventilation: Spontaneous, Impaired,*** related to respiratory muscle fatigue
- ***Anxiety (Child)*** related to difficulty breathing, unfamiliar surroundings, and procedures
- ***Injury, Risk for,*** related to small objects in environment

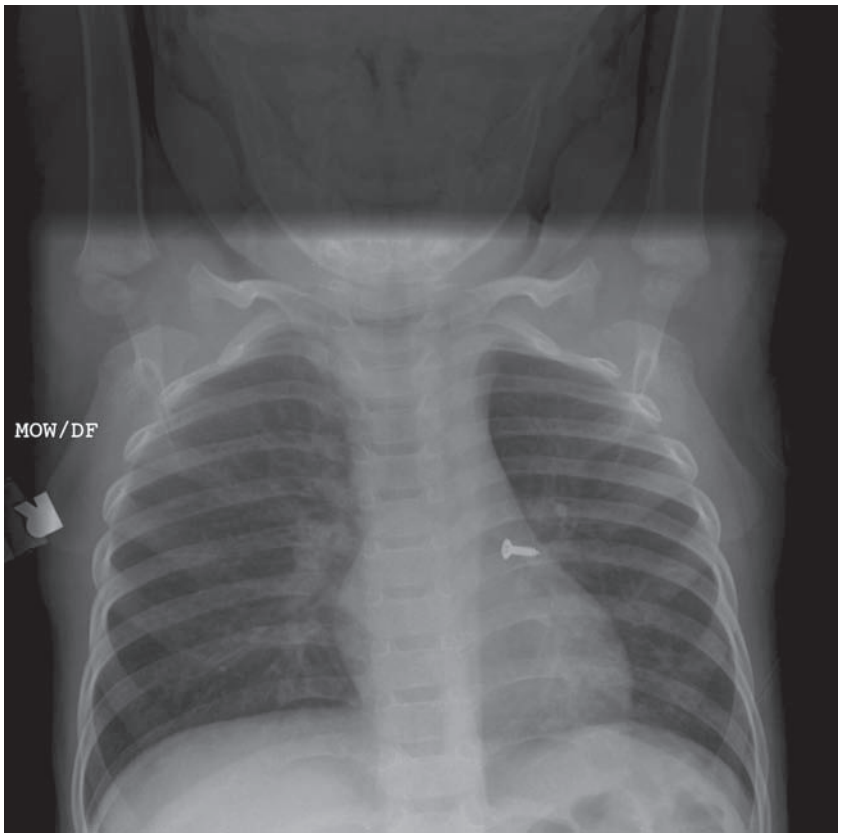


Figure 20–1 An aspirated screw is clearly visible in the child's left mainstem bronchus on this chest radiograph.

SOURCE: Courtesy of Evelyn Anthony, MD, Department of Radiology, Brenner Children's Hospital, Wake Forest University Health System.

Planning and Implementation

Be prepared to perform back blows and chest thrusts for an infant or abdominal thrusts for the child with complete obstruction. (See the *Clinical Skills Manual* SKILLS.) When the child has a partial obstruction, remain with the child and have resuscitation equipment at the bedside. Permit the child to stay in a position of comfort. Avoid performing procedures that increase the child's anxiety because sudden movements and increased respiratory efforts may cause the obstruction to move and completely obstruct the airway.

After the AFB is removed, the child is stabilized and observed for a few hours in a short-stay unit to ensure that there are no respiratory complications.

Clinical Tip

Accuracy of pulse oximetry readings (SpO_2) can be improved by doing the following:

- Place the sensor over clean dry skin (e.g., finger, foot, ear lobe). Select a site or extremity that will not be moved extensively and where perfusion is adequate. Make the sensor secure to prevent movement of the sensor.
- Position the sensor for a reading at the level of the heart.
- Avoid placing the sensor probe over sites covered with dark nail polish or false nails.
- Cover the sensor with a light barrier when the child is in intense internal or external light to reduce interference.
- Confirm that the child's heart rate matches that detected by the pulse oximeter.
- Shivering, vasoconstriction, poor capillary refill, hypothermia, intravenous dyes, and electromagnetic interference may result in a false low reading (Fouzas, Priftis, & Anthracopoulos, 2011). Anemia may result in a false high reading.

DISCHARGE PLANNING AND HOME CARE TEACHING

Prevention of future aspirations is a major focus for nursing care. Educate the family on the child's developmental characteristics and how to identify potential safety hazards in the home. Food should be cut in small pieces. Check toys for small or broken parts and remove from young children. Store small objects (e.g., batteries, screws, buttons, earrings, and coins) out of a child's reach. Encourage the parents to learn rescue breathing, back blows, chest thrusts, or abdominal thrusts.

Evaluation

Expected outcomes of nursing care include the following:

- The child breathes spontaneously after removal of the foreign body.
- Parents complete a home safety check to prevent future aspiration incidents.

Respiratory Failure

Respiratory failure occurs when the body can no longer maintain effective gas exchange. Poor ventilation of the alveoli initiates the process that leads to respiratory failure. Hypoventilation occurs when oxygen need exceeds oxygen intake, the airway is partially occluded, or the exchange of oxygen and carbon dioxide in the alveoli is disrupted. This disruption may occur when a malfunction of respiratory center stimulation occurs (the alveoli do not receive the message to diffuse, e.g., a narcotic overdose), muscles of ventilation are fatigued and do not work effectively (e.g., status asthmaticus), or the relationship between ventilation and blood flow to the alveoli (perfusion) is impaired. Hypoxemia and **hypercapnia** (an excess of carbon dioxide in the blood) result from hypoventilation. When the blood levels of oxygen and carbon dioxide reach abnormal levels, hypoxia occurs and respiratory failure begins.

Signs of impending respiratory failure include worsening respiratory distress with increased respiratory effort (dyspnea, tachypnea, nasal flaring, and intercostal retractions), irritability, lethargy, and cyanosis. Grunting in infants is a sign of severe disease and the potential need for mechanical ventilation (Prodhan, Sharoor-Karni, Lin, et al., 2011). *Hypoxemia that persists when supplemental oxygen is given is a sign of respiratory failure.* See Table 20–2.

CLINICAL THERAPY

Arterial blood gas values help identify hypoxemia and hypercapnia. Pulse oximetry helps determine when an arterial blood gas measurement is needed. When pulse oximetry (SpO_2) readings are between 76% and 90%, an arterial blood gas should be obtained as the SpO_2 reading may be falsely high (Ross, Newth, & Khemani, 2014). See Appendix D for expected arterial blood gas values and the *Clinical Skills Manual* SKILLS. Refer to Chapter 18 for interpretation of acidosis and alkalosis that must be considered simultaneously.

Medical management is focused on treating the cause of respiratory failure and reversing the severe hypoxemia with oxygen, mechanical ventilation, and positive end-expiratory pressure (PEEP) to increase functional residual capacity. These children are admitted to the pediatric intensive care unit (PICU).

TABLE 20–2 Clinical Manifestations of Respiratory Failure and Imminent Respiratory Arrest

PHYSIOLOGIC CAUSE	CLINICAL MANIFESTATIONS
INITIAL SIGNS OF RESPIRATORY FAILURE	
The child is trying to compensate for oxygen deficit and airway blockage. Oxygen supply is inadequate; behavior and vital signs reflect compensation and beginning hypoxia.	Restlessness Tachypnea Tachycardia Diaphoresis
EARLY DECOMPENSATION	
The child tries to use accessory muscles to assist oxygen intake; hypoxia persists and efforts now waste more oxygen than is obtained.	Nasal flaring Retractions Grunting Wheezing Anxiety, irritability Mood changes Headache Hypertension Confusion
SEVERE HYPOXIA AND IMMINENT RESPIRATORY ARREST	
The oxygen deficit is overwhelming and beyond spontaneous recovery. Cerebral oxygenation is dramatically affected; central nervous system changes are ominous.	Dyspnea Bradycardia Cyanosis Stupor and coma

The child's ability to maintain an open airway decreases as the level of responsiveness declines. Endotracheal (ET) intubation is a short-term, emergency measure to stabilize the airway by placing a tube in the trachea. The ET tube must be protected and stabilized to prevent its displacement. End-tidal CO_2 monitoring is used to ensure that the tube is correctly positioned in the trachea (see the *Clinical Skills Manual* SKILLS). A **tracheostomy**, the creation of a surgical opening into the trachea through the anterior neck at the cricoid cartilage, is performed when long-term airway management is needed.

Assisted ventilation may be needed until mechanical ventilation is provided or the child breathes spontaneously. Children are often sedated to improve ventilation. Continuous positive airway pressure is one therapy used to improve oxygenation and lung compliance. Respiratory arrest results if respiratory failure cannot be managed.

Nursing Management

Early recognition of impending respiratory failure is the most important aspect of care for a child with any signs of respiratory compromise. Assess the child using guidelines found earlier in this chapter in the *Assessment Guide*. Monitor the child for changes in vital signs, respiratory status, SpO_2, and level of responsiveness. When the child has a chronic respiratory condition, development of respiratory failure may be gradual and signs will be subtle. Be particularly alert to behavior changes in addition to respiratory signs. Serial blood gases may be needed to monitor the child.

SAFETY ALERT!

As the child tires from the prolonged effort of breathing, the respiratory rate may begin to decrease. This is an ominous sign and may progress to respiratory arrest without intervention.

Place a child who has respiratory compromise in an upright position (elevate the head of the bed). Respiratory distress, anxiety, excessive crying, and even fever can deplete metabolic reserves and increase the child's need for oxygen. Administer oxygen as ordered and keep emergency equipment at the child's bedside. Be prepared to provide assisted ventilation if the respiratory status deteriorates. (See the *Clinical Skills Manual* SKILLS.)

Clinical Reasoning **Oxygen Delivery Devices**

Oxygen delivery devices are selected to match the concentration of oxygen needed by the child. In respiratory failure, a higher concentration of oxygen is needed to reverse the hypoxemia. Which oxygen delivery device should be used? Are there any contraindications to oxygen use in a child who is hypoxic?

The child with an endotracheal or tracheostomy tube cannot talk or cry because vocal cord vibration is obstructed. Infants and young children often express initial frustration when they realize they cannot communicate verbally. When the child is alert, provide a bell or noisemaker as a way to gain attention. A communication board can be used with older children. Suction airway secretions as needed and provide tracheostomy care if present. (See the *Clinical Skills Manual* SKILLS.)

Many children are discharged from the hospital and cared for at home for an extended period with a tracheostomy tube in place. Parents must demonstrate competence in all aspects of tracheostomy care (how to maintain and suction the airway, clean the tracheostomy site, and change the tube), as well as emergency resuscitation skills adapted to the tracheostomy. A home healthcare nurse can provide follow-up care and support for the child and family. (See the *Clinical Skills Manual* SKILLS.)

Apnea

Infants commonly have **periodic breathing**, an irregular rhythm, and may have pauses of up to 20 seconds between breaths. This breathing pattern is not apnea. **Apnea** is the cessation of respiration lasting longer than 20 seconds, or any pause in respiration associated with cyanosis, marked pallor, hypotonia, or bradycardia. Apnea may be the first major sign of respiratory dysfunction in the newborn.

Apparent Life-Threatening Event (ALTE)

Apparent life-threatening event (ALTE) is defined as a frightening episode of apnea accompanied by a color change (e.g., cyanosis or pallor), limp muscle tone, choking, or gagging. Most affected infants are younger than 6 months of age (Chu & Hageman, 2013).

Potential causes of ALTE include gastroesophageal reflux, seizures, and lower respiratory disorders. Other causes may include ear, nose, and throat abnormalities; trauma; metabolic disorder; cardiac arrhythmias; sepsis; pertussis; and child abuse. ALTE and sudden infant death syndrome (SIDS) have different clinical and epidemiologic factors; however, some infants with ALTE are at increased risk for mortality (Chu & Hageman, 2013).

A detailed history helps identify the potential condition associated with ALTE. Diagnostic tests may include an electrocardiogram, complete blood count with differential, serum electrolytes, swallowing studies, gastrointestinal imaging, cultures, serum ammonia levels, and a chest radiograph. A medical cause is found for about 50% of ALTE cases (Chu & Hageman, 2013). Physical stimulation or emergency resuscitation may be required to revive the infant. Treatment is targeted at the underlying condition.

Nursing Management

After ALTE, many infants are admitted to the hospital for evaluation and cardiorespiratory monitoring. Assess the infant's responsiveness and behavior (e.g., irritability or unexplained sleepiness). Monitor vital signs, and assess the child's growth. The focus of the physical examination is to detect signs of injury, infection, neurologic abnormalities, or features suggestive of a genetic or metabolic syndrome.

Attach a cardiorespiratory monitor and pulse oximeter to continuously assess the heart rate, respiratory rate, and oxygenation status while the infant is awake and asleep. Because the infant who has had ALTE may be at risk for cardiopulmonary arrest, keep emergency resuscitation equipment and drugs readily accessible at all times.

Provide emotional support. Establishing rapport and open communication with the parents is essential for creating a sense of trust. To obtain further information about the episode, use

open-ended questions and active listening skills. Parents are fearful and anxious about the infant's prognosis. Explanations of tests and treatment help to decrease their anxiety and increase their understanding of the situation.

Encouraging parents' participation in the infant's care helps to promote the infant's sense of security, and it promotes family bonding. Teach parents how to hold the infant without disconnecting the monitoring cables. Wrapping the cable inside the infant's blanket helps secure the wires, increasing parents' feelings of confidence in handling the infant.

Support the mother to continue breastfeeding and maintaining a supply of breast milk by pumping, if necessary. Ensure that the mother gets adequate fluids and nutrition. Provide privacy for breast pumping, and store breast milk for future feedings.

DISCHARGE PLANNING AND HOME CARE TEACHING

Address home care needs in advance of the infant's discharge. Review guidelines for safe sleep positions. Some infants may be discharged with a cardiorespiratory monitor. Teach parents how to operate the monitor, what to do when the infant has an apnea episode, and how to perform cardiopulmonary resuscitation (CPR) and choking-intervention techniques (see the *Clinical Skills Manual* SKILLS). See *Families Want to Know: Home Care Instructions for the Infant Requiring a Cardiorespiratory Monitor.*

Obstructive Sleep Apnea

Obstructive sleep apnea syndrome (OSAS) is a disorder of breathing during sleep that involves increased respiratory resistance leading to recurrent episodes of partial and complete upper airway obstruction that disrupt normal ventilation during sleep and sleep patterns (Marcus et al., 2012). This results in labored breathing and snoring when the child tries to move air past the obstruction. OSAS is believed to affect 1% to 5% of school-age children (Marcus et al., 2012).

The upper airway contains about 30 muscles that permit the pharynx to collapse, enabling the child to talk and swallow, but also maintain airway patency. When the child is awake, muscle tone is maintained and the airway remains patent even when potential obstructions are present. During sleep, the airway muscles relax, the pharynx becomes obstructed, and airway resistance increases, leading to snoring. Reduced upper airway tone and obstruction cause apnea episodes that lead to hypoxemia, hypercapnia, and an elevated blood pressure. Hypertrophy of the adenoids and tonsils is the most common

Families Want to Know

Home Care Instructions for the Infant Requiring a Cardiorespiratory Monitor

Apnea Equipment

- Review how the monitor operates, the lead wires, placement of skin electrodes and pulse oximetry sensor, and how to set the event recorder. Keep the battery fully charged, and keep the manual for troubleshooting handy.

Emergency Preparation

- Have an emergency plan and complete an emergency information form about the infant's health problem. Notify the telephone company, electric company, local ambulance service, and the local emergency department (to get priority service status).
- Post the emergency response phone numbers by all phones and save in cell phones, along with the phone numbers for the healthcare provider, medical equipment company, power company, neighbor, and key family members.
- Take a cardiopulmonary resuscitation (CPR) course.

Safety Precautions

- Place monitor on firm surface; keep away from other appliances (television, microwave oven) and water.
- Ensure that alarms are audible from all locations.
- Double-check that the monitor and event recorder are on before putting the infant down for a nap or at bedtime.
- Thread cable and wires through lower end of infant's clothes.
- Ensure integrity of leads, monitor cable, and power cord (replace if frayed).

Routine Care

- Explain the reasons for the apnea monitor and frequency of use. Use it whenever the infant sleeps. Review the manual for troubleshooting.
- Show how to attach and detach infant chest leads and belt. Evaluate the skin for irritation or sores under the electrodes, and move the electrode if skin is irritated. Use no oils or lotions on the chest.

Responding to an Alarm

- Observe the infant for breathing first to determine if this is a real event or a loose lead.
- Stimulate the infant if respirations are absent or infant is lethargic. Start by calling the infant's name and gently touching, proceeding to vigorous touch if needed.
- If no response, proceed with CPR and call 9-1-1.
- If a loose lead is suspected, determine if electrode patches are loose. Check the wires from the electrode or monitor cable. Check the power supply. Is the monitor malfunctioning?

cause of OSAS, followed by craniofacial abnormalities, obesity, and neuromuscular disorders (e.g., cerebral palsy, muscular dystrophy).

Children with OSAS snore and have labored breathing during sleep such as retractions and paradoxical breathing. After snoring or breathing pauses, the child may snort, gasp, choke, move, or arouse to take a breath. Sleep is restless and the child may sleep in unusual positions to hyperextend the neck and airway. Symptoms of sleep deprivation (daytime sleepiness, poor attention, aggression, acting-out behavior, and poor school performance) may be noted. The child may also have enuresis, a morning headache, obesity, hypertension, failure to thrive, and cardiac dysfunction.

Healthy People 2020

(SH-1) Increase the proportion of persons with symptoms of obstructive sleep apnea who seek medical evaluation

Initial diagnosis occurs with a detailed history about snoring. **Polysomnography**, a sleep study that simultaneously records the sleep state, gas exchange, breathing efforts, cardiac rhythm, and muscle activity and movement, is performed. Adenotonsillectomy (adenoidectomy and tonsillectomy) is the most common treatment for OSAS, and the condition resolves in the majority of children. Children are evaluated 6 to 8 weeks after adenotonsillectomy to determine if some degree of OSAS persists that needs other treatment. Continuous positive airway pressure (CPAP) is used for children with surgical contraindications or those with persistent OSAS (craniofacial anomalies or neuromuscular disorders) after adenotonsillectomy. Weight loss strategies may be implemented for children with obesity. Some children with mild OSAS may be treated with nasal steroids. Without treatment, complications can include failure to thrive, pulmonary hypertension, **cor pulmonale** (obstruction of pulmonary blood flow that leads to right ventricular hypertrophy and heart failure), systemic hypertension, and cognitive impairment.

Nursing Management

In the community setting, all children should be screened for snoring as part of their routine health care. Assess the child for signs of nasal obstruction, mouth breathing, and enlarged tonsils. Determine if the child has symptoms of sleep deprivation or if a condition is present that places the child at high risk for OSAS. When snoring is present, encourage the family to keep a sleep diary.

When a polysomnogram is ordered, talk with the parents about how to prepare the child for the strange setting and wires that will be attached during the sleep study. Most pediatric centers will allow the parent to stay with the child during the study.

Following adenotonsillectomy, the child with OSAS is commonly hospitalized overnight because respiratory complications may occur. The hospital nurse monitors the child for bleeding and respiratory distress, such as obstructive sleep apnea and pulmonary edema. Continuous pulse oximetry is used to detect oxygen desaturation. See Chapter 19 for care of the child having adenoidectomy and tonsillectomy.

Sleep center nurses provide education and support to families of children who need to use CPAP to treat OSAS. The nurse helps identify the best fitting mask or nasal prong system for CPAP delivery. Parents may need guidance about helping children go to sleep wearing the mask until they are accustomed to it.

Sudden Infant Death Syndrome

Sudden and unexpected infant death (SUID) is a leading cause of infant mortality. Sudden infant death syndrome (SIDS), a subset of SUID, is defined as the sudden death during sleep of an infant under 1 year of age that remains unexplained after a thorough investigation, including an autopsy, a review of the circumstances of death, and the clinical history. Some unexpected infant deaths may be classified as accidental suffocation or positional asphyxia (e.g., face against bedding or rolled from side to abdomen) depending on the circumstances. SIDS is the third leading cause of infant mortality in the United States (Heron, 2013). Most SIDS deaths occur in infants between 2 and 4 months of age, and it accounts for 50% of SUID cases (Matthews & Moore, 2013). SIDs is currently unpredictable and, in some cases, unpreventable.

SIDS is called a "syndrome" because infants are believed to have a vulnerability that increases their risk for sudden death during the first 6 months of life, a critical period of developing homeostatic control. An environmental stressor (e.g. secondhand smoke, overheating, soft bedding, prone or side-lying position) compounds the vulnerability. Abnormalities associated with the neurotransmitter serotonin in the medulla oblongata may interfere with arousal responses during sleep in a critical development period (Matthews & Moore, 2013). See Table 20–3 for factors that place infants at risk for sudden infant death.

Typically, parents find the infant unresponsive in the crib in the morning or after a nap. They usually report hearing no cries or disturbances during the night. Clinical findings include evidence of a struggle or change in position during sleep and the presence of frothy, blood-tinged secretions from the mouth and nose.

TABLE 20–3 Risk Factors for Sudden Infant Death

INFANT RISK FACTORS
• Preterm or low birth weight, small for gestational age, multiple birth
• Native American and African American infants are at higher risk; Whites, Asians, and Hispanics are at lower risk
• Males are at higher risk
• Maternal smoking, alcohol use disorder, or substance abuse
• Socioeconomic disadvantages
ENVIRONMENTAL RISK FACTORS
• Sleeping prone or side-lying position
• Bed sharing—higher risk in infants 0–3 months old
• Soft bedding, pillows, blankets, and stuffed animals that infants roll into—higher risk in infants over 3 months old
• Overheating
• Secondhand tobacco smoke exposure

Nursing Management

The sudden, unexpected nature of the infant's death is often confirmed in the emergency department. The nurse's role is to be empathetic and provide support during one of the greatest crises a family must face. The focus is on supporting the family during the communication of bad news and the shock of the infant's death. See Chapter 13.

Reassure the parents that they are not responsible for the infant's death and help them contact other family members and mobilize support. Older children may need reassurance that SIDS will not happen to them. They may also believe that bad thoughts or wishes about their baby brother or sister caused the death. Support groups can help parents, siblings, and other family members express these fears and work through their feelings about the infant's death. The First Candle organization can help families locate a support group in their area.

Nurses play an important role in SUID and SIDS prevention. Educate the parents of all newborns and infants about the recommended infant sleep position—on the back on a firm surface. The Safe to Sleep Campaign, encouraging the placement of infants in the supine position for sleeping, was initiated in 1992 and has led to a 50% decrease in SIDS deaths (Flook & Vincze, 2012). However, no further reduction in deaths due to SUID or SIDS has been noted for the last decade. Ask parents to make sure the infant is placed to sleep on the back when cared for by another family member or childcare provider. Parents should also use a firm mattress and avoid the use of loose bedding, toys, and pillows. A sleeper suit rather than a blanket should be used to keep the infant warm while sleeping. See *Evidence-Based Practice: Infant Sleep Environment and Positioning*. A pacifier is also recommended for nap and bedtime (Task Force on Sudden Infant Death Syndrome, 2011). See Chapter 27 for issues related to infant skull flattening from sleeping on the back.

EVIDENCE-BASED PRACTICE | Infant Sleep Environment and Positioning

Clinical Question

In 2010, 13.5% of all infants were reported to be placed to sleep in the prone position (Matthews & Moore, 2013). An unknown number of infants are placed to sleep in a manner that increases their risk of suffocation. What strategies might help increase safe sleep environments and positioning for young infants?

The Evidence

A study used focus groups and interviews with 83 African American mothers from diverse socioeconomic groups to learn about surfaces and soft bedding used for their infants. Findings revealed that parents had different interpretations of firm bedding, and they believed that soft bedding (pillows, blankets, and crib bumper pads) increased the infant's comfort and, in some cases, safety. For example, parents believed that the surface was firm if a pillow or blanket was placed between the mattress and the sheet and the sheet was tucked tautly around the pillow or blanket. Misconceptions about firm and soft bedding increase the risk for suffocation and SIDS as the infant sleeps (Ajao, Oden, Joyner, et al., 2011).

A bed audit in a large neonatal intensive care unit (NICU) identified that only 39% of infants were sleeping in supine position, and 45% had no soft objects in their bed. A telephone survey to parents of infants discharged from the NICU identified only 23% of infants had safe sleep practices that met all criteria. A quality improvement initiative led to nursing guidelines and nursing education on safe sleep practices. An algorithm was developed to assess when an infant could be transitioned to supine sleep position. Cue cards were placed in an infant's crib when the infant met criteria to begin supine sleep positioning. The card reminded nurses to use and to begin educating parents about safe sleep practices. Parent education about safe sleep practices included a DVD and written discharge guidelines. A crib audit revealed an increase in supine sleep position use in eligible infants from 39% before interventions to 83% 3 months after the intervention. Rates also increased for firm bedding surface and no soft items in the bed. A follow-up survey of parents after discharge also reflected a significant increase in safe sleep practices (23% before interventions and 82% after the intervention) (Gelfer, Cameron, Masters, et al., 2013).

A study investigated factors in the sleep environment by age of infants who died of SIDS or SUID. Data collected by state child death review teams for infants less than 12 months of age who died during sleep or in the sleep environment were analyzed for the following factors: infant and caregiver characteristics, object (e.g., clothing, blanket, bumper pads, stuffed toys) in the sleep environment, and sleep place and position. Bedsharing was associated with 69.2% of study infant deaths, and the rate was significantly higher in infants less than 3 months of age (73.8%) than in older infants (58.9%). Deaths in younger infants were less likely to be associated with an object in the sleep environment or a change in sleep position for supine or side-lying to prone. Older infants were more likely to die in the prone position and to have objects in the sleep environment (Colvin, Collie-Akers, Schunn, et al., 2014).

Best Practice

While the Safe to Sleep Campaign has successfully promoted supine sleep positions for infants, additional sleep environment factors can increase the risk for an infant's death during sleep. Parent education needs to focus on more than just supine positioning. Modeling the safe sleep environment and position for parents when infants are hospitalized is an effective message. As infants develop an ability to roll over and move in the bed, parents should be reminded to keep objects out of the bed, especially soft objects that can suffocate when the infant rolls from supine to prone. Nurses also need to understand a parent's perspective on issues such as bedding and bedsharing so that education can appropriately address beliefs and concerns.

Clinical Reasoning

Identify if policies exist for infant sleep position in the maternity and pediatric sections of your hospital. Conduct an audit of cribs and bassinets to determine what proportions of infants are sleeping in the supine position and if any objects are in the bed.

Developing Cultural Competence Safe Sleep for Infants

While African American infants are at higher risk for SIDS, many of these families do not follow guidelines for safe sleep practices, even when stating they have heard about recommendations to avoid bed sharing and to use supine sleep positioning for the infant. Reasons parents gave for not following medical advice included perceived safety (less risk of aspiration), convenience (do not have to walk to the crib), and better infant sleep quality when prone. Cultural and familial influences were a factor in not following medical advice (Gaydos et al., 2015). Nurses, when counseling about safe sleep, should more thoroughly explain the rationale for the safe sleep recommendations and address cultural and familial beliefs.

Croup Syndromes

Croup is a term applied to a broad classification of upper airway illnesses that result from inflammation and swelling of the epiglottis and larynx. The swelling usually extends into the trachea and bronchi. Viral croup syndromes include acute spasmodic laryngitis (spasmodic croup) and laryngotracheobronchitis (LTB). Bacterial croup syndromes include bacterial tracheitis and epiglottitis (see *Pathophysiology Illustrated: Airway Changes With Croup*).

Acute spasmodic laryngitis, LTB, and bacterial tracheitis affect a large number of children across all age groups in both genders. Epiglottitis, previously a common serious respiratory illness, is rare in the United States because of the *Haemophilus influenzae* type B vaccine. The initial symptoms of all four conditions include inspiratory stridor (a high-pitched, musical sound that is created by narrowing of the airway), a "seal-like" barking cough, and hoarseness. Acute spasmodic croup and LTB are the most common disorders, but epiglottitis and bacterial tracheitis are more serious. See Table 20–4 for information on the etiology, clinical manifestations, and clinical therapy for these disorders.

Clinical Tip

A review of several studies evaluated the relationship between breastfeeding and SIDS. Findings revealed that breastfeeding for any period of time is protective, and greater protection occurs if breastfeeding is exclusive (Hauck, Thompson, Tenabe, et al., 2011). Place hospitalized infants to sleep in supine position rather than side-lying or prone.

SAFETY ALERT!

Throat cultures and visual inspection of the inner mouth and throat are contraindicated in children with LTB and epiglottitis. These procedures can cause **laryngospasms** (spasmodic vibrations that close the larynx) as a result of the child's anxiety or of probing this reactive and already compromised area. A complete airway obstruction may result.

Pathophysiology Illustrated: **Airway Changes With Croup**

Upper airway tissues respond to the invading virus with inflammation and edema. The epiglottis swells, occluding the airway, and the trachea swells against the cricoid cartilage, narrowing the airway. Copious secretions increase the respiratory distress and can obstruct the airway.

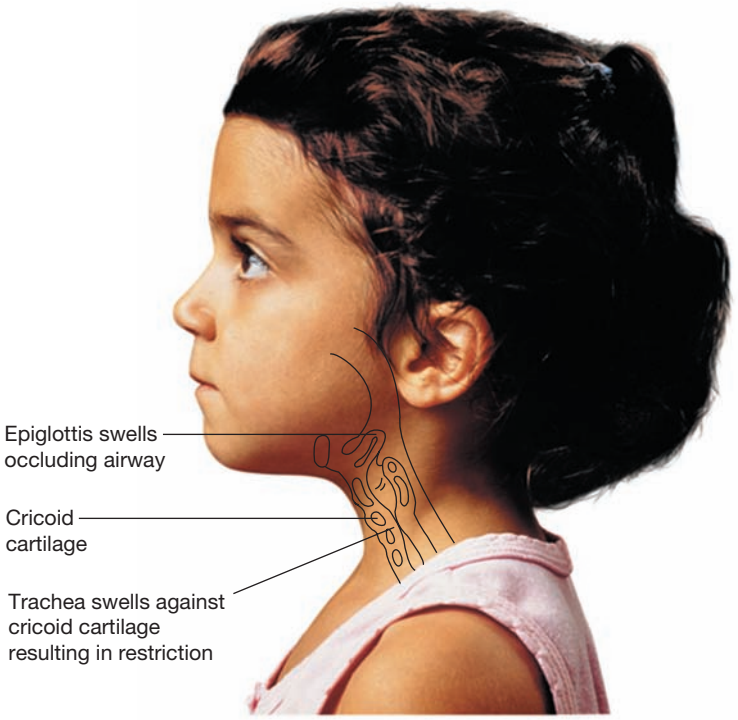

TABLE 20–4 Summary of Croup Syndromes

	VIRAL SYNDROMES		BACTERIAL SYNDROMES	
	ACUTE SPASMODIC LARYNGITIS (SPASMODIC CROUP)	LARYNGOTRACHEITIS/ LARYNGOTRACHEO-BRONCHITIS (LTB)	BACTERIAL TRACHEITIS	EPIGLOTTITIS (SUPRAGLOTTITIS)
Etiology	Recurrent; suspect allergies with sensitivity to viruses that cause LTB; also associated with gastroesophageal reflux	Parainfluenza, types I, II and III, RSV, influenza, enteroviruses, adenoviruses, or *Mycoplasma pneumoniae*	*Staphylococcus*, *Moraxella catarrhalis*, and nontypeable *H. influenzae*; may follow viral LTB as a secondary infection	*Haemophilus influenzae*, Group A beta-hemolytic streptococcus, staphylococcus
Severity	Least serious	Serious; progresses if untreated	Can be life threatening; requires close observation	Most life threatening (medical emergency)*
Age affected	3 months to 8 years	3 months to 3 years	1 month to 13 years*	2 years to 8 years
Onset	Abrupt nighttime onset; resolves over 24 to 48 hours; recurs*	Gradual onset as a URI, progressing to respiratory distress and potential airway obstruction over 24 to 48 hr	Progressive over 2 to 5 days, may present like LTB initially but condition worsens after LTB treatment	Progresses rapidly (hours)*; may progress to complete airway obstruction
Clinical manifestations	Afebrile; mild respiratory distress; barking-seal cough; signs of respiratory infection are not present*	*Early:* mild fever (less than 40.0°C [102.2°F]); barking-seal, brassy, croupy cough; rhinorrhea; sore throat; stridor (inspiratory); apprehension; restless or irritable May progress to retractions; increasing stridor; cyanosis	High fever (higher than 39.0°C [102.2°F]); URI appears as viral croupy cough and croup initially; stridor (tracheal); purulent secretions; child often prefers to lie flat; toxic appearance; dysphagia and drooling area rarely present	High fever (higher than 39.0°C [102.2°F]); URI; intense sore throat; dysphagia*; drooling*; increased pulse and respiratory rate; prefers upright position (tripod position with neck extended)*; cherry red epiglottis; barking cough is absent*
Clinical therapy	Oral dexamethasone; treatment for gastroesophageal reflux may reduce recurrences; other airway disorders may need to be considered such as aspirated foreign body	Oral dexamethasone; nebulized epinephrine for severe symptoms; supplemental oxygen if hypoxic; monitor for airway obstruction	May have initial treatment for LTB but condition worsens; blood cultures, endotracheal intubation to protect the airway, and intravenous antibiotics	Immediate endotracheal intubation to protect the airway, supplemental oxygen, blood cultures, culture of epiglottis, intravenous antibiotics for gram-positive organisms that are changed as needed to match culture sensitivities

* Classic signs that distinguish the condition.

Source: Data from Roosevelt, G. E. (2016). Acute inflammatory upper airway obstruction (croup, epiglottitis, laryngitis, and bacterial tracheitis). In R. M. Kliegman, B. F. Stanton, J. W. St. Geme, & N. F. Schor (Eds.), *Nelson textbook of pediatrics* (20th ed., pp. 2031–2036). Philadelphia, PA: Elsevier; Sharma, G. D., & Conrad, C. (2011). Croup, epiglottitis, and bacterial tracheitis. In American Academy of Pediatrics Section on Pediatric Pulmonology, *Pediatric pulmonology* (pp. 347–363). Elk Grove Village, IL: Author; Zoorob, R., Sidani, M., & Murray, J. (2011). Croup: An overview. *American Family Physician, 83*(9), 1067–1073.

Emergency management consists of maintaining and improving respiratory effort with medications, and, in some cases, supplemental oxygen. Children with acute spasmodic croup and LTB who respond well to oral medication are often sent home from the emergency department after an observation period. Children with moderate to severe symptoms may need additional nebulized epinephrine, and may be admitted for further treatment if the respiratory status does not improve. Most children who are admitted respond to medications and oxygen therapy and are discharged within 48 to 72 hours.

Clinical Tip

No studies of therapies for acute spasmodic croup or LTB support routine exposure of the child to cold air, decongestants, or cough medications (Zoorob, Sidani, & Murray, 2011). However, some children with mild recurrent acute spasmodic croup get relief from exposure to cold air or warm humidity in a closed bathroom with warm steam. Children who do not have relief from these complementary therapies should be seen by a healthcare provider for treatment.

Children with bacterial tracheitis and epiglottitis have a more severe airway obstruction. These children usually are intubated in the operating room because the obstruction can rapidly become life threatening. These children are then transferred to the PICU for care.

Nursing Management

For the Child With Croup Syndrome

Nursing Assessment and Diagnosis

The initial and ongoing physical assessment of the child with one of the croup syndrome disorders focuses on adequacy of respiratory functioning and severity of illness. Attach a cardiorespiratory monitor and pulse oximeter. Have the child in an area where continuous visual monitoring is possible to detect changes in severity of respiratory distress. Assess vital signs, including temperature.

Pay particular attention to any progressive changes in the child's respiratory effort that may signal the need for intubation. Regularly assess the respiratory rate, heart rate,

retractions, use of accessory muscles, stridor, breath sounds, preferred position, and responsiveness (Figure 20–2). Exhaustion can diminish the intensity of retractions and stridor. As the child uses remaining energy reserves to maintain ventilation, breath sounds may actually diminish. Noisy breathing (audible airway congestion, coarse breath sounds) in this situation verifies adequate energy stores. Responsiveness decreases as hypoxemia increases.

SAFETY ALERT!

If the child is suspected of having epiglottitis or a severe airway obstruction, do not leave the child's side until intubation occurs. Observe the child continuously for inability to swallow, absence of voice sounds, increasing degree of respiratory distress, and acute onset of drooling. A change in the child's level of consciousness—from anxiety to lethargy to stupor—occurs as hypoxia increases. If any of these signs occur, get medical assistance immediately. The quieter the child, the greater the cause for concern.

The following nursing diagnoses might be appropriate for the child with a croup syndrome disorder (NANDA-I © 2014):

- ***Breathing Pattern, Ineffective,*** related to airway narrowing, decreased energy, and fatigue
- ***Fluid Volume: Deficient, Risk for,*** related to fever and swallowing difficulty
- ***Fear (Child)*** related to dyspnea, unfamiliar surroundings, procedures, and separation from support system

Figure 20–2 Children with severe respiratory distress and a narrowed airway often sit in a tripod position, leaning forward with arms on the legs. The head and neck are extended with the jaw thrust forward to help keep the airway open. This position may also be seen in a child with an acute asthma flare.

Planning and Implementation

MAINTAIN AIRWAY PATENCY

Allow the child to assume a comfortable position. Be immediately available to attend to the child's respiratory needs, and keep resuscitation equipment and an intubation tray at the bedside. Supplemental oxygen with humidity may be needed for hypoxemia. Ensure that a means of communication (sign language or simple word cues) is established so the older child can alert nursing staff to respiratory difficulty.

Postpone anxiety-provoking procedures such as venipuncture until the airway is considered to be secure. Anxiety associated with procedures often causes increased respiratory distress. Crying stimulates the airway, increases oxygen consumption, and in some cases, such as epiglottitis, can precipitate laryngospasm that can obstruct the airway.

When the child is intubated, care is provided in the PICU to ensure continual observation (see the *Clinical Skills Manual* SKILLS). Provide humidified air or supplemental oxygen if prescribed. The child with bacterial tracheitis needs frequent suctioning because of thick tracheal secretions that pool in the upper airway.

MEET FLUID AND NUTRITIONAL NEEDS

The illness preceding the emergency department visit may have compromised the child's fluid status, or the child may have difficulty swallowing because of inflammation. Recognize the potential fluid deficit and monitor the child's hydration and nutritional status. Fluids help thin secretions and provide calories for energy and metabolism.

When the child can drink fluids provide cool, noncarbonated, nonacidic drinks such as oral rehydration fluids or fruit-flavored drinks, gelatin, and popsicles. Encourage the parents to gain the child's cooperation in taking oral fluids. When the child's airway is compromised an intravenous infusion is needed to rehydrate the child, maintain fluid balance, or provide emergency access.

ADMINISTER MEDICATIONS

Administer medications as prescribed. Children with acute spasmodic laryngitis and LTB are treated with oral dexamethasone, and some children need nebulized epinephrine. Children with bacterial tracheitis or epiglottitis are initially treated with IV antibiotics until inflammation is reduced and the airway becomes stable without an endotracheal tube. Antibiotics are then administered orally.

PROVIDE FAMILY SUPPORT

Support parents who may be very anxious about the abrupt onset of life-threatening respiratory distress. When the child is intubated, reassure the child and family that their inability to make sounds is temporary. Explain the need for various pieces of equipment to help reduce the child's stress.

DISCHARGE PLANNING AND HOME CARE TEACHING

During the child's observation period for acute spasmodic laryngitis and LTB, educate the parents about actions to take if symptoms recur. For example, the child should return to the healthcare provider if:

- Mild symptoms do not improve after 1 hour of exposure to cool outdoor air or air conditioning.
- The child's breathing is rapid and labored with nasal flaring and retractions.
- The child does not drink adequate fluids and the urine output is reduced.

Ensure that parents of children with bacterial tracheitis or epiglottitis understand the importance of completing the full course of antibiotics.

Evaluation

Expected outcomes of nursing care include the following:

- The child responds to medications with decreased respiratory distress.
- The child's fear and anxiety is managed with family support and explanations about care.

Lower Airway Disorders

Lower airway disorders occur because a structural or functional problem interferes with the lungs' ability to complete the respiratory cycle. Disorders of the lower airway include bronchitis, bronchiolitis, pneumonia, and tuberculosis.

Bronchitis

Acute bronchitis, inflammation of the trachea and bronchi, rarely occurs in childhood as an isolated problem. The bronchi can be affected simultaneously with adjacent respiratory structures during a respiratory illness. Bronchitis occurs most commonly in the winter months.

The classic symptom of bronchitis is a dry, hacking cough that increases in severity at night. The cough may or may not be productive. The child may swallow sputum and vomit as a result. The chest and ribs may be sore because of the deep and frequent coughing. Over several days breath sounds may become coarse with fine crackles, and some scattered high-pitched wheezing may be heard. Treatment is palliative unless a secondary bacterial infection occurs that needs antibiotic therapy.

Nursing Management

Nursing management includes supporting respiratory function through rest, humidification, hydration, and symptomatic treatment. Refer to the sections in this chapter on asthma and pneumonia for detailed information on treatment measures.

Home care should emphasize the self-limiting nature of the disorder. Advise parents who smoke that quitting or not smoking in the child's presence may benefit the child.

Bronchiolitis and Respiratory Syncytial Virus

Bronchiolitis is a lower respiratory tract illness that occurs when a viral or bacterial organism causes inflammation and obstruction of the bronchioles. It is a leading cause of hospitalization during the first year of life (Weinberger, 2011). Infants who develop bronchiolitis have an increased risk for recurrent wheezing during the first year of life (Blanken et al., 2013).

ETIOLOGY AND PATHOPHYSIOLOGY

Respiratory syncytial virus (RSV) is the most common cause of bronchiolitis, but adenovirus, parainfluenza virus, and human metapneumovirus may also be responsible. RSV occurs in annual epidemics from October to March. It is transmitted through direct contact with respiratory secretions or indirectly through contaminated surfaces. The infected child sheds the virus for 3 to 8 days, and the incubation period is 2 to 8 days. Nearly all children have been infected with RSV by 2 years of age, and reinfection throughout life is common (American Academy of Pediatrics [AAP], 2015, p. 667–668). Risk factors for severe RSV infection include immunosuppression, very low birth weight, lung disease, severe neuromuscular disease, or complicated congenital heart defects (Brashers & Huether, 2014).

Viruses, acting as parasites, are able to invade the mucosal cells that line the small bronchi and bronchioles. The invaded cells die when the virus bursts from inside the cell to invade adjacent cells. The membranes of the infected cells fuse with adjacent cells, creating large masses of cells or "syncytia." The resulting cell debris clogs and obstructs the bronchioles and irritates the airway. In response, the airway lining swells and produces excessive mucus. Despite this protective effort by the bronchioles, the actual effect is partial airway obstruction and bronchospasms.

The cycle is repeated throughout both lungs as the airway cells are invaded by the virus. The partially obstructed airways allow air in, but the mucus and airway swelling cause air trapping, and hyperinflation of the alveoli. Areas of atelectasis may occur. Normal gas exchange is affected, leading to hypoxemia. The child with severe RSV is at risk for apnea and respiratory failure as hypoxemia and hypercarbia develop.

CLINICAL MANIFESTATIONS

Some children have mild symptoms such as rhinitis, cough, low-grade fever, wheezing, tachypnea, poor feeding, vomiting, and diarrhea. Dehydration may be present if the child has been sick for several days. Parents report that the infant or child is acting more ill—appearing sicker, less playful, and less interested in eating. Infants, especially, may refuse to feed or may spit up what they eat along with thick, clear mucus.

The infant or child with a more severe infection has tachypnea greater than 70 breaths per minute, grunting, increased wheezing, crackles, retractions, nasal flaring, irritability, lethargy, poor fluid intake, and a distended abdomen from overexpanded lungs. As hypoxia develops the infant becomes cyanotic and has decreasing mental status. As the airflow continues to decrease, breath sounds diminish. Thus the noisier the lungs, the better, as this indicates that the child is still able to move air in and out of the lungs. Although RSV bronchiolitis resolves in 5 to 7 days, increased airway resistance and airway hypersensitivity may persist for weeks or even months.

CLINICAL THERAPY

The history and physical examination provide the data needed to diagnose bronchiolitis. Chest radiographs show hyperinflation, patchy atelectasis, and other signs of inflammation. Enzyme-linked immunoabsorbent assay (ELISA) or immunofluorescent assay performed on a posterior nasopharyngeal wash or swab specimen are used to identify the virus causing bronchiolitis (see the *Clinical Skills Manual* SKILLS).

Treatment is supportive. Most children have mild disease and can be managed at home. See *Families Want to Know: Home Care for the Infant With Mild Bronchiolitis.* The child is placed on respiratory and contact isolation when hospitalized to minimize the spread of the virus to other hospitalized children. Humidified oxygen is provided to infants with severe hypoxemia. Other supportive care includes hydration with oral or IV fluids and nasal suctioning before feeding. Continuous positive airway pressure (CPAP) may be used in the child with moderate to severe bronchiolitis. Chest physiotherapy is not recommended (Niergarten, 2015).

Few medications are prescribed for RSV and bronchiolitis. Bronchodilators, corticosteroids, and epinephrine are not recommended. Antipyretics may be used. Nebulized hypertonic saline (3%) may be used in hospitalized infants. Antibiotics are used only when a bacterial infection is present (Nierengarten, 2015).

Families Want to Know

Home Care for the Infant With Mild Bronchiolitis

General care instructions:

- Use the bulb syringe to suction the nares of an infant under 1 year of age.
- Give fluids to help thin secretions and provide calories for energy.
- Encourage active toddlers to rest and take naps during recovery.

Advise parents to call the physician if:

- Respiratory symptoms interfere with sleeping or eating.
- Breathing is rapid or difficult.
- Symptoms persist in a child who is less than 1 year old, has heart or lung disease, or was premature and had lung disease after birth.
- The child acts sicker—appears tired, less playful, and less interested in food (parents just "feel" the child is not improving).

Prevention of RSV is a focus for children at highest risk for severe bronchiolitis. Examples include infants born prematurely (less than 32 weeks' gestation) and those who required supplemental oxygen for several weeks after birth. Some children less than 2 years of age being treated for chronic lung disease of prematurity, congestive heart failure, or pulmonary hypertension are also at higher risk. The American Academy of Pediatrics has specific criteria for selecting children to receive passive immunity protection (AAP, 2015, pp. 673–675).

Intramuscular palivizumab (Synagis) provides passive immunity to help protect these high-risk infants. A dose of 15 mg/kg is given every 30 days for 5 months beginning in October or November at the onset of the RSV season. Palivizumab is expensive, but it is believed to offer benefits to the infants at high risk who might require hospitalization for RSV. Palivizumab does not interfere with administration of normal recommended childhood vaccines (AAP, 2015, p. 40).

Nursing Management

For the Child With Bronchiolitis and RSV

Nursing Assessment and Diagnosis

PHYSIOLOGIC ASSESSMENT

Assess airway and respiratory function carefully. Good observation skills are important to ensure timely interventions for worsening respiratory symptoms and prevention of respiratory failure (see the *Assessment Guide* and Table 20–2 earlier in this chapter). Assess the child's hydration status, weigh the child daily, and monitor the intake and output. Attach a cardiorespiratory monitor and pulse oximeter. An oxygen saturation level below 90% is the best indicator of the condition's severity.

SAFETY ALERT!

RSV bronchiolitis often increases in severity before beginning to resolve. Stay alert for signs of increasing respiratory distress and a greater need for oxygen. Signs of life-threatening illness include central cyanosis, respiratory rate greater than 70 breaths a minute, listlessness, diminished breath sounds, and apneic episodes. Inform the physician immediately of any significant changes in respiratory status.

PSYCHOSOCIAL ASSESSMENT

Observe children and their parents for signs of fear and anxiety. The unfamiliar hospital environment and procedures can increase stress. Parents' questions, as well as their nonverbal cues, help direct nursing interventions during admission and throughout hospitalization.

The accompanying *Nursing Care Plan: The Child With Bronchiolitis* lists common nursing diagnoses for the child with bronchiolitis. Others that might also be appropriate include (NANDA-I © 2014):

- ***Airway Clearance, Ineffective,*** related to increased airway secretions in bronchioles
- ***Activity Intolerance*** related to imbalance between oxygen supply and demand
- ***Family Processes, Interrupted,*** related to sudden acute illness of the infant

Planning and Implementation

Nursing management of the hospitalized child with bronchiolitis focuses on maintaining respiratory function, supporting overall physiologic function and hydration, reducing the child's and family's anxiety, and preparing the family for home care.

MAINTAIN RESPIRATORY FUNCTION

Close monitoring is essential to evaluate the child's improvement or to spot early signs of deterioration. Patent nares are important to promote oxygen intake. A bulb syringe and saline nose drops can be used to quickly clear the nasal passages. Elevate the head of the bed to ease the work of breathing and drain mucus from the upper airways. Supplemental oxygen with humidity may be provided via nasal cannula, mask, hood, or tent. When the child resists or is frightened by the oxygen apparatus, engage the parent to soothe the child and promote acceptance of the therapy.

SUPPORT PHYSIOLOGIC FUNCTION

Group nursing tasks to decrease stress and promote rest. Medications may be administered to control temperature and promote comfort as needed. Infants may have feeding difficulty and are at risk for aspiration. Suction the nasal passages before giving oral feedings. Feed smaller volumes more frequently to help conserve energy in infants who are formula-fed or breastfed. When the risk of aspiration is high, nasogastric tube feedings may be used to provide nutrition. An IV infusion may be ordered to rehydrate the child and maintain fluid balance until oral fluid intake is adequate.

Nursing Care Plan: The Child With Bronchiolitis

1. Nursing Diagnosis: *Breathing Pattern, Ineffective,* related to increased work of breathing (NANDA-I © 2014)

GOAL: The child will return to respiratory baseline and will not experience respiratory failure.

INTERVENTION	RATIONALE
• Assess respiratory status (see *Assessment Guide*) when child is calm and not crying at least every 2–4 hr, or more often as indicated for an increasing or decreasing respiratory rate and episodes of apnea.	• Changes in breathing pattern may occur quickly as the child's energy reserves are depleted. Baseline and subsequent assessments help detect changes in the respiratory rate and respiratory effort.
• Attach a cardiorespiratory monitor and pulse oximeter with alarms set. Record and report changes promptly to physician.	• The alarm can alert the nurse to any sudden respiratory changes and lead to more rapid interventions.

EXPECTED OUTCOME: Child will return to respiratory baseline within 48–72 hr.

GOAL: The child's oxygenation status will return to baseline.

INTERVENTION	RATIONALE
• Administer humidified oxygen via mask, nasal cannula, hood, or tent.	• Humidified oxygen loosens secretions, helps maintain oxygenation status, and eases respiratory distress.
• Assess and compare the child's SpO_2 level on room air and when on supplemental oxygen.	• Comparison of SpO_2 levels provides information about improvement status.
• Note child's response to ordered medications.	• Medications act systemically to improve oxygenation and decrease inflammation.
• Position head of bed up or place child in position of comfort on parent's lap, if crying or struggling in crib or bed.	• Position facilitates improved aeration and promotes decrease in anxiety (especially in infants) and energy expenditure.
• Assess tolerance to feeding and activities.	• Provides an assessment of condition improvement.

EXPECTED OUTCOME: Child's respiratory effort will ease. The SpO_2 level will remain above 90% during treatment. Child will tolerate therapeutic measures with no adverse effects. Child will rest quietly in position of comfort.

2. Nursing Diagnosis: *Fluid Volume: Deficient, Risk for,* related to inability to meet body requirements and increased metabolic demand (NANDA-I © 2014)

GOAL: The child's immediate fluid deficit will be corrected.

INTERVENTION	RATIONALE
• Evaluate need for intravenous fluids. Maintain IV, if ordered.	• Previous fluid loss may require immediate replacement.

EXPECTED OUTCOME: Child's hydration status will be maintained during acute phase of illness as demonstrated by appropriate urine output and moist mucous membranes.

GOAL: The child will be adequately hydrated, be able to tolerate oral fluids, and progress to normal diet.

INTERVENTION	RATIONALE
• Calculate maintenance fluid requirements and give oral fluids, IV fluids, or both.	• Assessment of fluid requirements enables the child to maintain hydration while transitioning to oral fluids.
• Offer clear fluids and incorporate parent in care. Offer fluid choice when tolerated.	• Choice of fluid offered by parent gains the child's cooperation.
• Maintain strict intake and output monitoring and evaluate specific gravity at least every 8 hours.	• Monitoring provides objective evidence of fluid loss and ongoing hydration status.
• Perform daily weight measurement on the same scale at the same time of day. Evaluate skin turgor.	• Further evidence of improvement of hydration status.
• Assess mucous membranes and presence of tears.	• Moist mucous membranes and tears are signs of adequate hydration.

EXPECTED OUTCOME: Child will take adequate oral fluids after 24–48 hr to maintain hydration. Child will accept beverage of choice from parent or nursing staff. Child's weight will stabilize after 24–48 hr; skin turgor will be supple. Child will show evidence of improved hydration.

3. Nursing Diagnosis: *Anxiety (Child and Parent)* related to acute illness, hospitalization, uncertain course of illness and treatment, and home care needs (NANDA-I © 2014)

GOAL: The child and parents will demonstrate behaviors that indicate less anxiety.

INTERVENTION	RATIONALE
• Encourage parents to express fears and ask questions; provide direct answers and discuss care, procedures, and condition changes.	• Parents have the opportunity to vent feelings and receive timely, relevant information. This helps reduce parents' anxiety and increase trust in nursing staff.
• Incorporate parents in the child's care. Encourage parents to bring familiar objects from home. Ask about and incorporate in care plan the home routines for feeding and sleeping.	• Familiar people, routines, and objects decrease the child's anxiety and increase parents' sense of control over an unexpected, uncertain situation.

EXPECTED OUTCOME: Parents and child will show less anxiety as symptoms improve and as child and parents feel more secure in hospital environment. *Parents* will freely ask questions and participate in the child's care. *Children* will cry less and allow themselves to be touched or held by staff.

GOAL: Parents will verbalize knowledge of bronchiolitis symptoms and use of home care methods before the child's discharge from the hospital.

INTERVENTION	RATIONALE
• Explain symptoms, treatment, and home care of bronchiolitis.	• Anticipating the potential for recurrence assists the family to be prepared should respiratory symptoms recur after discharge.
• Provide written instructions for follow-up care arrangements, as needed.	• Written and verbal instructions reinforce knowledge. Parents may not "hear" and remember details if only given verbally.
• Make sure parents can read the instructions provided in family's primary language.	• Many families have reading difficulties or may read a language other than English.

EXPECTED OUTCOME: Parents will accurately describe respiratory symptoms and initial home care actions.

REDUCE ANXIETY

The need for hospitalization and assistive therapies creates anxiety and fear in the child and parents. The parents may be frightened by the child's continued respiratory difficulty. Infants may respond to their parents' anxiety and be more irritable. Provide parents with thorough explanations and daily updates, and encourage their participation in the child's care. Reassure them that holding or touching the child will not dislodge wires or tubing, and that their presence will calm and support the child.

If the child has been ill for a few days before admission, the parents are likely to be tired. Acknowledging parents' physical and emotional needs creates a spirit of caring and enhances communication between staff and family. Encourage the parents to take turns at the child's bedside and to take breaks for meals and rest.

DISCHARGE PLANNING AND HOME CARE TEACHING

The child is discharged once oxygenation is stable (pulse oximetry at least 90%) on room air and full oral feedings have been possible for at least 12 hours (Weinberger, 2011). In most children, respiratory efforts and decreased mucus production decrease within 24 to 72 hours, but all symptoms like coughing may take weeks to resolve.

Teach the parents proper administration of medications. Acetaminophen or ibuprofen may be prescribed for persistent low-grade fevers and general discomfort. Advise parents that RSV infection can recur. Educate them to recognize symptoms and when to call the healthcare provider.

Evaluation

Expected outcomes of nursing care for the child with bronchiolitis are provided in the *Nursing Care Plan*.

Pneumonia

Pneumonia, an inflammation or infection of the bronchioles and alveolar spaces of the lungs, occurs most often in infants and young children. More than 150,000 children are hospitalized for pneumonia annually in the United States (Queen et al., 2014). Pneumonia can be community acquired (CAP) or hospital acquired (e.g., associated with mechanical ventilation). The focus of this discussion is CAP.

Pneumonia may be viral, mycoplasmal, or bacterial in origin. Viral-bacterial coinfection also occurs. Children under 5 years of age most often have viral pneumonia caused by RSV, human metapneumovirus, influenza virus, parainfluenza virus, or adenovirus. Bacterial pneumonia occurs in all age groups. Mycoplasmal pneumonia is more common in children 5 years and older. Common bacterial organisms include *Streptococcus pneumoniae*, *Chlamydophila pneumoniae*, and *Staphylococcus aureus.* Group B streptococcus, enteric gram-negative bacilli, and *Chlamydia trachomatis* are found in infants younger than 3 months of age. Children with cystic fibrosis or immunosuppression are susceptible to other bacterial, parasitic, or fungal infections.

Bacterial and viral invaders act differently within the lungs:

- Bacteria enter the lungs after aspiration of nasopharyngeal bacteria and colonize in the trachea and bronchi.

Prior damage by a viral infection may damage the epithelium and reduce the child's ability to clear the organisms. Inflammation leads to edema and purulent exudates. Cellular debris and mucus cause airway obstruction. Bacteria tend to be distributed evenly throughout one or more lobes of a single lung, a pattern termed *unilateral lobar pneumonia.*

- Viruses enter through the upper respiratory tract, damaging the ciliated epithelium in the distal airway. Viruses invade and kill cells causing cell debris. The alveoli become infiltrated nearest the bronchi of one or both lungs. Adjacent areas become invaded in a scattered, patchy pattern referred to as bronchopneumonia.
- Aspiration of food, emesis, gastric reflux, or hydrocarbons causes a chemical injury and inflammatory response, which sets the stage for bacterial invasion.

Community acquired pneumonia is often preceded by an upper respiratory tract infection including rhinitis and a cough. Other symptoms include fever, rhonchi, crackles, wheezes, dyspnea, tachypnea, chest pain, restlessness, and abdominal pain. Newborns and infants may have tachypnea, grunting, nasal flaring, retractions, irritability, lethargy, and a poor appetite. Diminished breath sounds may be noted.

Diagnosis is based on history and physical findings. Rapid influenza and other respiratory virus testing is recommended to help distinguish between viral and bacterial causes of CAP. Bacterial pneumonia is more often associated with a higher fever, absolute neutrophil count, and percentage of bands (Brashers & Heuther, 2014). A chest radiograph and blood cultures may be performed when the child requires hospitalization.

Clinical management for all types of pneumonia includes pain and fever control, and supportive care through airway management, fluids, and rest. Children with severe CAP are hospitalized, and may be treated with antibiotics, supplemental oxygen, and IV fluids. Current antibiotic guidelines are high-dose ampicillin or amoxicillin for 5 days in children with uncomplicated CAP (Greenberg, Givon-Lavi, Sadaka, et al., 2014). Antiviral therapy is prescribed for some children.

Nursing Management

If the child with CAP is hospitalized, assess the child, paying particular attention to respiratory rate, heart rate, and temperature, and observe color for pallor or cyanosis. Attach a pulse oximeter to monitor the SpO_2 level. Assess hydration status. Assess for the presence of pain with coughing.

Nursing measures used for the child with bronchiolitis are generally applicable (see earlier section in this chapter). Teach the child and parent how to splint the chest by hugging a small pillow or teddy bear to make coughing less painful. Acetaminophen or ibuprofen may be prescribed for pain management and temperature control. Administer antibiotics as prescribed. Promote hydration and nutrition by encouraging the intake of preferred clear liquids and small servings of soft foods.

For home management, teach parents about administering prescribed antibiotics, any potential side effects, and the need to give the full course. Educate parents about signs that the child's condition may be worsening (increased breathing difficulty or refusal to take fluids). Most children recover uneventfully, but some continue to have worsening reactive airway problems or abnormal results on pulmonary function tests.

Preventive measures are limited. The *Haemophilus influenzae* type B (Hib) and pneumococcal conjugate (PCV13) vaccines protect against some causes of pneumonia. The 23-valent pneumococcal vaccine is recommended for children over 2 years of age with immunosuppression or some chronic conditions (see Chapter 16).

Tuberculosis

Tuberculosis (TB) is an infection caused by *Mycobacterium tuberculosis,* which is transmitted through the air in infectious particles called *droplet nuclei*. About 1000 active TB cases occur in children each year, and rates are highest among children and adolescents with at least one foreign parent (Starke & Cruz, 2014). Children account for 7% of all cases reported in the United States each year (Winston & Menzies, 2012).

ETIOLOGY AND PATHOPHYSIOLOGY

Children usually acquire a TB infection from infected adults who cough, sneeze, speak, or sing, and send out tiny droplets containing the bacillus. When inhaled, the bacillus is small enough to travel directly to the alveoli and cause infection. When the organism reaches the alveoli, an immune response is initiated, and macrophages surround and wall off the bacillus in a small hard capsule, called a *tubercle*. The tubercle bacilli grow slowly, dividing every 25 to 32 hours. The bacilli grow for 2 to 12 weeks until they number 1000 to 10,000, at which point the cellular immune response to a TB skin test (TST) would occur if the test were administered.

In persons with intact cell-mediated immunity, activated T cells and macrophages form granulomas around the tubercles that limit multiplication. The proliferation of TB is arrested, but small numbers of viable bacilli remain in the tubercle. These individuals have latent tuberculosis infection (LTBI), a positive TST, and no clinical or radiographic signs of disease. They are not infectious and cannot transmit the disease.

Active TB can develop as the bacilli grow, divide within the tubercle, and break free. Progression to active TB generally occurs within 1 year of infection in infants and adolescents, who have the greatest risk of transitioning from LTBI to active TB (Perez-Velez & Marais, 2012). Factors further increasing that risk include immunosuppressive therapy, HIV coinfection, immunodeficiency, malnutrition, and chronic medical conditions (AAP, 2015, p. 808). Most children under age 10 years with active TB are not contagious because they have small pulmonary lesions and unproductive coughing during which few or no bacilli are expelled (AAP, 2015, pp. 827).

Disseminated, or extrapulmonary, TB occurs more commonly in infants and young children. Bacilli are released from the primary site into the bloodstream, spreading to the liver, spleen, kidney, bone marrow, or meninges (miliary TB).

CLINICAL MANIFESTATIONS

Children with LTBI are asymptomatic. Children with pulmonary TB may have a persistent cough, weight loss or failure to gain weight, fever, fatigue, wheezing, and decreased breath sounds. Adolescents may have fever, anorexia, weight loss or growth delay, productive cough, and night sweats. **Hemoptysis** (coughing up blood from the respiratory tract) is a late sign of advanced pulmonary TB. When TB spreads outside the pulmonary system, additional signs are specific to the system invaded:

- *Superficial lymphadenitis:* firm, nontender, matted lymph nodes

- *Miliary:* high fever, vomiting, lethargy, headache, seizures, nuchal rigidity, cranial nerve palsies, and irritability; also hepatosplenomegaly and generalized lymphadenopathy
- *Osteoarticular:* inflammation, pain, swelling, fever, and limited range of motion of the affected bone or joint

CLINICAL THERAPY

Screening to identify a child's risk for LTBI should occur during the first health visit, every 6 months until age 2 years, and then annually. Administer a tuberculin skin test (intradermal purified protein derivative [PPD]) or collect blood for an interferon-gamma release assay (IGRA) if one or more of these risk factors are present (AAP, 2015, p. 812; Desale, Bringardner, Fitzgerald, et al., 2013; Rose et al., 2014; Seddon, Hesseling, Godfrey-Faussett, et al., 2013):

- The child's parents or family members immigrated from a country or region where TB is an established health problem, such as Asia, India, the Middle East, Africa, or Latin America.
- The child was born in one of the countries or regions mentioned.
- The child traveled to any of the countries or regions mentioned and had close contact with residents, such as residing in the home of residents, for a week or longer.
- A family member has tested positive with a PPD or IGRA.
- The child has clinical signs or radiologic findings that could be associated with TB.
- The child infected with HIV should have annual tuberculin testing.

A positive PPD or IGRA indicates that the child has been exposed to and infected with TB, and antibodies have been produced against the bacillus.

An interferon-gamma release assay (IGRA; e.g., quantiFERON or T.Spot.TB) may help clarify PPD findings. For example, a child vaccinated with bacille Calmette-Guérin (BCG) may have a false-positive response to multiple PPDs, but IGRA does not cross-react with BCG and gives a more accurate result (Riazi et al., 2012). Like the PPD, the IGRA cannot distinguish between latent or active TB. Other diagnostic tests include acid-fast stains of blood, gastric aspirate, sputum cultures, and a chest radiograph.

Active and latent TB are treated with isoniazid, rifampicin, pyrazinamide, and ethambutol. Therapy for active TB usually involves a 6-month regimen consisting of isoniazid, rifampin, pyrazinamide, and ethambutol for the first 2 months and isoniazid and rifampin for the remaining 4 months. LTBI in children less than 12 years of age is treated with a single daily dose of isoniazid for 9 months (or rifampin for 6 months if TB is drug resistant to isoniazid). Direct-observed drug therapy administered by a healthcare provider 2 times a week for the duration of treatment is recommended for children with active TB and when daily therapy adherence is not assured for children with LTBI (AAP, 2015, p. 816). Healthy youth with LTBI, ages 12 years and older, may receive once-weekly direct-observed drug therapy with isoniazid and rifampin for 12 weeks (Jereb, Goldberg, Powell, et al., 2011). Children with a positive PPD and negative IGRA who do not receive treatment for LTBI should be followed for 1 to 2 years to monitor for transition to active disease (Amanatidou, Syridou, Mavrikou, et al., 2012).

The local public health department is notified to search for disease contacts of the child with newly diagnosed LTBI or active TB. The child is considered a sentinel case and the adult contact with active TB must be identified.

Nursing Management

Assessment focuses on identifying children at high risk of TB exposure and performing a PPD as appropriate. Infant and young children with a positive PPD are at greater risk to develop active TB, so assess them carefully for weight loss, fever, fatigue, coughing, and respiratory status. Consider the child's immunosuppression status. If active TB is suspected, implement airborne isolation precautions until the infection status is known.

SAFETY ALERT!

Airborne isolation precautions are intended to protect the nurse as well as to reduce the risk for transmission of infection to other clients. Use all recommended personal protective equipment (PPE) correctly, perform hand hygiene, and appropriately dispose of linens, PPE, and trash to protect yourself and others from infection.

Nursing care of the child with LTBI focuses on administering medications and providing supportive care. Teach parents about the disease process, medications, possible side effects, and the importance of completing long-term therapy. Emphasize the importance of taking medications as prescribed on an empty stomach. Initiate direct-observed drug therapy twice a week if poor adherence is suspected.

Encourage proper nutrition and rest to promote normal growth and development. The child can return to school or child care when effective therapy has been instituted, adherence to therapy has been documented, and clinical symptoms have diminished substantially (AAP, 2015, p. 829). Children should receive all usual immunizations. Most children treated for TB can lead essentially normal lives. See the discussion of pneumonia earlier in this chapter and of tubercular meningitis in Chapter 27 for other nursing care measures.

Chronic Lung Conditions

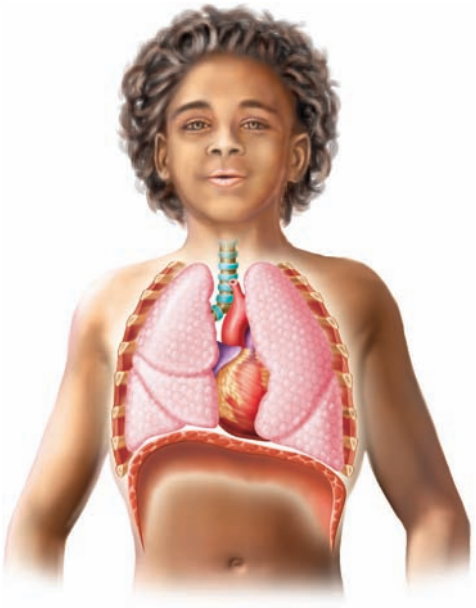
Bronchopulmonary Dysplasia (Chronic Lung Disease)

Bronchopulmonary dysplasia (BPD), also called chronic lung disease of prematurity, is defined as the need for supplemental oxygen for at least 28 days after premature birth. BPD more commonly develops in infants born at less than 28 weeks' gestation when lungs are immature. It is estimated to occur in 35% to 50% of newborns born at less than 28 weeks' gestation (Strueby & Thébaud, 2014).

ETIOLOGY AND PATHOPHYSIOLOGY

Preterm infants less than 28 weeks' gestation are born before alveolar development occurs. BPD results from positive-pressure ventilation and oxygen needed to treat respiratory failure and respiratory distress syndrome. The treatment injures the immature lungs leading to fewer and larger alveoli with less functional surface area and a smaller vascular bed in the lungs, which has greater tone and reactivity. These changes potentially lead to long-term chronic lung disease (Strueby & Thébaud, 2014). A patent ductus arteriosus may also contribute to BPD development. Antenatal corticosteroids and surfactant replacement therapy have reduced the incidence of BPD in more mature preterm infants.

Pathophysiology Illustrated: **Barrel Chest**



A barrel chest may result from chronic respiratory conditions such as asthma or bronchopulmonary dysplasia, in which air trapping or hyperinflation of the alveoli occurs. The chest's anterioposterior diameter increases to give a rounded chest shape.

CLINICAL MANIFESTATIONS

The infant with BPD has persistent signs of respiratory distress: tachypnea, nasal flaring, grunting, retractions, wheezing, crackles, and irritability. Normal activities like feeding create increased oxygen demands and fatigue that may lead to failure to thrive. The infant has intermittent bronchospasms, mucous plugging, and chronic air trapping, which may lead to a barrel-shaped chest (see *Pathophysiology Illustrated: Barrel Chest*). Cyanosis may be seen in severe cases.

CLINICAL THERAPY

Medical management for BPD involves therapies to support respiratory function and good nutrition, which helps to accelerate lung maturity. Medications are administered such as surfactant, corticosteroids, vitamin A, and caffeine (Strueby & Thébaud, 2014). Supplemental oxygen with humidity is used. Nasal continuous or intermittent positive pressure ventilation is often used. An endotracheal tube or tracheostomy may be needed for long-term airway management to prevent narrowing of the trachea in more severe cases. Infants with severe BPD are carefully weaned off of assisted ventilation. Increased calories are needed to support growth, but fluids are restricted to prevent pulmonary edema. Some infants need gastrostomy or nasogastric tube feeding to get adequate calories.

Severity of BPD is determined at 36 weeks' corrected gestational age by the ongoing need for supplemental oxygen or positive-pressure ventilation in an infant who required supplemental oxygen at 28 days of life. Pulmonary artery hypertension is a complication when severe lung disease exists (see Chapter 21). Surviving infants are at risk for cognitive delays, cerebral palsy, growth failure, and abnormal lung function. Infants with severe BPD often have chronic lung disease.

After discharge from the neonatal ICU (NICU), some infants require ongoing oxygen therapy and some may have a tracheostomy. Infants with severe BPD often require frequent hospitalization because of respiratory infections or pulmonary hypertension. Antibiotics are used to aggressively treat infections. An annual influenza vaccine is recommended, and palivizumab may be given monthly to prevent RSV (see the section on bronchiolitis earlier in this chapter). Infants and children with continuing airway hyperactivity may have bronchodilator therapy and asthma controller medications prescribed (see the section on asthma later in this chapter).

Nursing Management

For the Child With Bronchopulmonary Dysplasia

Nursing management focuses on assessing and managing the infant's acute episodes, ensuring adequate nutrition, and promoting growth and development.

Nursing Assessment and Diagnosis

At each healthcare visit, assess the infant's respiratory status and growth. The infant may have poor weight gain because the work of breathing requires extra calories. Assess how well the family is managing care for the child in the home and any stressors that might exist. Evaluate development regularly because the infant may have motor, language, and cognitive delays. Coordinate a periodic assessment of hearing and vision. Infants with BPD may become acutely ill at any time, so observe for signs of infection.

During hospitalization for acute infections, a cardiorespiratory monitor and pulse oximeter are used. Assess airway and respiratory function, vital signs, color, and behavior changes to identify signs of worsening respiratory symptoms even when oxygen is provided. Observe for airway obstruction when the infant has a tracheostomy and suction as needed. See the *Clinical Skills Manual* SKILLS for tracheostomy care.

Nursing diagnoses that may be appropriate include (NANDA-I © 2014):

- ***Gas Exchange, Impaired,*** related to ventilation-perfusion imbalance
- ***Nutrition, Imbalanced: Less than Body Requirements,*** related to high metabolic needs and fatigue associated with feeding
- ***Caregiver Role Strain*** related to 24-hour responsibility for infant with BPD
- ***Development: Delayed, Risk for,*** related to chronic condition and limited opportunities to practice motor skills

Planning and Implementation

Organize care for the hospitalized child to reduce unnecessary physical stimulation. Position the infant to facilitate breathing.

Administer medications as prescribed. Careful fluid management is essential to reduce the risk for pulmonary edema. Provide nutrition to meet energy needs. Support the mother who desires to breastfeed. A high-calorie formula (24 to 30 calories/oz) may be given to promote weight gain. Some children need nasogastric or enteral feedings to get adequate nutrition when cyanosis is noted with feeding.

Once home, many infants need oxygen, tracheostomy care, multiple medications, and high-calorie feedings (Figure 20–3). Make referrals for needed oxygen, respiratory supplies, medications, an early intervention program, and follow-up care well in advance of the infant's discharge. Some families need home health nursing assistance, especially during the initial transition period. Teach parents to provide the complex care needed by the infant and to identify the signs of respiratory compromise indicating a need for rapid intervention.

Figure 20–3 **Many children with BPD are cared for at home, with the support of a home care program to monitor the family's ability to provide airway management, oxygen, and ventilator support. This premature infant girl, who is now 4 months old but weighs only about 5 lb, still requires supplemental oxygen.**

All infants with BPD need more frequent health promotion visits and all immunizations. Suggest ways to provide for the infant's normal development through rest, nutrition, stimulation, and family support (see *Health Promotion: The Child With Bronchopulmonary Dysplasia*).

Clinical Reasoning Infant With BPD

Emily is an 8-month-old infant with BPD cared for at home by her parents. She has a tracheostomy and receives humidification. Emily has periodic infections and episodes of respiratory distress that require hospitalization. When she develops a fever, more secretions than usual collect in the trachea. Suctioning is needed to ease Emily's breathing. What signs indicate that Emily needs to be suctioned? How do you select the correct size of suction catheter? How do you suction Emily without causing hypoxia? When is it necessary to change Emily's tracheostomy tube?

Evaluation

Expected outcomes of nursing care may include:

- The infant receives adequate calories to sustain growth.
- The family identifies acute illness episodes rapidly and seeks appropriate care.
- The infant's acute respiratory decompensation episodes are effectively managed.

Asthma

Asthma is a common chronic disorder in children characterized by bronchial constriction, hyperresponsive airways, and airway inflammation. An estimated 10.5 million (14%) of children in the United States have received an asthma diagnosis, and 7.1 million children continue to have asthma episodes. Children report that asthma episodes result in missing 1 or more days of school and some activity limitation (Centers for Disease Control and Prevention, 2013). Asthma results in an increased number of health center and emergency department visits for treatment; sometimes hospitalization is necessary. The rate of death due to asthma in children and youth in the United States is 2.6 per million (Centers for Disease Control and Prevention, 2013). See *Developing Cultural Competence: Asthma Prevalence*.

Healthy People 2020

(RD-1) Reduce asthma deaths

(RD-2) Reduce hospitalizations for asthma

(RD-3) Reduce emergency department (ED) visits for asthma

Developing Cultural Competence Asthma Prevalence

Current asthma prevalence in children was higher among males (10%) compared to females (7.1%). Among racial and ethnic groups, Black children (14.0%) and multirace children (13.2%) have a higher prevalence than White children (7.4%) (Centers for Disease Control and Prevention, 2013).

Health Promotion The Child With Bronchopulmonary Dysplasia

Health Supervision

- Assess blood pressure to detect abnormal findings associated with pulmonary hypertension.
- Coordinate vision screening by an ophthalmologist every 2 to 3 months during the first year of life. Myopia and strabismus are common in children who were born prematurely.
- Coordinate pulmonary function tests annually or as needed for clinical condition.
- Perform hearing and other screening tests as recommended for age.

Growth and Developmental Surveillance

- Assess growth and plot measurements on a growth chart corrected for gestational age. Even if length and weight are lower than normal, monitor for continued growth following the growth curves.
- Perform a developmental assessment, correcting for gestational age.

Nutrition

- Review caloric intake. Ensure that increased calories are provided to support growth. Assess feeding difficulties related to oral motor function associated with long-term enteral feeding. Refer to a nutritionist as necessary.

Physical Activity

- Organize care to provide rest periods during the day.
- Give parents ideas for promoting the infant's motor development, such as reaching for and moving toward toys and objects of interest.

Family Interactions

- Identify ways to coordinate nighttime care to reduce child and family sleep disturbances.
- Provide discipline appropriate for developmental age.

Disease Prevention Strategies

- Reduce exposure to infections. Encourage selection of a childcare provider who cares for a small number of children, if one is used. If possible, avoid the use of childcare centers during respiratory syncytial virus (RSV) season.
- Immunize the child with the routine vaccine schedule based on chronologic age.
- Administer the 23-valent pneumococcal vaccine at 2 years of age.
- Provide monthly injections of palivizumab throughout the RSV season.

Condition-Specific Guidance

- Develop an emergency care plan for times when the infant's condition rapidly worsens.

ETIOLOGY AND PATHOPHYSIOLOGY

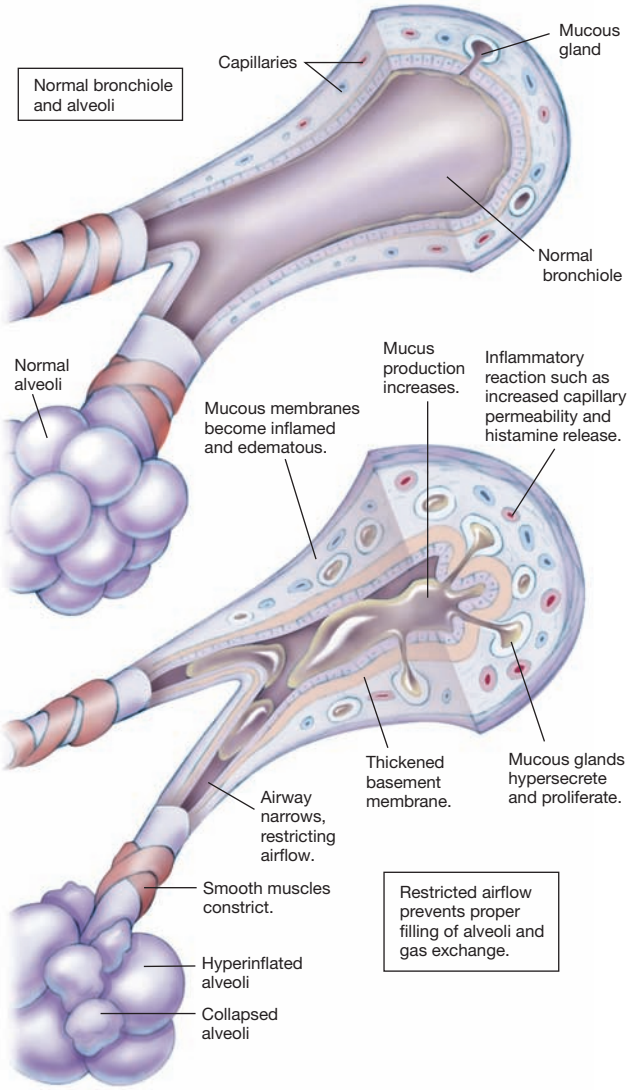
Asthma is a chronic inflammatory disease caused by multiple factors (e.g., environmental exposures, viral illnesses, allergens, and a genetic predisposition) that occur at a crucial time in the immune system's development. Asthma is now considered to be a collection of several diseases that have similar characteristics and symptoms (Custovic, Lazic, & Simpson, 2013).

Many potential genes or regions of chromosomes are associated with asthma, such as those that are associated with increased immune and inflammatory response and airway remodeling. Approximately 70% of children have an allergic or atopic form of asthma, whereas other children have genetic factors that reduce their responsiveness to beta-adrenergic inhaled medications (Brashers & Huether, 2014; Chang, 2012). Environmental exposures also increase the risk for asthma, including passive tobacco smoke, indoor air contaminants (e.g., pet dander, cockroach feces), and outdoor air pollutants. Recurrent respiratory viral infections also increase risk. Protective factors are believed to include a large family size, later birth order, childcare attendance, and exposure to certain organisms. In theory, these factors increase exposure to infections early in life, enabling the child's immune system to develop along a nonallergic pathway (Brashers & Huether, 2014).

Persistent inflammation causes the normal protective mechanisms of the lungs (mucous formation, mucosal swelling, and airway muscle contraction) to overreact in response to a **trigger** (an inflammatory or noninflammatory stimulus that initiates an asthma episode). Triggers include exercise, infectious agents, allergens, fragrances, food additives, pollutants, weather changes, emotions, and stress. Inflammatory mechanisms enhance airway responsiveness, and triggers stimulate bronchospasms (smooth muscle contractions).

The trigger leads B cells to activate IgE and cytokines that then activate the migration and proliferation of eosinophils and the release of proinflammatory mediators. Direct tissue injury, increased bronchial hyperresponsiveness, fibroblast proliferation, and airway scarring result. An exaggerated inflammatory response leads to vasodilation, increased capillary permeability, mucosal edema, contraction of smooth bronchial muscle, and secretion of thick mucus, which narrow and obstruct the airways. Impaired expiration leads to air trapping, hyperinflation, and dyspnea, the physiologic sequence that results in an acute asthma episode (see *Pathophysiology Illustrated: Asthma*). Decreased perfusion of the alveolar capillaries results from hypoxic vasoconstriction and increased pressure due to hyperinflation of the alveoli. Hypoxemia leads to an increased respiratory rate, but because of airway resistance, less air is inspired per minute, worsening hypoxemia.

Pathophysiology Illustrated: **Asthma**



Some asthma triggers are exercise, infection, and allergies. Airflow is obstructed through constriction and narrowing of the airway, along with increased production of mucus. Alveoli may become hyperinflated or collapse because of obstruction, leading to impaired gas exchange.

CLINICAL MANIFESTATIONS

The sudden onset of breathing difficulty (cough, wheeze, or shortness of breath) is an acute asthma episode or asthma attack. The infant or child who has had frequent episodes of coughing or respiratory infections should be evaluated for asthma. Frequent coughing, especially at night, is a signal that the child's airway is very sensitive to stimuli, and this could be a sign of "silent" asthma.

During an acute episode, respirations are rapid and labored and the child often appears tired because of the ongoing effort to breathe. Nasal flaring and intercostal retractions may be visible. The child exhibits a productive cough and expiratory wheezing, a prolonged expiratory phase, decreased air movement, accessory muscle use, and respiratory fatigue. The child may complain of chest tightness. Anxiety increases as the acute episode worsens, and the increasing anxiety intensifies the child's physical responses.

In a severe acute episode, wheezing may not be heard because of low airflow. Head bobbing may be seen in young children using the accessory muscles to breathe. Hypoxia and the cumulative effect of administered medications may cause behaviors ranging from wide-eyed agitation to lethargic irritability. In children who have repeated acute episodes, a barrel chest and accessory muscle use are common findings.

CLINICAL THERAPY

Diagnosis is made by history, physical examination and pulmonary function testing (spirometry) that shows evidence of episodic airflow obstruction (that is at least partially reversible), and airway hyperresponsiveness. Spirometry readings are most commonly measured as forced expiratory volume in 1 second (FEV_1) and expressed as a percentage of predicted FEV_1 for the child's height, age, gender, and race. A chest radiograph may help determine if a foreign body could account for symptoms. Skin testing may be used to identify allergens (asthma triggers).

Clinical Tip

Spirometry testing is performed when the child is able to cooperate, usually by 5 to 6 years of age. Coughing interferes with a good result, so perform testing when asthma is well controlled. Coach the child to give the best effort each time. Allow children to practice using the mouthpiece and nose clip. To perform the test, have the child exhale forcefully. With the mouth forming a tight seal around the mouthpiece, ask the child to take a rapid deep breath without breathing through the nose. Have the child to keep a tight seal around the mouthpiece and to exhale forcibly for at least 6 seconds. Three acceptable readings are obtained, but limit the child to eight efforts (Banasiak, 2014). Be sure to record the child's age, height, weight, gender, race, and time and dose of the last medications, which are used for interpretation of the test.

Several clinical patterns (phenotypes) of asthma have been noted and can sometimes be identified from the history. Asthma management that specifically addresses a child's clinical pattern is being investigated. Examples of clinical patterns include the following (Howrylak et al., 2014):

- Intermittent asthma is triggered only by a viral respiratory infection. No allergic component exists, and lung function is not impaired. Symptoms are seasonal, matching the timing of increased viral infections. The most effective asthma maintenance treatments do not prevent the viral infection trigger.
- Persistent or chronic asthma presents daily and has year-round symptoms. Most have an allergic component to their disease, such as atopic dermatitis. Viral infections may also trigger symptoms. Airway hyperresponsiveness is present and lung function is affected. Symptom-free days occur only with effective maintenance treatment.
- Seasonal allergic asthma is triggered by inhalant allergens (mold, grasses, other pollens) and cause daily symptoms during that allergy season. Seasonal asthma treatment versus continuous asthma treatment may be an effective strategy.

Asthma may go into remission or increase in severity over time. Asthma severity is categorized by how often the child has symptoms and nighttime awakening, how many days a week a short-acting beta$_2$-agonist (SABA) medication is needed, and how many times a year a child needs oral corticosteroid therapy. Spirometry measurement of lung function is an additional method used to determine asthma severity in children 5 years and older. See Table 20–5 for classification of asthma severity in children. See accompanying *Medications Used to Treat: Asthma*.

TABLE 20–5 Classification of Asthma Severity in Children

ASTHMA SEVERITY	CHARACTERISTICS
Intermittent	Symptoms 2 or fewer days a week
	No nighttime awakenings
	SABA use for symptom control 2 or fewer days a week
	No interference with activity
	Oral corticosteroid use no more than once a year
	Normal FEV_1 between exacerbations, FEV_1 greater than 80% predicted, FEV_1/FVC greater than 85% (5–11 years) or normal (12 years and older)
Mild persistent	Symptoms greater than 2 days a week, but not daily
	Nighttime awakenings 1 to 2 times a month (age under 5 years) or 3 to 4 times a month (5 years and older)
	SABA use for symptom control 2 or more days a week, but not daily
	Minor activity limitation
	Oral corticosteroid use 2 or more times a year
	FEV_1 greater than 80% predicted, FEV_1/FVC greater than 80% (5–11 years) or normal (12 years and older)
Moderate persistent	Daily symptoms
	Nighttime awakenings 3 to 4 times a month (age under 5 years) or more than once a week but not nightly (5 years and older)
	SABA use for symptom control daily
	Some activity limitation
	Oral corticosteroid use 2 or more times a year
	FEV_1 equals 60%–80% predicted, FEV_1/FVC equals 70%–80% (5–11 years) or FEV_1/FVC reduced more than 5% (12 years and older)
Severe persistent	Symptoms throughout the day
	Nighttime awakening greater than 1 time a week (age under 5 years) or every night (5 years and older)
	SABA use several times a day
	Extremely limited activity
	Oral corticosteroid use 2 or more times a year
	FEV_1 less than 60% predicted, FEV_1/FVC less than 75% (5–11 years) or FEV_1/FVC reduced more than 5% (12 years and older)

Note: SABA = short-acting beta$_2$-agonist; FEV_1 = forced expiratory volume in 1 second; FVC = forced vital capacity.

Medications Used to Treat: Asthma

QUICK RELIEF MEDICATIONS, ROUTE, AND ACTION	NURSING MANAGEMENT
Short-acting beta$_2$–agonists (SABA) Albuterol, levalbuterol, pirbuterol *Metered-dose inhaler or nebulizer* Relaxes smooth muscle in airway leading to rapid bronchodilation (within 5–10 min) and mucus clearing. Drug of choice for acute therapy and prevention of exercise-induced bronchospasm.	• Use before inhaled steroid, wait 1–2 min between puffs, wait 15 min to give inhaled steroid. Child should hold breath 10 sec after inspiring. Then rinse mouth and avoid swallowing medication. Use a spacer. • Differences in potency exist, but all products are comparable on a per puff basis. • Dose-related side effects include tachycardia, nervousness, nausea and vomiting, headaches. • Regular use more than 2 days a week for symptom control indicates a loss of control and need for additional therapy.
Corticosteroids Methylprednisolone, prednisone, prednisolone *Oral* Diminishes airway inflammation, secretions, and obstruction; enhances bronchodilating effect of beta$_2$–agonists. Used for acute episodes not fully responsive to beta$_2$–agonists; reduces hospitalization rates.	• Short-term therapy should continue until child achieves 80% peak expiratory flow personal best, or until symptoms resolve. • Give with food to reduce gastric irritation. • Give oral dose in early morning to mimic normal peak corticosteroid blood level. • Assess for potential adverse effects of long-term therapy, such as decreased growth, unstable blood sugar, immunosuppression.
Anticholinergic Ipratropium *Metered-dose inhaler or nebulizer* Inhibits bronchoconstriction and decreases mucus production.	• Not for primary emergency treatment because of 30- to 90-min time of onset. • Rinse mouth afterward to get rid of bitter taste. • Side effects include increased wheezing, cough, nervousness, dry mouth, tachycardia, dizziness, headache, palpitations. • Prevent medication contact with eyes.
DAILY CONTROL MEDICATIONS, ROUTE, AND ACTION	**NURSING MANAGEMENT**
Long-acting beta$_2$–agonists (LABA) Salmeterol, formoterol *Dry powder inhaler* Relaxes smooth muscle in airway; increases ciliary motility. Used for nocturnal symptoms and prevention of exercise-induced bronchospasm. Used as an add-on therapy.	• Do not use for acute asthma episode. • Take preexercise dose 30–60 min before activity. Do not use additional dose before exercise if already using twice daily doses, which should be 12 hr apart. • Caution against overdosage because side effects such as tachycardia, tremor, irritability, insomnia will last 8–12 hr. • Report failure to respond to usual dose because this may indicate need for stepped-up therapy.
Inhaled corticosteroids (ICS) Beclomethasone, budesonide, flunisolide, fluticasone, mometasone, triamcinolone *Metered-dose inhaler or nebulizer* Anti-inflammatory, controls seasonal, allergic, and exercise-induced asthma; effectively reduces mucosal edema in airways.	• Administer with spacer or holding chamber. • Separate parts and clean inhaler daily. • Rinse mouth and gargle following treatment to remove drug from oropharynx to reduce chance of cough, thrush, and dysphonia. • Prevent eye exposure through proper metered-dose inhaler, nebulizer, or dry powder inhaler (DPI) administration. • Monitor for headache, gastrointestinal upset, dizziness, infection. • Use exactly as prescribed.

Medications Used to Treat: Asthma (*continued*)

Methylxanthines Theophylline *Oral* Relaxes muscle bundles that constrict airways; dilates airway; provides continuous airway relaxation. Used for long-term control; may help reduce need for increased corticosteroid dosages. Less commonly used than inhaled medications because of side effects.	• Do not crush or chew tablet. Give at same time each day. • Maintain therapeutic serum level of 10–20 mcg/L; requires serum level checks and dose adjustment. • Limit caffeine intake. • Side effects include tachycardia, dysrhythmias, restlessness, tremors, seizures, insomnia, hypotension, severe headaches, vomiting, and diarrhea.
Mast cell inhibitors Cromolyn sodium, nedocromil *Metered-dose inhaler or nebulizer* Anti-inflammatory, inhibits activation and release of inflammatory mediators for early and late phase asthma response to allergens and exercise-induced bronchospasm. May be used for unavoidable allergen exposure.	• Do not use at time of symptom development or acute episode. • Must be used up to 4 times a day to be effective. • Therapeutic response seen in 2 weeks, maximum benefit may not be seen for 4–6 weeks. • Adverse reactions include wheezing, bronchospasm, throat irritation, nasal congestion, and anaphylaxis. Immediately report these symptoms to physician.
Leukotriene receptor antagonist (LTRA) Montelukast, zafirlukast *Oral* Reduces inflammation cascade responsible for airway inflammation; improves lung function and diminishes symptoms and need for quick-relief medications.	• Available in granules for infants and chewable tablets for young children. • Administer montelukast in the evening; may be given with food or without. • Make sure child chews montelukast chewable tablet rather than swallowing whole. Granules may be mixed in applesauce or ice cream; do not mix in liquid. • Administer zafirlukast 1 hour before or 2 hr after meal. • Report fever, acute asthma episodes, flulike symptoms, severe headaches or lethargy. • Take as prescribed; do not withdraw abruptly.
Immunotherapy Omalizumab *Subcutaneous* A therapeutic antibody that blocks IgE from causing reactions leading to asthma symptoms.	• Approved for children 12 years and older with moderate or severe persistent asthma. • Injections required every 2–4 weeks based on serum IgE levels. • Be alert for anaphylaxis; it should be administered in a health center prepared to treat anaphylaxis.
Other Hyposensitization (allergy shots) *Subcutaneous* Series of injections with gradual dose increase that can increase the child's tolerance of unavoidable allergens (e.g., mold, pollen).	• May be of value for child with persistent asthma having allergies that can be addressed by immune therapy.

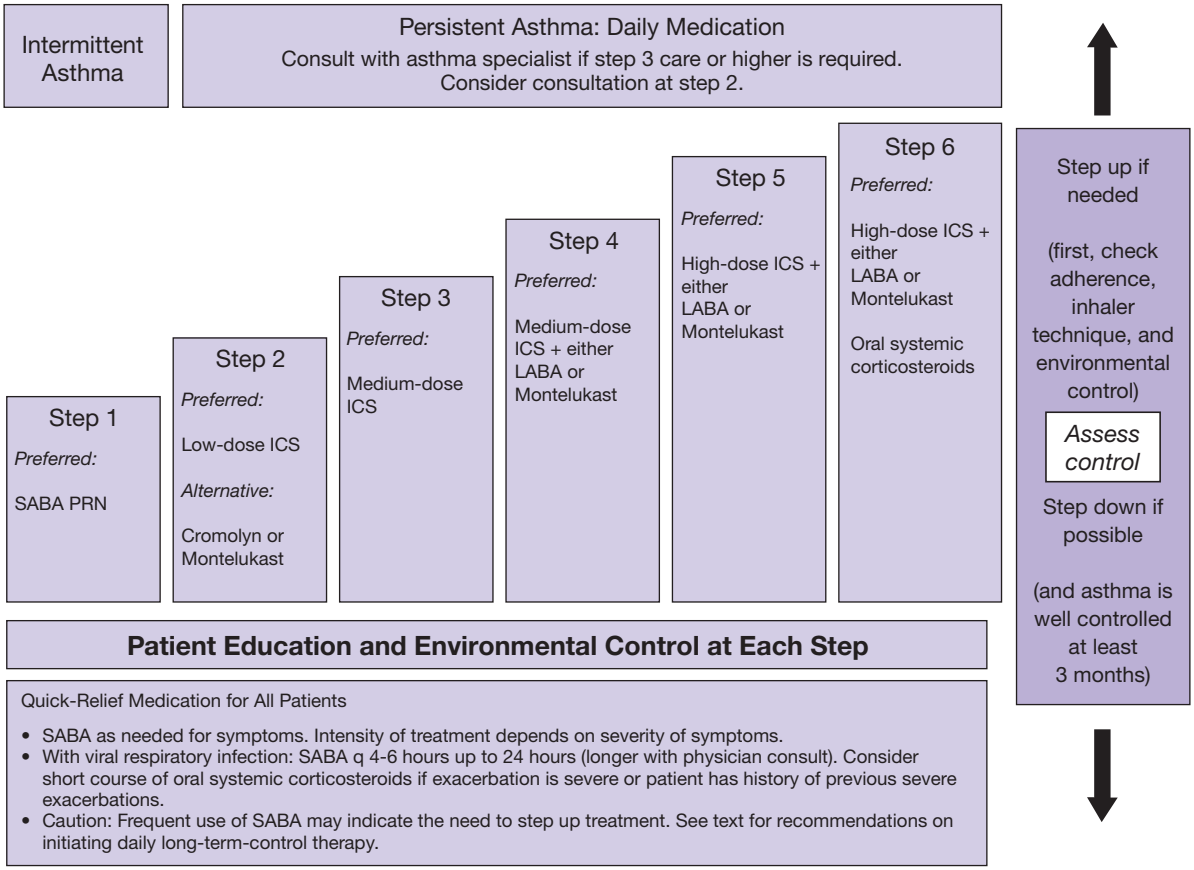
Recommended therapy is tied to asthma severity classification. Clinical therapy includes medications, hydration, education, and support of parents and child. Pharmacologic treatment is matched to the severity of asthma for daily control and for management of acute episodes. The goal is to maintain asthma control long term, using the least amount of medication and reducing the risk for adverse effects.

Clinical Tip

Signs of good control in children during a week include few or no episodes of dyspnea or wheezing during the day or waking the child at night, no interference with normal activity, school, or exercise, and few uses of a short-acting beta$_2$-agonist for symptom control (Nguyen et al., 2014). Various questionnaires to measure asthma control in children have been proposed and studies to validate them are in process.



Key: **Alphabetical order is used when more than one treatment option is listed within either preferred or alternative therapy.** ICS, inhaled corticosteroid; LABA, inhaled long-acting beta$_2$-agonist; SABA, inhaled short-acting beta$_2$-agonist

Figure 20–4 Stepwise approach to managing asthma in children 0 to 4 years of age.

SOURCE: From National Asthma Education and Prevention Program. (2007). *Expert panel report 3: Guidelines for the diagnosis and management of asthma* (p. 305). Bethesda, MD: National Institutes of Health, National Heart Lung and Blood Institute. Retrieved from http://www.nhlbi.nih.gov/guidelines/asthma

The main goal of asthma therapy is to manage symptoms and the disorder. Medication therapy and other therapies are divided into six progressive steps intended to match the child's asthma severity. Specific step guidelines are established for different age groups: 0 to 4 years, 5 to 11 years, and 12 years and older. The child's response to therapy is reviewed periodically to determine if medications should be stepped up or down to correspond to the child's symptoms. See Figure 20–4 for the nationally recommended stepwise approach for children aged 0 to 4 years. An asthma action plan is recommended to guide home management of asthma symptoms.

Recommendations for children with persistent asthma include the use of daily inhaled corticosteroids and additional long-term control medications as severity increases. A peak flow meter is often recommended in addition to an asthma management plan to guide the parents and child in treating asthma episodes. Children with intermittent asthma may only need short-acting beta$_2$-agonist. When asthma control is difficult to achieve, the child is referred to an asthma specialist.

Acute Asthma Episodes. Most children with acute exacerbations respond to aggressive management in the emergency department with continuous albuterol by nebulizer, oral systemic corticosteroids, and inhaled ipratropium. Children who do not respond or who are already being managed at home on corticosteroids have a greater chance of hospital admission.

Exercise-Induced Asthma. Up to 70% of children and youth report shortness of breath, wheezing, coughing, difficulty taking a deep breath, noisy breathing, or chest tightness to occur during and after exercise. Pretreatment with a short-acting beta$_2$-agonist 5 to 20 minutes before exercise often prevents exercise-induced asthma and provides relief for 2 to 4 hours (Parsons et al., 2013).

Severe Asthma Episodes. Some asthma episodes do not respond to repeated doses of albuterol and corticosteroids, and progress to potentially life-threatening episodes. The child has increased hypoxemia, decreased expiration due to air trapping, and ineffective ventilation. Respiratory acidosis develops. Children often require treatment in the intensive care unit. Intravenous magnesium sulfate may be added to other medications, such as theophylline and intravenous beta$_2$ agonists, for the acute episode. Heliox (70% helium:30% oxygen or 80% helium:20% oxygen) gas is less dense than supplemental oxygen and causes less airflow resistance in narrowed airways. Ketamine and inhaled anesthetics are used in some critical cases along with assisted ventilation (Wong, Lee, Turner, et al., 2014). A few children progress to respiratory failure and die.

Nursing Management

For the Child With Asthma

Nursing Assessment and Diagnosis

The nurse usually encounters the child and family in the emergency department, health center, or nursing unit. Often, acute care has become necessary because the child's level of respiratory compromise cannot be managed at home. In some cases, the child and family are seen following acute episodes to have education for asthma management at home or in school.

PHYSIOLOGIC ASSESSMENT

Identify the child's current respiratory status first by assessing the ABCs—airway, breathing, and circulation—to make sure the child's condition is not life threatening. If the child is moving air or talking, assess the quality of breathing. Observe the child's color, and assess the respiratory and heart rates. Auscultate the lungs for the quality of breath sounds and for the presence or absence of wheezing. Note whether a cough or stridor is present. Inspect the chest for retractions to assess the severity of respiratory distress. Move on to other aspects of assessment only after finding no life-threatening respiratory distress.

Attach a pulse oximeter; a SpO_2 reading of less than 92% indicates hypoxemia. Assess skin turgor, intake and output, and urine specific gravity. A spirometry reading may be attempted, but the child may be unable to use the spirometer because of respiratory distress. Because asthma symptoms can be associated with an infection or other condition, perform a head-to-toe assessment to identify other associated problems. See the *Assessment Guide* at the beginning of this chapter.

ASSESS ASTHMA MANAGEMENT

Key questions to consider asking parents and older children or adolescents include the following:

- How often in the past month has the child had shortness of breath, coughing, chest tightness, or chest pain during the day? During the night?
- How many times a week does the child need to use rescue medications?
- Have asthma symptoms limited the child's work or play at school or home?
- Which medicines is the child currently taking? How often?
- Have any medication dosages been missed in the last week? How many?
- What are your concerns about the medicines prescribed (e.g., not really needed, side effects, worried about "steroids")?
- Is there any issue with the cost or ability to obtain the medicines?
- Have you tried any other treatments for asthma (e.g., complementary therapies recommended by a healer)?
- Show me how you use your inhaler.

Additionally, several questionnaires have been developed to help health professionals assess an adolescent's asthma control, such as the Asthma Control Test.

PSYCHOSOCIAL ASSESSMENT

Assess the child's anxiety or fear related to the asthma episode or hospitalization. How are parents responding to the current acute episode? Are they anxious, concerned, or frustrated? Do they potentially have concerns about finances, missing work, or other family members at home? Assess whether the child thinks this episode could have been avoided if medications had been used.

Examples of nursing diagnoses for the child experiencing an acute asthma episode include the following (NANDA-I © 2014):

- ***Airway Clearance, Ineffective,*** related to airway compromise, copious mucous secretions, and coughing
- ***Gas Exchange, Impaired,*** related to airway obstruction
- ***Fluid Volume: Deficient, Risk for,*** related to inability to drink adequate fluids when in respiratory distress
- ***Anxiety/Fear (Child and Parents)*** related to difficulty breathing
- ***Health Management, Family, Ineffective,*** related to lack of understanding about the need for daily management of a chronic disease

Planning and Implementation

Pharmacologic and supportive therapies are used to reverse the airway obstruction and promote respiratory function. Nursing interventions focus on maintaining airway patency, meeting fluid needs, promoting rest and stress reduction for the child and parents, supporting the family's participation in care, and providing the family with information to enable them to manage the child's disease.

MAINTAIN AIRWAY PATENCY

If the child is exhibiting breathing difficulty, give supplemental humidified oxygen by nasal cannula or face mask. Humidity prevents drying and thickening of mucous secretions. Place the child in a sitting (semi-Fowler) or upright position to promote and ease respiratory effort. Evaluate the effectiveness of positioning and oxygen administration by pulse oximeter and by observing for improved respiratory status. (See the *Clinical Skills Manual* SKILLS.)

The respiratory distress and need for supplemental oxygen can be stressful for parents and child alike (Figure 20–5). Encouraging the parents' presence can be reassuring for the child. Keep the parents informed of procedures and results, and get their input when developing the treatment plan.

Figure 20–5 **An acute asthma episode requires management in the emergency department. The child is placed in a semi-Fowler position to facilitate respiratory effort. Support both the child and parent during these acute episodes. This mother looks exhausted after a sleepless night of caring for her son.**

Growth and Development

Metered-dose inhalers (MDIs), nebulizers, and dry powder inhalers (DPIs) are devices used for inhalation therapy. These devices cause special challenges for infants and young children because many devices require cooperation and coordination. The appropriate technique must be taught and reinforced frequently.

- Children over 5 years usually have the ability to use an MDI. Using the closed mouth technique, have the child insert the mouthpiece in the mouth between the teeth and seal the lips. Look straight ahead, and keep the tongue away from the mouthpiece opening. Just as the child starts to breathe, press down on the canister to release the medication. Continue to breathe in slowly through the mouth for at least 5 seconds, and then hold the breath for another 10 seconds. No mist should be seen coming from the mouth after the breath or from the top of the inhaler after actuation, both of which are signs the technique was not good. Teach the child to use an MDI without a spacer, by breathing slowly through a straw.
- Younger children need a spacer with a mask attachment, while other children prefer to use a spacer with the MDI. Select a spacer with a mask for infants and young children that fits from the top of the nose to just under the mouth. The seal should be flexible to prevent an air leak. Crying leads to prolonged exhalation and short inspiration, reducing lung deposition. Use play and distraction to improve cooperation for medication delivery. When use of a spacer or holding chamber is preferred, put the mask on firmly over the nose and mouth or the mouthpiece in the mouth with mouth closed around it. Release a puff of medication and have the child take 4 to 6 quiet deep breaths over 10 seconds. Move the spacer away from the face or mouth, and have the child hold a breath for 10 seconds. Follow this with the second puff. Wash the child's face after using a spacer with a mask. Wash the plastic spacer with household detergent and air dry it to reduce the static charge that can attract medication particles.
- A nebulizer changes liquid medication into aerosol particles. No coordination of breathing is required, making nebulizers easier for young children to use. Nebulizers are not more efficient than MDIs with a spacer, but the outcome may be better since the child can breathe normally. Make sure the nebulizer mouthpiece is sealed by the lips, and mouth breathing is used. If the child cannot coordinate mouth breathing, use a face mask. Nebulizers take 8 to 10 minutes per treatment, so distraction may be needed to improve the cooperation of infants and young children for that duration.
- Dry powder inhalers are activated when the child takes a breath, so puffs do not need to be coordinated with inhalation. No spacer or propellant is used. Children starting at age 5 years may be able to take the rapid, deep, and sustained breath needed to effectively use the device. Children less than 6 years of age who are wheezing may not be able to inspire at a rate fast enough to obtain the optimal amount of medication. Steps for using DPI include the following: Remove the lid, load the dose (puncturing the blister or capsule), fully breathe out away from the device, put the mouthpiece between the lips and teeth, and breathe in deeply and forcefully. Hold the breath for 10 seconds and remove the mouthpiece from the mouth.
- Some MDIs or DPIs have a whistle. It may warn that the inhaled breath is too fast or too shallow, but in other devices, it indicates the breath was adequate. Be sure to inform the child and family about what the whistle on the child's inhaler indicates.

Source: Data from Dinakar, C., & Welch, M. J. (2014). Device how-tos. *Contemporary Pediatrics, 31*(May). Retrieved from http://contemporarypediatrics.modernmedicine.com/contemporary-pediatrics/content/tags/asthma/device-how-tos; Sleath, B., Ayala, G. X., Gillette, C., Williams, D., Davis, S., Tudor, G., . . . Washington, D. (2011). Provider demonstration and assessment of child device technique during pediatric asthma visits. *Pediatrics, 127*(4), 642–648; Asthma Initiative of Michigan for Healthy Lungs. (2011). *How to use a metered-dose inhaler the right way*. Retrieved from http://www.getasthmahelp.org/inhalers_main.asp

Most medications are given by inhalation (Figure 20–6). (See the *Clinical Skills Manual* SKILLS.) The aerosol droplets provide the added benefit of moisture. Continuous nebulizer treatments may be used for some children with severe acute episodes. See *Growth and Development* for considerations in administering medications with inhalation devices. Monitor the child for medication side effects. The frequency of vital sign assessment is determined by the severity of symptoms.

Figure 20–6 **Medications given by inhalation therapy reach the bloodstream rapidly while minimizing the systemic effects. A nebulizer works well for young children because it does not require coordination of breathing with medication inhalation.**

SOURCE: greenland/Shutterstock

MEET FLUID NEEDS

Fluid therapy is often necessary to restore and maintain adequate fluid balance. Adequate hydration is essential to thin and break up trapped mucous plugs in the narrowed airways. An intravenous infusion may be needed if the child cannot meet fluid needs by mouth, and for administering certain medications and glucose. Monitor the child's intake, output, and specific gravity to avoid overhydration that could lead to pulmonary edema in severe asthma episodes.

As respiratory difficulty diminishes, offer oral fluids slowly. The child's fluid preferences should be determined and choices given where possible. Involve parents to help gain the child's cooperation in taking oral fluids.

Clinical Tip

Iced beverages precipitate bronchospasms in some children with asthma. Offer room-temperature or slightly cooled fluids instead.

PROMOTE REST AND STRESS REDUCTION

The child having an acute asthma episode is usually very tired from prolonged labored breathing when admitted to the nursing unit. Put the child in a quiet room that is accessible for frequent monitoring to promote relaxation and rest. Group tasks to avoid repeatedly disturbing the child.

SUPPORT FAMILY PARTICIPATION

Recognize that parents may be exhausted after spending hours with their child in respiratory distress. Give parents the *option* of assisting with the child's treatments, rather than *expecting* them to help, in addition to comforting the child. Provide frequent updates about the child's condition and encourage the parents to take breaks as needed.

Length of hospitalization depends on the child's response to therapy. Any underlying or accompanying health problem, such as preexisting lung disease or pneumonia, can complicate and extend the child's hospital stay. Communicate with the family of the hospitalized child frequently about the child's condition.

DISCHARGE PLANNING AND HOME CARE TEACHING

Parents need a thorough understanding of asthma—how to prevent asthma episodes and how to follow the child's asthma action plan to manage symptoms. Support of parents and the child should focus on helping them to understand and cope with the diagnosis and the need for daily management to promote near-normal respiratory function while the child continues to grow and develop normally.

Discharge planning for the child with asthma focuses on increasing the family's knowledge about the disease, medication therapy, and the need for follow-up care. Make sure the child receives an appointment with an allergist or asthma specialist if moderate to severe persistent asthma exists. Refer the child and parents to a healthcare provider for more comprehensive education that considers cultural factors for asthma management. See *Developing Cultural Competence: Asthma Disparity Factors*.

COMMUNITY-BASED NURSING CARE

Nurses provide care to children with asthma in pediatricians' offices, specialty asthma clinics, schools, and summer camps. The child's asthma control and management should be assessed at each visit.

Promoting Asthma Management Skills

Review the family's daily plan for monitoring the child's respiratory status. Encourage the school-age child or the parents of younger children to keep a symptom diary that includes peak exploratory flow rate (PEFR) for 2 weeks prior to a health visit as well as all daytime and nighttime symptoms. The Asthma Tracker is one tool a family can use to monitor the young child's asthma symptoms (Nkoy et al., 2013). Evaluate the child's use of the MDI or DPI, and correct the child's technique as needed. Teach the family or review the child's technique about how to measure and interpret peak expiratory flow readings (see *Families Want to Know: Using a Peak Expiratory Flow Meter*).

Clinical Tip

A study revealed that using a peak expiratory flow meter provided parents with an objective measure of the child's asthma symptoms and empowered them to initiate treatment earlier than without the meter. Communication with the child's healthcare provider was more effective when a peak expiratory flow meter was used (Burkhart, Rayens, & Oakley, 2012).

Assess the parent's ability to identify the timing and type of stepped-up care needed to manage worsening symptoms identified on the child's asthma action plan. The asthma action plan should include the daily control medications, quick-relief medications to take once symptoms of an asthma episode are identified, and when to call the healthcare provider. Identify routines that may improve adherence to daily medication use, such as keeping medications where they will be seen at mealtime. The goal is to bring asthma episodes under control with stepped-up care before emergency care is needed. Reassure the family that most children with asthma can lead a normal life with some modifications.

Developing Cultural Competence Asthma Disparity Factors

African American and Hispanic children have a higher prevalence rate for asthma. A major factor may be lower access to high-quality ambulatory care that does not provide education within the cultural beliefs of the family. Other factors associated with the high prevalence rate may include (Kueny, Berg, Chowdhury, et al., 2013):

- Environmental housing conditions (indoor allergen exposure to rodents, molds, and cockroaches)
- Employment options that increase potential introduction of allergens into the home
- Air pollution in urban areas such as nitrogen dioxide from engine exhaust fumes
- Medication beliefs associated with concerns over safety of inhaled corticosteroids and development of tolerance with daily use, or following the advice of healers
- Emotional stress within the home

Identify potential factors contributing to the child's asthma to provide effective education and support to the child and family.

Healthy People 2020

(RD-6) Increase the proportion of persons with current asthma who receive formal patient education

(RD-7.1) Increase the proportion of persons with current asthma who receive written asthma management plans from their healthcare provider according to National Asthma Education and Prevention Program (NAEPP) guidelines

Refer parents to a local support group to gain additional knowledge and confidence in asthma management. Many hospitals have family resource centers that can assist parents to find helpful information on the Internet.

Child-Focused Education

Engage the child in learning about how the lungs work and what happens when an acute asthma episode occurs. Teach the child how to begin steps toward self-management as appropriate. Encourage the child to ask questions. Provide an activity or coloring book for the child and printed educational materials for the parents. See *Families Want to Know: Home Care for the Child With Asthma* to guide asthma education for the child and family.

Encourage school-age children to assume more responsibility for care, including avoidance of known triggers, early symptom recognition, relaxation breathing, and the proper use of inhaled medication. Help the child learn the early signs of an asthma episode (coughing, breathlessness, or peak expiratory flow meter reading) and to take quick-relief medication before signs become more serious.

Families Want to Know

Using a Peak Expiratory Flow Meter

A peak expiratory flow meter is a useful tool for asthma self-management. It measures the child's ability to push air forcefully out of the lungs. Changes in the peak expiratory flow rate (PEFR) signal worsening lung function and the beginning of an asthma episode. To use a peak expiratory flow meter:

- Set the device at zero or the base level.
- Stand up and take as deep a breath as possible.
- Put the mouthpiece of the meter in the mouth and firmly close the lips around it. Do not cough or let your tongue block the mouthpiece. Blow out as hard and fast as possible over 1 to 2 seconds. To help toddlers learn how to use a peak flow meter, have them practice by blowing into a noisemaker or party favor.
- Write down the reading.
- Repeat the process 2 times and record the highest of the 3 numbers on the chart.
- Measure and record the best PEFR reading twice a day for 2 weeks so the healthcare provider can determine the child's personal best reading. (Make sure the child is optimally treated with medications during the day to obtain the best reading.)
- The physician will use the child's personal best average readings to set the green, yellow, and red color zones to guide treatment in the child's asthma action plan. The child's personal best changes as the child grows taller, so the child's personal best should be measured every year.
- The physician provides guidelines for the child and family to use when monitoring the PEFR. If the child or parent suspects the child might have the onset of breathing difficulty, the peak flow meter can be used. Some children have problems identifying early symptoms of an acute asthma episode onset (increased cough, wheezing, or shortness of breath). The peak flow meter measures the change in how hard the child can blow out air. Using the zones established by the healthcare provider, the child and family can determine what action to take.
- **Green zone**: The PEFR reading is between 80% and 100% of the child's personal best. Air is moving well in the child's lungs. In this case, the child has good asthma control and can continue daily activities. No modification of the treatment plan is needed.
- **Yellow zone**: The PEFR reading is between 50% and 80% of the child's personal best. In this case, the child is developing breathing problems. The parents should follow directions in the child's asthma action plan, which usually involves quick-relief medications. The child should feel better and the PEFR should improve over the next hour. If symptoms and the PEFR do not improve, contact the child's healthcare provider for additional treatment guidance.
- **Red zone**: The PEFR is less than 50% of the child's personal best. In this case, the child has a severe asthma episode and needs urgent treatment with quick-relief medication. Call the child's healthcare provider for additional care guidelines or take the child to the emergency department.

Health Maintenance

Provide routine health promotion and maintenance care, including immunizations. Live virus vaccines may need to be postponed if the child has used oral corticosteroids recently. Carefully monitor the child's growth, especially when the child uses inhaled corticosteroids and episodic oral corticosteroids, which can slow growth and result in reduced adult height by an average of 1.2 cm (0.47 in.) (Kelly et al., 2012).

Assess the child's activity and exercise level, and any symptoms experienced such as chest tightening, wheezing, or shortness of breath. Exercise-induced bronchospasm typically occurs 5 to 10 minutes after stopping the activity and resolves 20 to 30 minutes later. First, make sure the child gets some exercise to improve fitness, and then assess how frequently the child has exercise-induced symptoms. Compare that information to the classification of asthma severity in Table 20–4. Teach the child about the timing of rescue medications before exercise to prevent exercise-induced bronchospasm. Make sure the child uses the daily control and quick-relief medication asthma action plan.

Environmental Control

Reducing allergens in the environment is an important part of asthma management. Focus efforts on reducing molds in the home with lowered humidity and removal of houseplants. When possible, remove pets from the home (especially from the child's bedroom). Dust mites live in the carpets, mattresses, upholstered furniture, bedcovers, soft toys, and clothes. Vacuum carpets and upholstered furniture frequently using a high-efficiency vacuum filter. Buy soft toys that can be washed. Controlling dust mites in the child's bed and bedroom is a high priority. Encase the child's mattress and pillow in plastic covers. Bathe pets frequently to reduce pet dander. Initiate cockroach eradication. Smoke from cigarettes, wood stoves, and fireplaces should be eliminated when possible. See Chapter 22 for *Families Want to Know: Removing Common Allergens From the Home*.

Professionalism in Practice Asthma Management by School Nurses

The National School Nurses Association joined eight organizations in a position statement to improve asthma management in school settings. School nurses are encouraged to implement a comprehensive asthma plan for the management of students with asthma in the school setting that includes identifying and monitoring all students with asthma and obtaining their asthma action plans. School nurses are additionally encouraged to collaborate with school officials to adopt and implement an environmental assessment and management plan that addresses environmental asthma triggers (American Lung Association, 2013). See Chapter 10 for more information on nursing care in the school setting.

Families Want to Know

Home Care for the Child With Asthma

Identify current knowledge about the condition and its impact on the child:

- What happens in the lungs during an asthma episode?
- What are the child's early warning signs of an asthma episode?
- What are the child's symptoms (wake up at night, cough a lot)? How does the child respond to them?
- Is the child involved in any exercise activity? If no, why not? Do asthma symptoms occur when the child is exercising?
- Does asthma interfere with social activities or activities with friends?
- What are the child's personal asthma triggers? (Suggest keeping a log of symptoms that occur during the day and night, including when and where, that will help identify triggers [e.g., home, school, outdoors, with exercise].) The symptom diary is very helpful in determining the need for more education or for stepped-up or stepped-down medications.

Set up a schedule for parents to learn asthma management:

- Make sure the parents and child know that asthma is a chronic condition that needs daily management and environmental control to reduce or prevent acute asthma episodes.
- Review the asthma action plan for daily management, quick relief, and when to call the physician or to seek emergency care.
- Assess the child's technique with a peak expiratory flow meter, and correct technique as needed. Discuss when to use the meter and how to interpret and use the results for asthma control. Keep a record of peak flow readings for 2 weeks prior to each health visit.

Review parents' understanding of medication therapy:

- Provide information about medications: name, type of drug, dose, method of administration, expected effect, possible side effects. Make sure families understand that daily control medications help prevent acute asthma episodes; the child will not feel them work like the quick-relief medications. Discuss any concerns the family has about the use of "steroid" medication, and describe how they differ from the anabolic steroids abused by athletes.
- Assess the child's MDI or DPI technique and correct as needed.
- When a nebulizer is used to treat an infant or young child, suggest diversions to promote cooperation during the 8- to 10-minute treatment.

Address associated issues:

- What are the financial considerations of medication cost and lifestyle changes?
- Have arrangements been made for the child to use medications at child care or school?
- Does the child have a medical identification bracelet or tag?
- Would a self-help group or camp experience be helpful for the child?

School Management

Provide a healthcare provider order so the child's asthma symptoms can be treated at school or at child care. The parents should work with school administrators to have an individualized health plan (that includes an asthma action plan) developed so the child can carry a rescue inhaler and medications can be administered, including pretreatment for exercise. Provide a supply of medications to the school or childcare organization. Make sure teachers of young children can help recognize signs of an acute asthma episode and reduce a child's anxiety about going to the nurse for quick-relief medications. Many schools are attempting to improve the environment and reduce asthma triggers.

Clinical Tip

All 50 states and the District of Columbia have legislation that entitles a child with asthma to carry and self-administer asthma medications at school (Allergy and Asthma Network, 2014). Families of children old enough to recognize worsening asthma symptoms and to self-administer rescue medications should make sure the school knows about the state law.

Evaluation

Expected outcomes of nursing care include the following:

- The child recognizes early asthma symptoms and promptly uses quick-relief medications, fluids, and relaxation breathing before severe respiratory distress occurs.
- The child learns to identify and avoid asthma triggers.
- The child and family implement the prescribed daily treatment plan and asthma action plan to reduce the number of asthma episodes the child has.
- The child with a serious asthma episode responds to oxygen, fluids, and medication therapy, avoiding hospital admission.

Cystic Fibrosis

Cystic fibrosis (CF) is a common inherited autosomal recessive disorder of the exocrine glands, leading to physiologic alterations in the respiratory, gastrointestinal, and reproductive systems. The incidence of CF varies by race—1:2500–3500 in non-Hispanic Whites, 1:4000–10,000 in Hispanics, 1:15,000–20,000 in non-Hispanic Blacks, 1:32,000 in Asian Americans, and 1:1500–3970 in Native Americans (Nakano & Tluczek, 2014). Gender is not a factor in disease incidence. Approximately 30,000 children and adults have CF in the United States, and approximately 50% are older than age 18 years. The median life span for individuals with CF is mid-40s (Cystic Fibrosis Foundation [CFF], 2014) (Figure 20–7).

ETIOLOGY AND PATHOPHYSIOLOGY

A gene isolated on the long arm of chromosome 7 directs the function of the transmembrane conductance regulator (*CFTR*), which regulates the hydration of epithelial cells of many body organs. More than 1900 mutations of the *CFTR* gene have been identified, but only 127 of these mutations produce CF symptoms (Nakano & Tluczek, 2014). An estimated 10 million persons in the United States are carriers of a defective *CFTR* gene, and have

Figure 20–7 **Cystic fibrosis is an inherited autosomal recessive disorder of the exocrine glands, so it is not uncommon to see siblings with it such as this brother and sister.**

no symptoms (Brashers & Huether, 2014). Disease severity varies by number of symptom-causing *CFTR* mutations. Children with more severe CF have 2 symptom-causing *CFTR* mutations (Nakano & Tluczek, 2014).

With a defective CFTR protein, chloride-ion transport across the exocrine and epithelial cells is impaired and increased sodium absorption reduces water movement across cell membranes. Secretions become thickened in the sweat ducts, the airways, pancreas, intestine, bile ducts, and vas deferens. The small airways in the lungs become clogged with thickened mucus that can harbor bacteria. The lubricating layer between the airway epithelium and mucus inhibits normal ciliary action and cough clearance.

Air becomes trapped in the small airways, leading to hyperinflation, atelectasis, and secondary respiratory infections. Even with antibiotics and a good response, over time the airways develop chronic bacterial and fungal colonization and **bronchiectasis** (a persistent abnormal dilation of the bronchi), followed by respiratory failure. Pneumothorax and hemothorax may occur in older children. The rate of disease progression is related to disease severity.

Obstructions in the pancreatic ducts impede the natural enzyme flow that enables the body to digest fats, fat-soluble vitamins, and proteins. Nutritional deficits may cause failure to thrive. As the child ages, the pancreas may stop producing sufficient insulin, leading to glucose intolerance and the development of cystic fibrosis–related diabetes mellitus.

Failure to secrete enough chloride and fluid into intestines causes meconium ileus (a small bowel obstruction in newborns), affecting 15% of newborns with CF (Henderson et al., 2012). Older children may have intermittent and recurrent episodes of partial small bowel obstruction that can progress to total obstruction, abdominal distention, and vomiting. Chronic inflammation may occur in the intestines, leading to the development of Crohn disease. In rare cases, children with CF develop liver disease.

TABLE 20–6 Clinical Manifestations of Cystic Fibrosis

PATHOPHYSIOLOGY	CLINICAL MANIFESTATIONS
UPPER RESPIRATORY	
Clogged sinuses	Nasal polyps Chronic sinusitis, frontal headaches, purulent nasal discharge, postnasal discharge
LOWER RESPIRATORY	
Reduced ciliary clearance; obstructed airways; air trapping and hyperinflation; bacterial colonization Chronic fibrotic lung changes	Chronic moist, productive cough; wheezing; coarse crackles Frequent infections Shortness of breath, decreased exercise tolerance Barrel chest Clubbing of fingers and toes (Figure 20–8)
PANCREAS	
Damaged pancreatic ducts obstruct enzymes needed for digestion Produced enzymes damage the pancreas, leading to inadequate insulin secretion	Poorly digested food Vitamin A, D, E, and K deficiencies Poor weight gain or failure to thrive; delayed onset of puberty CF-related diabetes mellitus
GASTROINTESTINAL	
Thickened intestinal secretions and decreased gut mobility Obstructed bile ducts	Meconium ileus at birth Abdominal distention Greasy, bulky stools (steatorrhea) that are frothy, foul smelling, and floating Constipation or intestinal obstruction Rectal prolapse Liver cirrhosis
REPRODUCTIVE	
Males—absence of vas deferens, low sperm count Females—thick vaginal discharge and decreased cervical secretions	Males—infertility Females—may have difficulty conceiving
SWEAT GLANDS	
Excess chloride and sodium electrolyte loss in the sweat	Salty sweat Salt depletion, hyponatremia

Figure 20–8 **Digital clubbing, enlargement of the distal phalanges, occurs in children with cystic fibrosis because of chronic fibrotic changes within the lungs.**

The imbalances created by excessive electrolyte loss through perspiration, saliva, and mucous secretion alter metabolic function. These children are at risk for hyponatremic dehydration secondary to electrolyte imbalance.

CLINICAL MANIFESTATIONS

One of the first signs of CF is that newborns fail to pass meconium in the first few days of life. Parents may notice a salty taste to the skin of their infant. Other primary symptoms are associated with thick, sticky mucus. See Table 20–6.

CLINICAL THERAPY

Cystic fibrosis is usually diagnosed in infancy. Newborn screening is performed (in all 50 states and the District of Columbia) on dried blood samples to measure pancreatic enzyme immunoreactive trypsinogen (IRT) concentrations, which are high in newborns with CF. If the reading is high, a second IRT concentration test is performed in 2 to 3 weeks. Some states perform a DNA analysis for the most common *CFTR* mutations on the same blood sample if the second IRT concentration is high. Newborn screening is positive if the IRT is elevated and DNA analysis identifies one or more *CFTR* mutations (Nakano, & Tluczek, 2014).

A sweat chloride test by pilocarpine iontophoresis, the gold standard for diagnosis of CF, is performed if the newborn screening is positive or if a *CFTR* mutation is found (Figure 20–9). A chloride concentration of 60 mEq/L or higher is diagnostic for all age groups. A sweat chloride concentration of 30 to 59 mEq/L in infants less than 6 months old or a concentration between 40 to 59 mEq/L for children and adults is suspicious. If suspicious, a repeat sweat chloride test or DNA analysis for additional *CFTR* mutations maybe performed. Genetic testing is also available for adults with a positive family history, partners of individuals with CF, and couples seeking prenatal testing to identify carriers of CF gene mutations.

A spirometer is used to monitor pulmonary function in children 6 years and older (see *Clinical Tip* on spirometry testing in the section on asthma). Forced vital capacity (FVC) and forced expiratory volume in 1 second (FEV_1) readings are taken. Sputum cultures are obtained to identify infectious organisms and antibiotic sensitivities.

Clinical therapy focuses on maintaining respiratory function, managing infections, promoting optimal nutrition and exercise, and preventing gastrointestinal blockage (Table 20–7). Newly diagnosed children without symptomatic lung disease are aggressively treated to slow the development of inflammation, chronic respiratory infections, reduction in pulmonary function, and to improve nutrition and support growth.

Figure 20–9 **This 6-month-old girl is being evaluated for cystic fibrosis using the sweat chloride test.**

Treatment is focused on controlling inflammation of the airways, treating infection, and on reducing mucus accumulation. Various devices and airway clearance techniques are used regularly to reduce the accumulation of mucus in the lungs, such as chest physiotherapy, forced expiratory technique (huffing), oscillating positive expiratory pressure, and high-frequency chest wall oscillation. Chest physiotherapy is often performed on infants and young children, but older children can learn to use other airway techniques independently.

Frequent prolonged courses of antibiotics for infections may be prescribed to improve pulmonary function, exercise tolerance, and quality of life. Sputum culture results and sensitivities help guide the selection of the specific antibiotics. Children with *Pseudomonas aeruginosa* or *Burkholderia cepacia* infections have a poorer outcome. Medications are used to reduce sputum viscosity and to dilate the airways. Anti-inflammatory treatment is sometimes prescribed. Vitamins and pancreatic enzymes are also provided to improve the child's nutritional status. A new medication, ivacaftor (Kalydeco), has been approved only for children 6 years and older who have the G551D *CFTR* mutation. See the following *Medications Used to Treat: Cystic Fibrosis*.

Collaborative care by healthcare providers including physicians, nurses, respiratory therapists, and nutritionists has resulted in improved medical management and nutrition that prolongs the lives of children and adults with CF. However, new complications such as CF-related diabetes (often with insulin insufficiency and insulin resistance) that develops in 20% of adolescents must be carefully managed along with the progression of the disease (see Chapter 30) (Delaney & Windemuth, 2014). CF-related diabetes is difficult to manage because the child needs a large caloric intake that must be balanced by insulin dosage.

End-stage lung disease from cystic fibrosis is the third most common reason for a lung transplant in the United States. About 67.8% of cases survive 1 year, 60% survive 5 years, and 43% survive 10 years (Dorgan & Hadjiliadis, 2014). Persons infected with *Burkholderia cepacia* have a lower rate of survival, making them ineligible for transplant at many centers. Respiratory failure from end-stage lung disease is the cause of death in most patients with cystic fibrosis.

Medications Used to Treat: Cystic Fibrosis

MEDICATIONS AND ACTIONS	NURSING MANAGEMENT
Beta$_2$–adrenergic receptor agonist bronchodilators *Aerosol* Used for airway hyperresponsiveness; may help prevent bronchospasm associated with inhaled therapies.	• Use before airway clearance procedure. Have the child hold the breath 10 sec after inhalation. • Avoid swallowing the medicine, and rinse the mouth afterward.
Dornase alpha (DNAse or Pulmozyme) *Aerosol* Loosens, liquefies, and thins pulmonary secretions to reduce exacerbations.	• Keep refrigerated until placed in the nebulizer. • Monitor for improvement in dyspnea and mucus clearance.
Hypertonic saline (7%) *Aerosol* Hydrates the airway mucus and stimulates coughing to improve lung function and reduce exacerbations.	• Use following a bronchodilator.
Ivacaftor (Kalydeco) *Oral* Promotes chloride ion transport and improves regulation of salt and water absorption and secretion in the tissues (Taketomo, Hodding, & Kraus, 2014). Only for children with G551D *CFTR* mutation.	• Monitor child's hepatic enzyme levels; hold medication if levels are significantly elevated. • Administer with high-fat foods. • Do not eat grapefruit or Seville oranges while taking medication.
Ibuprofen *Oral* Can slow the progression of lung pulmonary function decline (Mogayzel et al., 2013).	• Educate the child and parents to monitor for signs of gastrointestinal bleeding. • Ensure that the child does not take aspirin or other NSAIDs unless approved by healthcare provider.
Antibiotics (e.g., tobramycin, azithromycin, aztreonam, and others identified by culture sensitivity) *Aerosol, oral, or IV* Used to treat and suppress infections.	• Higher doses than normal and prolonged courses may be prescribed. • Teach the child and family to develop a schedule to give the correct dose at appropriate intervals.
Pancreatic enzyme supplements (Cotazym-S, Pancrease, Viokase) *Oral* Assists in digestion of nutrients decreasing fat and bulk.	• Given prior to food ingestion. • Ensure that enzymes are taken with meals and snacks.
Vitamins (A, D, E, and K) and antioxidants (selenium, zinc, and ascorbate) *Oral* Supplements vitamins not produced.	• Ensure that vitamins are prescribed in non–fat-soluble form to promote absorption. • Give twice a day.

Nursing Management

For the Child With Cystic Fibrosis

Care of the child with previously diagnosed CF is the focus of the following discussion.

Nursing Assessment and Diagnosis

PHYSIOLOGIC ASSESSMENT

Physical assessment of the child focuses on respiratory function. Inquire about the frequency and characteristics of the child's cough and sputum. Compare this information with the child's baseline. Changes in the cough may be more important than its presence or absence related to the development of a new infection. Auscultate the chest for breath sounds, crackles, and wheezes. Note any cyanosis or clubbing of the extremities. Obtain SpO_2 and spirometry readings if changes in respiratory status are suspected.

Determine if the child is maintaining an appropriate growth pattern by plotting the weight, height, and body mass index on a growth curve. Children with significantly lower percentiles for height and weight should be considered malnourished. Inquire about the child's appetite and dietary intake. Ask how nutritional supplements, pancreatic enzymes, and

TABLE 20–7 Clinical Therapy for Cystic Fibrosis

CLINICAL THERAPY	RATIONALE
RESPIRATORY THERAPY	
Exercise and physical fitness	Promotes maintenance of lung function.
Airway clearance techniques—chest physiotherapy twice a day for all lung segments (percussion or vibration with the child positioned to promote sputum drainage), oscillating chest vests, or other expiratory techniques	Helps secretions move to bronchi from smaller airways. Coughing and breathing airway clearance techniques help expel secretions.
Immunizations	Prevents viral and some bacterial infections.
Chest tube drainage of air leaks	Resolves pneumothorax.
Thoracoscopy to sew over ruptured alveoli	Repairs area of recurrent pneumothorax and prevents future episode in same location.
Lung transplantation	Reverses respiratory failure.
GASTROINTESTINAL TRACT THERAPY	
Acid suppression therapy	Gastroesophageal reflux worsens lung function; enteric coating of enzyme supplements is affected by high acid content in duodenum.
Hyperosmolar enemas, isotonic fluid lavage of the intestines (oral or by nasogastric tube)	Enema relieves meconium ileus in most infants; fluid lavage reduces distal intestinal obstruction.
NUTRITION	
Well-balanced, high-calorie, high-fat diet	Promotes essential nutrient balance for health, growth, weight maintenance, and increased lung capacity and survival.
Pancreatic enzyme supplements	Promotes digestion of fats and proteins.

vitamins are used. Observe the adolescent for the appearance of secondary sex characteristics, which are often delayed because of nutritional status.

Assess the child's stooling pattern. Identify whether the child has problems with abdominal pain or bloating, and whether these problems can be related to eating, stooling, or other activities. Palpate the abdomen for liver size, fecal masses, and evidence of pain.

PSYCHOSOCIAL ASSESSMENT

The emotional stress of this chronic disease may not be readily apparent, particularly if the child's symptoms are mild and not imminently life threatening. Ongoing observation of child and parent behaviors helps direct nursing interventions. Parents may feel guilt as carriers of the disease. Siblings may also show signs of difficulty in dealing with the illness, particularly if not affected by the disease. Siblings with CF may be affected if the child is showing signs of significant deterioration, being forced to acknowledge their own future course with the disease.

Ask parents how the child's illness has affected day-to-day functioning, potential conflicts with family activities, and how they have adapted to the child's plan of care. Investigate the need for respite care. Ask what the parents have told the child and siblings about the disease. What questions have the child and siblings asked about CF, and how have parents answered them? Has the child ever asked about the life expectancy of someone with CF? If not, what would parents say if asked?

Common nursing diagnoses for the child with CF include the following (NANDA-I © 2014):

- ***Airway Clearance, Ineffective,*** related to thick mucus in lungs
- ***Nutrition, Imbalanced: Less than Body Requirements,*** related to need for increased calories to meet growth and metabolic needs
- ***Infection, Risk for,*** related to the presence of mucous secretions conducive to bacterial growth
- ***Role Conflict, Parental,*** related to interruptions in family life due to the home care regimen and child's frequent exacerbations

Planning and Implementation

Nursing management involves supporting the child and family initially, when the diagnosis is made, during subsequent hospitalizations, and during visits to specialty and primary healthcare providers. The nurse's role begins with implementing specific medical therapies and providing nursing care to meet the child's physiologic and psychosocial needs. Airway clearance techniques, medications, and nutrition must be coordinated to promote optimal body function. Psychosocial support and reinforcement of the child's daily care needs are important in preparation for home care.

Children with CF require periodic hospitalization when a severe infection occurs or for a pulmonary and nutritional assessment. The child is often placed in a private room with standard precautions to reduce the spread of infectious organisms. Children with CF are not roomed together to reduce the risk for transmission of *Pseudomonas aeruginosa* and *Burkholderia cepacia* between them.

Respect the parents' experiences as the child's primary care provider and include them in the child's routine care as much as possible. However, parents may view the hospital stay as a break from the rigorous daily pulmonary routine at home and need support to take advantage of the respite. While the family is often proficient at providing physical care to the child, the nurse should take the opportunity to review basic and new information about airway clearance techniques, medications, and nutrition. This is especially important as the child matures and begins to assume some self-care responsibilities.

A B C

Figure 20–10 **Chest physiotherapy with postural drainage can be achieved by clapping with a cupped hand on the chest wall over the segment to be drained to create vibrations that are transmitted to the bronchi to dislodge secretions. *A,* If the obstruction is in the posterior apical segment of the lung, the nurse can do this with the child sitting up. *B,* If the obstruction is in the left posterior segment, the child should be lying on the right side. Several other positions can be used depending on the location of the obstruction. *C,* A high-frequency chest wall oscillation vest is another option for airway clearance that the child can independently manage.**

PROVIDE RESPIRATORY THERAPY

Chest physiotherapy or an alternate airway clearance technique is usually performed 1 to 3 times per day to facilitate the removal of secretions from the lungs. (See the *Clinical Skills Manual* SKILLS.) Perform this before meals because coughing may stimulate vomiting. Aerosol treatments with a bronchodilator, as well as DNAse and hypertonic saline to help thin respiratory secretions, may precede the airway clearance procedure. Respiratory therapists and nurses often collaborate in teaching parents and other family members the skills for these necessary treatments. Some children use an oscillating vest for 30 minutes twice a day rather than chest physiotherapy (Figure 20–10).

ADMINISTER MEDICATIONS AND MEET NUTRITIONAL NEEDS

Antibiotics for acute exacerbation are provided by oral, inhalation, and intravenous routes. Because children with CF have an increased clearance of most antibiotics, they need higher doses and longer treatment courses, often for at least 14 days until the child achieves the best possible lung function. Serum antibiotic drug levels may be ordered to ensure therapeutic dosing; however, monitor renal function tests to detect problems related to higher antibiotic dosages. In some cases, a portacath or peripherally inserted central catheter (PICC) line is placed so that IV antibiotics can be given at home.

Digestive problems can be eased with pancreatic enzymes and dietary modification. Pancreatic enzyme supplements come in powder sprinkles and capsule form and are taken orally with all meals and large snacks. The amount needed is individualized based on the child's nutritional needs and digestive response to these supplements. Help families identify any foods that contribute to a child's gastrointestinal problems. The goal is to achieve near-normal, well-formed stools and adequate weight gain.

Fat-soluble vitamins (A, D, E, and K) are not completely absorbed from food; therefore, they must be taken in water-soluble form. Multivitamins taken twice daily usually are sufficient to prevent deficiency.

Respiratory complications and a higher metabolic rate make additional calories essential. Some children and youth need supplemental nasogastric or gastrostomy feedings to gain and maintain weight. The diet should be well balanced, with an emphasis on high caloric value and high-fat content. Salt is also needed in the diet.

PROVIDE PSYCHOSOCIAL SUPPORT

Help the parents and child learn what they must do to maintain health after discharge. Emotional support is essential because the diagnosis of CF creates anxiety and fear in both the parents and the child. They need assistance with emotional and psychosocial issues relating to discipline, body image (stooling odor, barrel chest), frequent rehospitalization, the potential terminal nature of the illness, the child's feeling of being different from friends, and overall financial, social, and family concerns. Because CF is inherited, families may have more than one child with CF. Refer families to genetic counseling and support groups.

DISCHARGE PLANNING AND HOME CARE TEACHING

The financial burden of medications, supplies, and medical follow-up may not be recognized immediately by a family overwhelmed by the diagnosis. Initially, parents need assistance in obtaining necessary equipment. If the parents require financial assistance, refer them to social services and the Cystic Fibrosis Foundation. Home care of the child with CF is expensive and can impact the family's finances.

COMMUNITY-BASED NURSING CARE

Nurses may encounter the child with CF in specialty clinics, health centers, and schools. Use the assessment guidelines found

earlier in this chapter to assess the child. Observe the child's physical appearance, noting overall body proportions and any changes characteristic of CF. Respiratory function tests are usually performed every 6 months during CF visits. Assess hearing acuity on a regular basis, especially if the antibiotic tobramycin is used.

A psychosocial assessment is especially important when the child is going through major developmental stages. School-age children and adolescents are often embarrassed at being viewed as different from peers. Ask how the child or adolescent feels about the need to consume such a large amount of food, to take medications, and to follow the daily respiratory care routine.

Review the child's airway clearance technique. If additional short-term therapies are prescribed to help improve pulmonary status, educate the child and family about the techniques to use and help them identify the best time to fit the additional treatment into the daily schedule. Having to do the chest physiotherapy regimen 3 or 4 times a day has a significant impact on family time. Alternate airway clearance therapy techniques, such as a vest, huffing, or oscillating positive expiratory pressures, may be more easily accepted by the family, especially since the parent does not have to physically perform the percussion and vibration. Daily aerobic exercise is recommended to promote airway clearance and overall health.

Managing the child's nutrition is important and takes time and energy. Refer the parents to a nutritionist to customize a meal plan for the child's caloric needs. Despite the child's voracious appetite, parents may have difficulty getting the child with CF to eat enough calories for optimal nutrition and growth. Parents need suggestions for preparing calorie-dense meals and snacks. A gastrostomy tube for nighttime feeding may be needed when the child's weight is 85% to 90% of ideal for height. Children with adequate nutrition have a longer life expectancy.

Clinical Tip

Use of cream or half and half added to soups, casseroles, and puddings; cream cheese spread on breads, muffins, and crackers; sour cream added to casseroles; and powdered milk added to regular milk, meatloaf, and custards are all ways to increase the calories in food eaten. Adolescents should have high-calorie snacks they can store in their school locker to eat before after-school activities.

Children with CF lose more than normal amounts of salt in their sweat, especially during hot weather, strenuous exercise, and fever. During periods of exercise and increased sweating, encourage the child to drink more fluids and increase salt intake. Allow the child to add extra salt to food and permit some salty snacks (pretzels with salt, pickles, carbonated soda). Teach parents to recognize early symptoms of salt depletion, including fatigue, weakness, abdominal pain, and vomiting, and to contact the child's healthcare provider if these symptoms occur.

Gradual assumption of responsibility for daily disease management is necessary and may be challenging if the child rebels or is defiant regarding therapy. Individualize the child's daily care regimen to facilitate time for interaction with peers and participation in school activities. Link adolescents to vocational service planning programs to help plan for their future. Initiate palliative care planning when the child's disease progresses toward respiratory failure.

Adolescents with CF need special assistance in coping with their disorder, especially since the median survival is now more than 40 years. Help them identify normal adolescent changes versus those related to CF. Discuss ways to cope with the difference they know exists between themselves and peers. They need to develop normal relationships and establish intimacy with a partner. Information about potential infertility must be provided along with the guidelines for safe sexual practices to reduce the risk for sexually transmitted infections. Females with CF may be able to conceive and should be offered contraception.

Evaluation

Expected outcomes of nursing care include the following:

- The child and family develop proficiency in providing the daily pulmonary care and reducing the incidence of respiratory infections.
- The child and family develop a schedule and routine for daily pulmonary care that fits into family and school activities.
- The child consumes adequate calories and pancreatic enzymes to support growth and to stay within desirable weight ranges.
- The child and family cope effectively with the child's disease.

Injuries of the Respiratory System

Airway compromise after an injury to the respiratory system can cause death if not managed quickly and effectively. Children are vulnerable to changes in respiratory function after injury because their airway is small and can become easily obstructed. Airway obstruction can be caused by the tongue, small amounts of blood, mucus, or foreign debris, and swelling in the respiratory tract or adjacent neck tissue, leading to hypoxia. If the child's neck is flexed or hyperextended, the soft laryngeal cartilage may also compress and obstruct the airway.

Smoke-Inhalation Injury

Exposure of the child's face and airway to smoke or extreme heat leads to dramatic responses in the child's respiratory tract. Smoke and heat increase the child's risk for airway obstruction, carbon monoxide poisoning, acute respiratory distress syndrome, late complications such as pneumonia, and death. The child's higher respiratory rate also increases exposure to noxious chemicals.

The severity of the smoke-inhalation injury is influenced by the type of material burned and is more severe if the child was found in a closed space. Smoke, a product of the burning process that is composed of gases and particles, such as cyanide from synthetic materials, is generated in varying volumes and density. The type and concentration of toxic gases, which are usually invisible, affect the severity of pulmonary damage. The duration of exposure to the smoke and toxic gases contributes significantly to the child's prognosis.

Exposure to extreme heat, common in house fires, leads to surface injury and upper airway damage. The upper airway normally removes heat from inhaled gases, sparing the lower airway from thermal damage. Airway edema develops rapidly over a few hours and potentially leads to acute respiratory distress syndrome.

Carbon monoxide (CO) is a clear, colorless, odorless, and tasteless gas that develops as a fire consumes oxygen or from poorly ventilated heating systems. The CO molecule binds more firmly to hemoglobin than does oxygen. As a result, reduced amounts of oxygen in the blood rapidly produce tissue hypoxia in the child. The brain receives inadequate oxygen, resulting in confusion and progressing to loss of consciousness. This is one reason fire victims have difficulty escaping. The process can be rapidly reversed by the timely administration of 100% oxygen, if provided before hypoxia becomes too severe (Hampson, Piantadosi, Thom, et al., 2012).

Damage to the lower airway often results from chemical or toxic gas inhalation. Soot carried deeply into the lungs combines with water to deposit acid-producing chemicals on the lung tissue. These acids burn the tissue and destroy the cilia and surfactant. Tissue destruction, pulmonary edema, and disrupted gas exchange are the initial insult to the lungs. Days later, the damaged tissue sloughs off, obstructing the airways. The lungs become a breeding ground for microorganisms, leading to pneumonia. Healing leaves scars in the damaged alveoli that can reduce future lung function.

Clinical manifestations of inhalation injury associated with fire include burns of the face and neck, singed nasal hairs, soot around the mouth or nose, and hoarseness with stridor or voice change, even when the child initially has no respiratory distress. Edema develops rapidly over a few hours and may lead to airway obstruction with signs such as tachypnea, stridor, coughing, and wheezing. Respiratory distress develops and can lead to respiratory failure. If carbon monoxide poisoning is present, the child may have headache, dizziness, confusion, shortness of breath, and loss of consciousness.

Diagnosis is based on history of smoke exposure in a closed area, and physical signs of soot around the nose and mouth. Arterial blood gases and a carboxyhemoglobin level are obtained. The child with minimal signs and symptoms when seen in the emergency department may be admitted to monitor for progression of respiratory distress. Initial treatment is 100% humidified oxygen. If respiratory distress develops, aggressive airway management with endotracheal tube insertion and monitoring are provided in the PICU. Mechanical ventilation and high concentration oxygen may be necessary. Chest physiotherapy and suctioning may be provided in an effort to keep the airway clear. All other injuries sustained in the fire are treated.

Nursing Management

Assess the child for the development of respiratory distress. Check vital signs frequently, and monitor the SpO_2. Auscultate the lungs for crackles, wheezes, and decreased breath sounds. Assess for level of consciousness and behavior changes that could indicate increasing hypoxia.

Provide oxygen as ordered. Position the child to promote respiratory function. If the child's condition deteriorates, assist with procedures to secure the child's airway and prepare the child for transfer to the ICU. Assess the family's response to the life-threatening crisis and offer support with information about the child's condition (see Chapter 13).

Blunt Chest Trauma

Blunt chest trauma in infants and toddlers is most often due to motor vehicle crashes and abuse. Bicycles, scooters, skateboards, and skates are more commonly associated with blunt chest trauma in school-age children. Injuries from high-energy motor vehicle crashes more commonly occur in adolescents. Chest injuries may not be obvious and can be extremely difficult to evaluate.

Most children who die after sustaining severe blunt chest trauma were hypoxic because of poor airway and ventilatory control. A child's elastic, pliable chest wall and thin abdominal muscles provide minimal protection to underlying organs. This elasticity of the ribs often prevents rib fractures in children less than 12 years of age, but the energy from blunt trauma is transferred directly to the internal organs. A pulmonary contusion or pneumothorax may result.

Pulmonary Contusion

A pulmonary contusion is defined as bruising damage to the tissues of the lung that often results from the transfer of energy from a strong blow to the chest. It often occurs without rib fracture. The lung tissue is indirectly injured, causing capillaries to bleed into the alveoli. Edema develops in the lower airways. The blood and fluid from damaged tissues accumulate over a couple of days and may interfere with gas exchange. Acute respiratory distress syndrome and long-term respiratory dysfunction may result.

The child may initially appear asymptomatic if it is an isolated injury. With a large pulmonary contusion the child may develop respiratory distress, along with fever, wheezing, hemoptysis, and crackles over several hours. Careful observation is required during the first 12 hours after the injury to detect decreased perfusion related to ventilatory impairment.

Chest radiographs or computed tomography may be diagnostic for a pulmonary contusion several hours after the injury. Therapy includes supplemental oxygen, pain control, incentive spirometry, and avoiding prolonged immobilization. Children with severe injury to the lungs will require mechanical ventilation with low airway pressures. Pneumonia is a potential complication.

Nursing Management

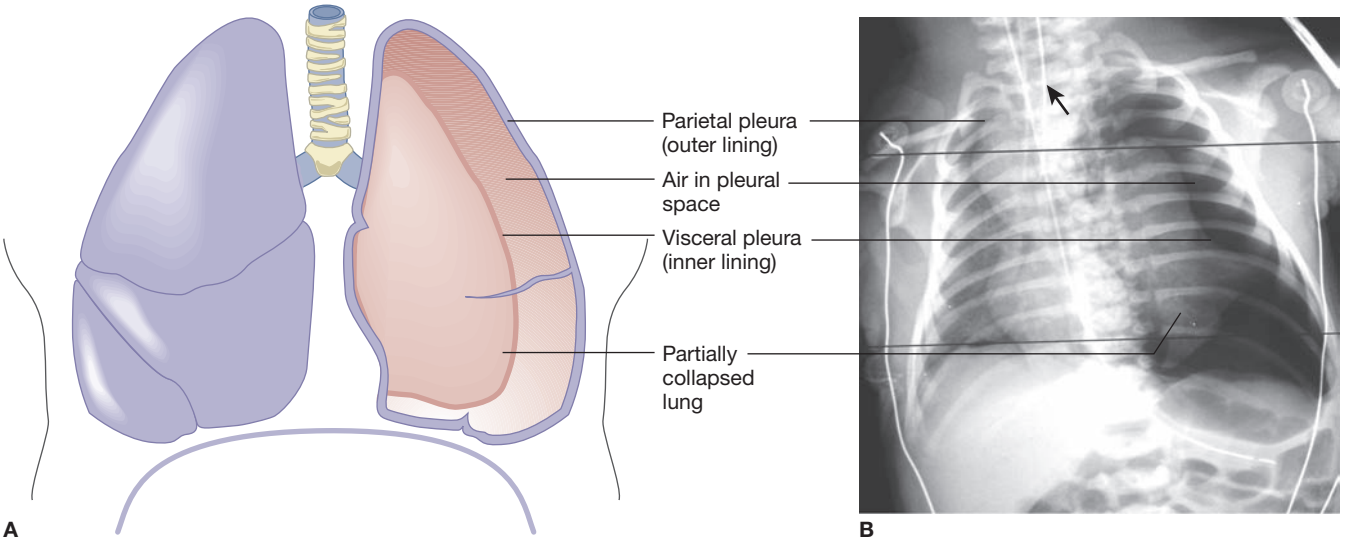
Nursing care centers on providing necessary physiologic support, such as oxygen therapy, positioning, incentive spirometry, fluid management, and comfort measures. Observe for hemoptysis, dyspnea, decreased breath sounds, wheezes, crackles, and a transient temperature elevation. Agitation and lethargy can signal increasing hypoxia. Inspect the thorax for symmetric chest wall movement, and auscultate for breath sounds in both lungs. The child may initially appear well but requires careful monitoring to detect signs of deterioration. Children with significant injuries are cared for in the ICU. Some children require ventilator support as the pulmonary tissues heal.

Pneumothorax

A pneumothorax occurs when air enters the pleural space because of a penetrating chest injury or tears in the tracheobronchial tree, the esophagus, or the chest wall. If blood collects in the pleural space, it is called a *hemothorax,* and if blood and air collect, it is called a *pneumohemothorax.* A pneumothorax is one of the more common thoracic injuries in pediatric trauma patients. The three types of pneumothorax are open, closed, and tension.

An *open pneumothorax* results from any penetrating injury that exposes the pleural space to atmospheric pressure, thereby collapsing the lung. A sucking sound may be heard as the air moves through the opening on the chest wall. The child may show signs of restlessness, cyanosis, and subcutaneous emphysema (air leakage in the tissue). Emergency treatment involves placing a water-tight bandage sealed on three sides over the opening to prevent more air from entering the chest during inspiration. The fourth side is left open so accumulated air can escape on expiration. A thoracostomy is performed, and a chest tube is inserted (see the *Clinical Skills Manual* SKILLS). A closed drainage

Pathophysiology Illustrated: **Pneumothorax**



***A,* A pneumothorax is air in the pleural space that causes a lung to collapse. Whether the air results from an open injury or from bursting of alveoli due to a blunt injury, it is important to focus on airway management and maintain lung inflation. *B,* Tension pneumothorax. Note the collapsed lung on the child's left side and the deviation of the child's heart and trachea to the right side of the chest (see arrow).**

SOURCE: Courtesy of Dorothy Bulas, MD, Professor of Radiology and Pediatrics, Children's National Medical Center, Washington, DC.

system is attached to remove the air and reinflate the lung by reestablishing negative pressure.

A *closed pneumothorax* is sometimes caused by blunt chest trauma with no evidence of rib fracture (see *Pathophysiology Illustrated: Pneumothorax*). The chest may be compressed against a closed glottis (such as with breath holding), causing a sudden increase in pressure within the thoracic cavity. The pressure increase is transferred to the alveoli, causing them to burst. A single burst alveolus may be able to seal itself off, but the lung collapses when many alveoli are damaged. Breath sounds are decreased or absent on the injured side, and the child is in respiratory distress. A thoracostomy is performed and a chest tube inserted and attached to a closed drainage system.

A *tension pneumothorax* is a life-threatening emergency that results when the air leaks into the chest during inspiration but cannot escape during expiration. Internal pressure continues to build, compressing the chest contents and collapsing the lung. Venous return to the heart is impaired as the mediastinum shifts and the trachea, heart, vena cava, and esophagus are compressed toward the unaffected lung, leading to decreased cardiac output. Signs of tension pneumothorax include increasing respiratory distress, decreased breath sounds, and paradoxical breathing. Immediate care for a tension pneumothorax is a needle thoracentesis to allow air to escape and relieve the tension. A chest tube is then inserted and attached to a closed drainage system.

Nursing Management

Nursing management focuses on airway management and maintaining lung inflation. The child arrives on the nursing unit with a chest tube and drainage system in place. Continued close observation for respiratory distress is essential. Carefully monitor vital signs. When the chest tube is removed, the site is covered with an occlusive dressing and the child's respiratory status is monitored for signs of respiratory distress. Complications include hemothorax (if the thoracostomy and chest tube are improperly placed), lung tissue injury, and scarring from poor tube placement (especially if the tube is placed too near the breast in girls).

Chapter Highlights

- Respiratory conditions are a leading cause of hospitalization for all children between 1 and 19 years of age.
- The child's airway is shorter and narrower than an adult's, increasing the risk for obstruction. The lungs have no muscles; the diaphragm and intercostal muscles power ventilation.
- Foreign-body aspiration is a major health problem for infants and toddlers, often related to their increasing mobility and tendency to put small objects such as food and small toy parts in their mouths.
- Signs of impending respiratory failure in infants and children include worsening respiratory distress, irritability, lethargy, mottled color or cyanosis, diaphoresis, and increased respiratory effort such as dyspnea, tachypnea, nasal flaring, grunting, and retractions.
- An apparent life-threatening event (ALTE) is an episode of apnea accompanied by a color change (e.g., cyanosis or pallor), limp muscle tone, choking, or gagging in an infant less than 12 months of age.
- Obstructive sleep apnea syndrome (OSAS) in children is commonly caused by enlarged tonsils and adenoids. Children snore loudly and have labored breathing during sleep.
- Sudden infant death syndrome (SIDS) is a leading cause of death in infants. Onset of the fatal episode occurs during sleep and remains unexplained after a thorough investigation, including an autopsy, a review of the circumstances of death, and the clinical history.
- Laryngotracheobronchitis (LTB) is a viral croup syndrome with signs of an upper respiratory illness, hoarseness, tachypnea, inspiratory stridor, and a seal-like barking cough. Fever may or may not be present.
- Epiglottitis is a bacterial infection that can cause a life-threatening airway obstruction. It is commonly prevented by the pneumococcal vaccine. Classic signs include dysphonia, dysphagia, drooling, and distressed respiratory effort.
- Respiratory syncytial virus (RSV) is the most common cause of bronchiolitis, a lower respiratory tract infection that causes inflammation and obstruction of the bronchioles.
- Symptoms of pneumonia in infants and children include elevated temperature, rales, crackles, wheezes, cough, dyspnea, tachypnea, restlessness, and decreased breath sounds if consolidation occurs.
- Children under 2 years are at increased risk for developing active tuberculosis, including tubercular meningitis and disseminated TB.
- Chronic lung disease or bronchopulmonary dysplasia (BPD) usually develops in neonates with a birth weight of 1000 g (2.2 lb) or less. Treatment with oxygen and positive-pressure ventilation causes inflammation and damages the bronchioles, resulting in fibrosis, edema of the bronchioles, and smooth muscle hypertrophy.
- An asthma episode results from inflammation and a stimulus causing excessive mucus formation, mucosal swelling, and airway muscle contraction, leading to airway obstruction.
- In cystic fibrosis, defective chloride-ion transport across the exocrine and epithelial cell walls results in an abnormal accumulation of viscous, dehydrated mucus that affects the respiratory, gastrointestinal, and reproductive systems.
- Signs of smoke-inhalation injury in children include burns of the face and neck, singed nasal hairs, soot around the mouth or nose, and hoarseness with stridor or voice change.
- A pneumothorax may become life threatening when air leaking into the chest cavity during inspiration cannot escape during expiration, increasing compression. Venous blood return to the heart is impaired as the mediastinum shifts toward the unaffected lung.

Clinical Reasoning in Action

Adam and his mother have come to the health center to follow up on his hospitalization to get an asthma action plan and to discuss how to reduce his asthma episodes. Adam, who is 7 years old, has a history of episodic wheezing and nebulizer treatments, but he had never been hospitalized for asthma until last week. During his 2-day hospitalization, his parents were given initial education about how to manage his moderate persistent asthma.

His mother has brought along Adam's medications (inhaled corticosteroid and salmeterol MDI for daily control, and an albuterol MDI for quick relief), his peak flow meter, spacer, and his asthma action plan. She tells you that he is also completing a dose of oral corticosteroids. You discuss the peak flow meter, the guidelines, and what type of action to take as needed. Based on his height of 48 in., his peak flow meter green zone is 160–128, his yellow zone is 128–80, and his red zone is 80 or below. Adam is to

use his daily control medications twice a day. If he has symptoms, he is to take his albuterol MDI with spacer, two puffs every 4–6 hours as needed.

1. What are some of the side effects associated with Adam's albuterol MDI?
2. What is the benefit to using a spacer on Adam's albuterol and inhaled corticosteroid MDI?
3. Address the concerns of Adam's mother about the daily use of inhaled corticosteroids.
4. What are the signs of respiratory distress to observe for with Adam?
5. What information should be shared with the school nurse for Adam's symptom management while at school?

Chapter 21
Alterations in Cardiovascular Function

Blend Images/Shutterstock

Brandy got sick so fast. Look how fast she is breathing. She gets tired before she can finish her formula. We didn't expect her to need heart surgery when she was still so small. We were told her chances for successful surgery would improve if she grew some more. I just want her to get stronger and have the chance to grow up to be like other kids.

—Mother of Brandy, 1 month old

Learning Outcomes

21.1 Describe the anatomy and physiology of the cardiovascular system, focusing on the flow of blood and the action of heart valves.

21.2 Describe the pathophysiology associated with congenital heart defects with increased pulmonary circulation, decreased pulmonary circulation, mixed defects, and obstructed systemic blood flow.

21.3 Develop a nursing care plan for the infant with a congenital heart defect cared for at home prior to corrective surgery.

21.4 Create a nursing care plan for the child undergoing open heart surgery.

21.5 Recognize the signs and symptoms of congestive heart failure in an infant and child.

21.6 Develop a nursing care plan for a child with congestive heart failure.

21.7 Differentiate among the heart diseases that are acquired or begin development during childhood.

21.8 Develop a nursing care plan for a child with Kawasaki syndrome.

21.9 List strategies to reduce a child's risk of adult-onset cardiovascular disease.

21.10 Plan the nursing management of hypovolemic shock.

Alterations in cardiovascular function may result from a congenital defect, acquired infection, or injury. Congenital heart defects are one of the most common birth defects, occurring in approximately 1% of all live births (Peterson et al., 2014). More than 35 types of heart defects have been documented. Examples of acquired cardiovascular conditions include rheumatic fever, Kawasaki disease, and hypertension.

Text continues on page 522

FOCUS ON:
The Cardiovascular System

Anatomy and Physiology

The heart is divided into four chambers: two atria and two ventricles. Atrioventricular valves (tricuspid and mitral) separate the atria from the ventricles. They open and close to control the flow of blood to the ventricles. The semilunar valves (pulmonary and aortic) open when the ventricles pump blood and close to prevent the backflow of blood to the ventricles. The great arteries (aorta and pulmonary artery) carry blood away from the heart to either the body or the lungs. Pulmonary veins and the superior and inferior venae cavae return blood to the heart. See Figure 21–1 for the anatomy of the heart and pressures generated by the blood.

The heart is the pump that circulates the blood through the systemic and pulmonary systems. Blood flows to the lungs for oxygen and carbon dioxide exchange. The oxygenated blood returns to the heart for distribution to the systemic circulation, organs, and tissues. See Table 21–1 for **hemodynamics** (passage of blood through the heart and pulmonary system and action of the valves) of the normal heart. The heart's electrical conduction system controls the rhythmic pumping (Figure 21–2).

TABLE 21–1 Hemodynamics of the Normal Heart

ACTION	RIGHT SIDE OF HEART	LEFT SIDE OF HEART
Blood return to heart	From the systemic circulation by way of the superior and inferior venae cavae.	From the lungs by way of the left and right pulmonary veins.
Diastolic phase	Pulmonary valve closes and tricuspid valve opens.	Aortic valve closes and mitral valve opens.
	Blood flows from the venae cavae through the right atrium and tricuspid valve into the right ventricle.	Blood flows from the pulmonary veins through the left atrium and mitral valve into the left ventricle.
Systolic phase	Tricuspid valve closes and pulmonary valve opens.	Mitral valve closes and aortic valve opens.
	Blood is pumped into the pulmonary artery and passes into the right and left pulmonary arteries and lungs.	Blood is pumped into the aorta where it enters the systemic circulation.

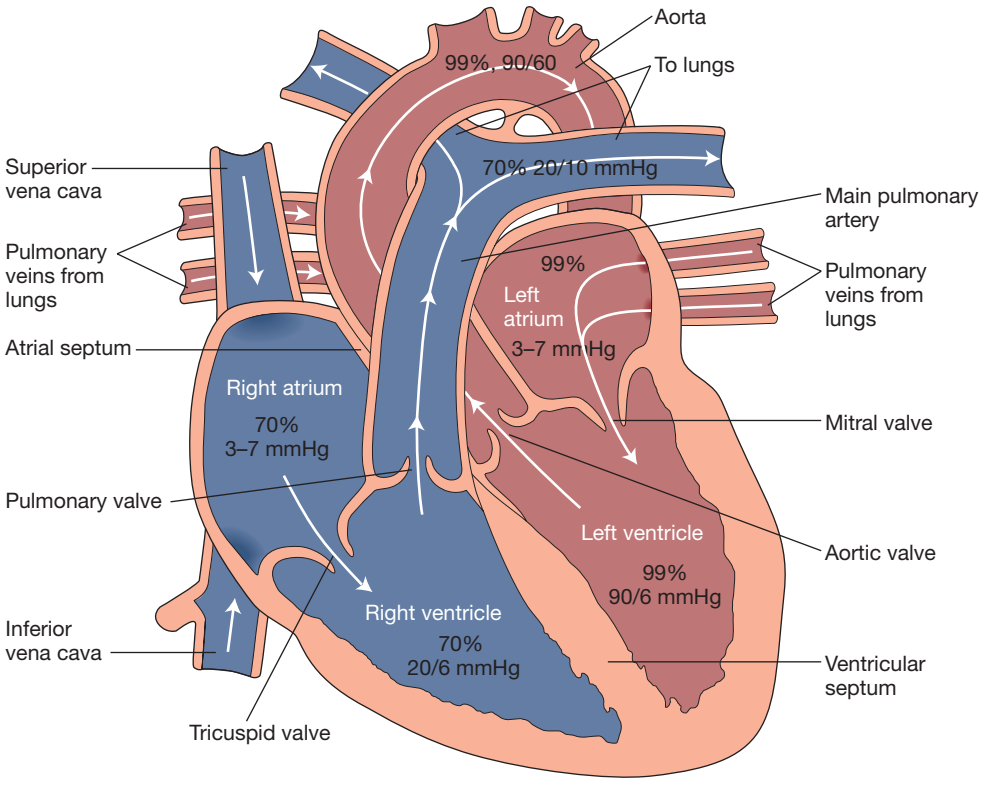

Figure 21–1 Anatomy of the heart, direction of blood flow, and the normal pressure gradients and oxygen saturation levels in the heart chambers and great arteries. The right ventricle has a lower pressure during systole than the left ventricle because less pressure is needed to pump blood to the lungs than to the rest of the body.

(*continued*)

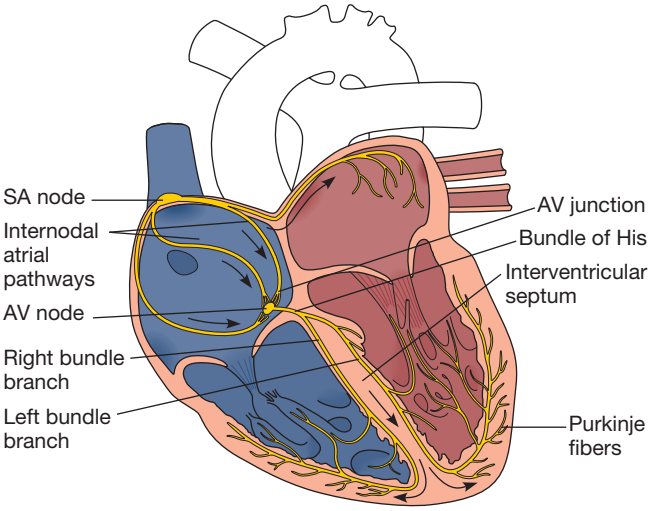

Figure 21–2 **Electrical conduction system of the heart. Depolarization normally follows a sequence that begins in the sinoatrial (SA) node and travels through the atrial muscle to the atrioventricular (AV) junction, and then through the AV node to the ventricular muscles. The pathway in the ventricles begins in the bundle of His and divides into the right and left bundle branches. The pathway terminates in the Purkinje system so that the impulse spreads across the myocardium.**

Transition From Fetal to Pulmonary Circulation

The transition from fetal to pulmonary circulation occurs within a few hours of birth (see *As Children Grow: Transition of Fetal Circulation to Pulmonary Circulation*). Permanent closure of the ductus arteriosus occurs by 10 to 21 days after birth, unless oxygen saturation remains low. Fetal tissues are accustomed to low oxygen saturation. This may explain why newborns with heart conditions with decreased pulmonary blood flow (cyanotic defects) appear relatively comfortable even when their arterial partial pressure of oxygen (PaO_2) is very low.

Pediatric Differences

Cardiac Functioning

Infants have a greater risk of heart failure than older children because the immature heart is more sensitive to volume or pressure overload. During infancy the heart's muscle fibers are less developed and less organized, resulting in limited functional capacity. Less **compliance** (amount of expansion the ventricles can achieve to increase stroke volume) of the heart muscle means that the **stroke volume** (the amount of blood ejected with each contraction) cannot increase substantially. The heart muscle fibers develop during early childhood, and by 9 years of age, the weight of the heart has increased by six times (McDaniel, 2014). As the child's heart grows and develops, the systolic blood pressure rises, reaching adult levels by puberty.

The infant maintains a high heart rate and high **cardiac output** (volume of blood ejected from the left ventricle each minute) to meet high metabolic rate and oxygen requirements. Infants and children with a fever, exercise, stress, or respiratory distress respond with tachycardia rather than increased stroke volume to increase their cardiac output. The newborn has little cardiac output reserve capacity until oxygen requirements begin to decrease at about 2 months of age (McDaniel, 2014).

Oxygenation

Oxygen bound to hemoglobin is transported to the tissues by the systemic circulation. Hematocrit and hemoglobin concentrations appropriate for the child's age are necessary for adequate oxygen transport (see Chapter 23). The arterial oxygen saturation is the amount of oxygen that can potentially be delivered to the tissues. **Desaturated blood** results when oxygenated and unoxygenated blood mix because of a congenital heart defect. Cyanosis, which indicates **hypoxemia** (lower than normal amounts of oxygen in the blood), results when a concentration of 5 g/dL of deoxygenated hemoglobin is present in the blood or from arterial oxygen saturation less than 85% (McDaniel, 2014).

The child's bone marrow responds to chronic hypoxemia by producing more red blood cells to increase the amount of hemoglobin to be oxygenated. This increase is known as **polycythemia**. A hematocrit value of 50% or higher is common in children with heart defects with decreased pulmonary blood flow.

Children respond to severe hypoxemia with bradycardia. Cardiac arrest in children generally results from prolonged hypoxemia related to respiratory failure or shock rather than from a primary cardiac insult as in adults. Bradycardia is therefore a significant warning sign of cardiac arrest. Appropriate management of hypoxemia often reverses bradycardia and prevents cardiac arrest.

Cardiac Assessment

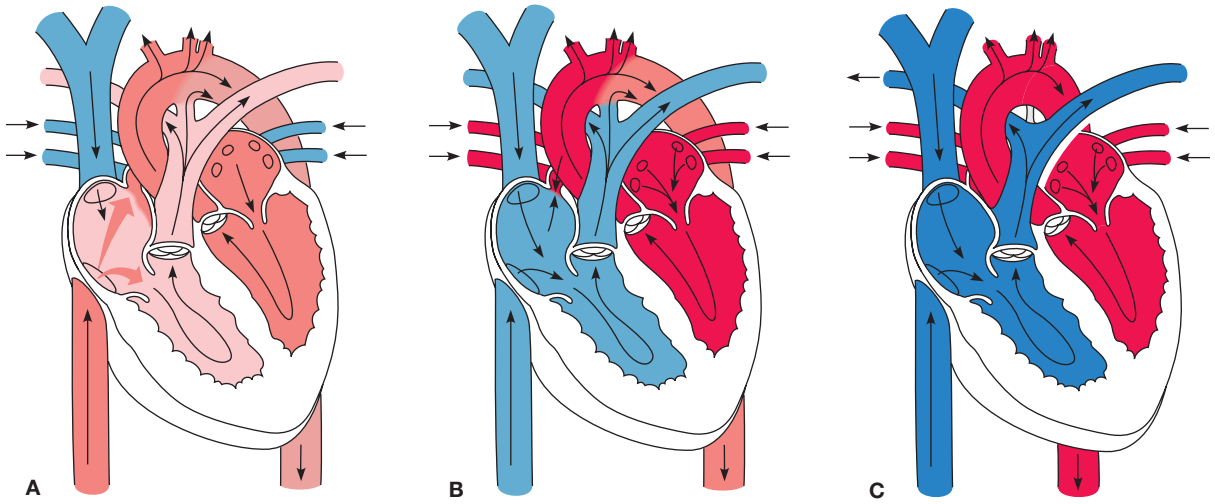
Performing a nursing assessment of the child with a potential or actual cardiac condition involves a careful review of the signs and symptoms in many body systems and analysis of their relationship to cardiac functioning. Use *Assessment Guide: The Child With a Cardiac Condition* to perform a comprehensive nursing assessment of the cardiovascular system. Numerous diagnostic procedures and laboratory tests are used for the diagnosis of cardiac conditions. See Table 21–2.

TABLE 21–2 Diagnostic Procedures and Laboratory Tests Used to Evaluate Cardiac Conditions*

DIAGNOSTIC PROCEDURES	LABORATORY TESTS
Cardiac catheterization	Complete blood count
Chest radiograph	Arterial blood gases
Echocardiogram (transthoracic and transesophageal)	Antistreptolysin-O antibody titer
Electrocardiography (ECG) and ambulatory ECG (Holter monitor)	Erythrocyte sedimentation rate
Exercise testing	C-reactive protein
Hyperoxitest	Serum lipid panel
Computed tomography	Serum drug tests (e.g., digoxin)
Magnetic resonance imaging	

*See Appendices D and E for information about these diagnostic procedures and expected laboratory values.

As Children Grow: **Transition of Fetal Circulation to Pulmonary Circulation**



A, During pregnancy blood flows to the fetus through the umbilical vein to the ductus venosus (the fetal vascular channel between the umbilical vein and the inferior vena cava) and into the heart's RA. The foramen ovale, an opening between the atria of the fetal heart, allows blood to flow from the RA to the LA and then into the LV. Blood then flows into the aorta and systemic circulation. Some blood returns from the head and upper extremities to the superior vena cava and RA. Some blood travels to the RV where it is pumped into the pulmonary artery, through the ductus arteriosus (the vascular channel between the pulmonary artery and the aorta), and into the systemic circulation. A small amount of the blood from the pulmonary artery goes to the fetal lungs. Blood eventually returns to the placenta by way of the umbilical arteries. After the umbilical cord has been cut, the newborn must quickly adapt to receiving oxygen from the lungs.

B, The first breath expands the lungs, and blood that previously flowed through the ductus arteriosus to the aorta begins flowing to the lungs. Pulmonary blood flow increases and pulmonary vascular resistance decreases. Pressure in the LA increases as increased blood flow is returned from the lungs through the pulmonary veins. Systemic vascular resistance (the force or resistance of the blood in the body's blood vessels that helps return blood to the heart) increases and pressure in the RA falls. Increased pressure in the left atrium stimulates closure of the foramen ovale unless there is excess pressure on the right side of the heart.

C, The ductus arteriosus, responding to higher oxygen saturation, normally constricts and closes within 10 to 15 hours after birth.

KEY: LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

ASSESSMENT GUIDE | The Child With a Cardiac Condition*

Assessment Focus	Assessment Guidelines
Respirations	• What is the respiratory rate and depth? • Are signs of increased respiratory effort present (e.g., tachypnea, dyspnea, retractions, nasal flaring, expiratory grunting)? • Is a cough present? • Auscultate breath sounds. Are any adventitious sounds present (e.g., wheezes, crackles)?
Pulse characteristics	• Assess the pulse rate, rhythm, and quality. • Compare pulse sites for strength and rate (apical to brachial, radial, femoral, pedal).
Blood pressure	• Compare the blood pressure to expected value for age, gender, and height percentile. (See Appendix B.) • Compare blood pressure values between upper and lower extremities.

(*continued*)

ASSESSMENT GUIDE | The Child With a Cardiac Condition* (*continued*)

Assessment Focus	Assessment Guidelines
Color	• Observe overall color. Note pallor, dusky color, or cyanosis. • Compare the color in peripheral and central locations (e.g., nail beds to mucous membranes). Does crying improve or worsen the color? • Assess pulse oximetry.
Chest	• Inspect the anterior chest for bulging or **heaving** (lifting of the chest wall during contraction). • Palpate the chest wall over the heart for pulsations, heaves, or vibrations. • Locate the point of maximum intensity.
Heart auscultation	• Auscultate the heart for the heart sounds and their quality (loud versus weak, distinct versus muffled). • Are any extra heart sounds or murmurs present? Describe murmurs by their intensity, location, radiation, timing, and quality. • Auscultate the heart with the child sitting and reclining to detect differences in heart sounds.
Fluid status	• Observe for signs of periorbital, facial, or peripheral edema, or for dehydration. • Observe for abdominal distention. • Palpate the liver to detect hepatomegaly. • Assess capillary refill.
Activity and behavior	• Is exercise tolerance present? Does the child tire with feeding? • Note presence of diaphoresis and when it occurs. • Identify changes in activity level or behavior (lethargy, restlessness, irritability, and decreased responsiveness).
General	• Assess pattern of growth.

**See Chapter 5 for assessment techniques.*

Congenital Heart Disease

Congenital heart disease refers either to a defect in the heart or great vessels or to persistence of a fetal structure (e.g., patent foramen ovale or patent ductus arteriosus) after birth. The incidence is about 8 to 12 per 1000 live births (Park, 2014, p. 7). A critical congenital heart defect is life threatening and requires emergency care, surgery, or catheter intervention within the first days or weeks of life. These defects account for 25% of infant deaths related to a birth defect during the first year of life (Peterson et al., 2014).

Etiology and Pathophysiology

Most congenital heart defects develop during the first 8 weeks of gestation. They can develop as the result of a combined or interactive effect of genetic and environmental factors, such as:

- Fetal exposure to drugs (e.g., phenytoin, angiotensin-converting enzyme [ACE] inhibitors, lithium, warfarin, valproic acid, retinoic acid) and alcohol
- Maternal viral infections such as rubella or coxsackievirus B5
- Maternal metabolic disorders such as phenylketonuria, diabetes mellitus, and hypercalcemia
- Increased maternal age
- Multifactorial genetic patterns
- Chromosomal abnormalities (e.g., Turner, Noonan, Marfan, DiGeorge, and trisomy [13, 18, 21] syndromes)

Because of the genetic component, the incidence of congenital heart defects (CHDs) is expected to slowly rise; for example, a mother with a CHD has an increased risk of having an affected child.

Congenital heart defects are categorized by pathophysiology and hemodynamics rather than by the presence of cyanosis. These categories are described in more detail later in this chapter and include the following:

- Increased pulmonary blood flow
- Decreased pulmonary blood flow
- Obstructed systemic blood flow

Mixed defects fall into one of these three classifications, but the infant's survival depends on mixing systemic and pulmonary blood. Children with mixed defects and decreased pulmonary blood flow have similar clinical therapy and nursing management, so these categories will be discussed together.

Clinical Manifestations

The presence of a heart murmur is often the first indication of a congenital heart defect. A murmur indicates blood is flowing with higher pressure than normal to get through a narrowed valve or vessel or through a **shunt** (an abnormal anatomic opening in the septum between the systemic and pulmonary circulation). Other clinical manifestations and the timing of their appearance vary by the pathophysiology and severity of the defect. See Table 21–3. Newborns may become symptomatic as soon as the umbilical cord is cut or within the first few days of life. Some children may be asymptomatic except for a heart murmur. Signs and symptoms in older children may include exercise intolerance, chest pain, arrhythmias, syncope, and sudden death.

TABLE 21–3 Clinical Manifestations of Heart Defects by Pathophysiology

PATHOPHYSIOLOGY AND TYPE OF DEFECT	CLINICAL MANIFESTATIONS
Increased pulmonary blood flow (PDA, ASD, VSD, AV canal)	Tachypnea, tachycardia, murmur, congestive heart failure (CHF), poor weight gain, diaphoresis, periorbital edema, frequent respiratory infections
Decreased pulmonary blood flow (PS, TOF, pulmonary or tricuspid atresia, TGA)	Cyanosis, hypoxic spells, poor weight gain, polycythemia
Obstruction to systemic blood flow (COA, AS, HLHS, MS, interrupted aortic arch)	Diminished pulses, poor color, delayed capillary refill time, decreased urine output, CHF with pulmonary edema
Mixed defects—postnatal survival is dependent on mixing of systemic and pulmonary blood (TGA, TAPVR, truncus arteriosus, double outlet right ventricle)	Cyanosis, poor weight gain, pulmonary congestion, CHF may occur with increased shunting

Key: AS, aortic stenosis; ASD, atrial septal defect; AV, atrioventricular; COA, coarctation of aorta; HLHS, hypoplastic left heart syndrome; MS, mitral stenosis; PDA, patent ductus arteriosus; PS, pulmonic stenosis; TAPVR, total anomalous pulmonary venous return; TOF, tetralogy of Fallot; TGA, transposition of great arteries; VSD, ventricular septal defect

Clinical Therapy

Multiple tests are used to diagnose cardiac defects (Table 21–2). Blood tests such as a hematocrit and hemoglobin are taken to assess for anemia or polycythemia. Arterial blood gases may be obtained, especially when cyanosis or a complex heart defect is suspected. Newborn screening with pulse oximetry is used to identify critical congenital heart disease (Association of Maternal and Child Health Programs, 2013).

Treatment for congenital heart defects depends on the severity of symptoms and whether the condition is imminently life threatening. Interventional cardiac catheterization or surgical correction with restoration of normal hemodynamics and physiology is the treatment of choice for many defects. A **palliative procedure** (a surgical procedure that does not create normal anatomic or hemodynamic results) may be performed in children with a potentially fatal or lethal condition. It may also be performed as an initial procedure, allowing an infant to grow before definitive corrective surgery. Table 21–4 lists the types of interventions during cardiac catheterization and surgical procedures performed on children with congenital heart defects.

TABLE 21–4 Clinical Interventions for Congenital Heart Defects

CARDIAC CATHETERIZATION INTERVENTIONS AND THERAPEUTIC USE	PURPOSE
Balloon atrial septostomy—Rashkind, or with transatrial needle puncture and balloon dilation	
Palliative for TGA	Creates a larger defect (at the foramen ovale) between atria to increase blood mixing.
Balloon dilation procedure	
Corrective for PS and MS; palliative for AS, COA	A deflated balloon is inserted and inflated to open a narrowed valve or blood vessel. A stent may be inserted to keep the vessel (e.g., ductus arteriosus) open.
Device closure	
Corrective for PDA, ASD, VSD	Closure of ductus arteriosus by an umbrella or coil device, and closure of a septal defect by a septal occluder.
SURGICAL PROCEDURES AND THERAPEUTIC USE	**PURPOSE**
Aorta end-to-end anastomosis	
Corrective for COA	Resection of the narrowed section of the aorta and connection of the proximal and distal sections.
Blalock-Taussig shunt, modified	
Palliative for TOF, single ventricle lesions with pulmonary outflow obstruction	Creation of aortopulmonary conduit (from the brachiocephalic artery to pulmonary artery) to increase pulmonary blood flow.
Brock	
Corrective for PS	Blind incision of pulmonary valve.
Damus-Kaye-Stansel—pulmonary artery-to-aortic anastomosis	
Corrective for TGA, complex single ventricle defects	Pulmonary artery is cut in two with the proximal section attached to the ascending aorta; the distal section is sewn over, and a shunt is created between the systemic circulation and the pulmonary artery to send blood to the lungs.
Fontan	
Palliative for HLHS, single ventricle defects	Creation of a conduit between inferior vena cava and pulmonary artery to increase pulmonary blood flow—total right heart bypass. The single ventricle assumes responsibility for the systemic circulation and ejects blood into the aorta.

(*continued*)

TABLE 21–4 Clinical Interventions for Congenital Heart Defects (*continued*)

SURGICAL PROCEDURES AND THERAPEUTIC USE	PURPOSE
Glenn or Bidirectional Glenn	
Palliative for HLHS, single ventricle defects	Superior vena cava connected to right pulmonary artery along with closure of aortopulmonary shunt. Systemic venous blood from the head is sent to the lungs directly without ventricular pumping.
Jatene—arterial switch	
Corrective for TGA	Aorta and pulmonary arteries are transected and reattached to the opposite stumps; coronary arteries are moved to new aorta area.
Nikaidoh	
Corrective for TGA when a VSD and severe PS are present	The aortic root is translocated from the right ventricle, with attached coronary vessels, to the left ventricle after reconstructing the left and right outflow tracts and patching the VSD.
Norwood	
Palliative for aortic hypoplasia, single ventricle defects (e.g., HLHS)	Atrial septectomy, anastomosis of the main pulmonary artery to the aorta, and an arterial-pulmonary shunt (e.g., modified Blalock-Taussig shunt).
Norwood with Sano modification	
Palliative for HLHS	Creation of a right ventricle to pulmonary artery conduit so that both the direct pulmonary and aorta blood flow originate in the right ventricle.
Patch aortoplasty	
Corrective for COA	Insertion of a Dacron patch or opened left subclavian vein to expand the lumen of the aorta.
Pulmonary artery banding	
Palliative for VSD, AV canal, single ventricle defects	Placement of constricting band around pulmonary artery to reduce pulmonary blood flow and pressure.
Rastelli	
Corrective for TGA with pulmonic stenosis, TOF, tricuspid atresia, truncus arteriosus, and some cases of double outlet right ventricle	Creation of a conduit between the right ventricle to pulmonary artery with closure of the ventricular septal defect. In the case of truncus arteriosus, the pulmonary arteries are removed from the truncus.
Ross	
Corrective for AS	The diseased aortic valve is replaced with the patient's pulmonic valve (pulmonary autograft), and a homograft (valve from a human donor) replaces the pulmonic valve.
Subclavian flap aortoplasty	
Corrective for COA	Division of the distal subclavian artery and insertion of a flap into the aorta through the coarcted segment.
Transplant	
Corrective for HLHS, complex defects, cardiomyopathies	Replacement of diseased heart with donor heart.

Key: AS, aortic stenosis; ASD, atrial septal defect; AV, atrioventricular; COA, coarctation of aorta; HLHS, hypoplastic left heart syndrome; MS, mitral stenosis; PDA, patent ductus arteriosus; PS, pulmonic stenosis; TOF, tetralogy of Fallot; TGA, transposition of great arteries; VSD, ventricular septal defect

Nursing Management

For the Child Having Cardiac Catheterization

Cardiac catheterization performed for examination or for therapeutic intervention is often an outpatient procedure. The child is NPO for several hours, except for medications, and arrives at the catheterization laboratory 1 to 2 hours before the procedure. In preparation for the procedure, the child is asked to void and is given an oral sedative. Infants and young children often need sedation to keep them still during the procedure.

Nursing Assessment and Diagnosis

Before the procedure, assess the child using the assessment guidelines found earlier in this chapter, *Assessment Guide: The Child With a Cardiac Condition*. Collect baseline data on skin temperature, color, strength of pedal and popliteal pulses, and hematocrit and hemoglobin levels for comparison with postcatheterization assessments.

After the procedure, monitor the child for potential complications such as arrhythmia, bleeding, hematoma development, thrombus formation, and infection for several hours. No bleeding should occur at the catheterization site. Assess vital signs and perfusion of the lower extremities (pulses, temperature, color, capillary refill, and sensation) and compare to precatheterization status. The child's temperature and vital signs should remain stable. Monitor intake and output because the contrast medium may cause diuresis.

Clinical Tip

A pulse oximeter provides a noninvasive measurement of the percutaneous arterial oxygen saturation level (SpO_2) and may provide an early clue that hypoxemia is developing before cyanosis is visualized. A reading of 95% to 98% is normal in children. See Chapter 20 for a review of pulse oximetry use.

The following nursing diagnoses may apply to the child who undergoes cardiac catheterization (NANDA-I © 2014):

- ***Fear*** related to separation from support system in a stressful situation

- ***Fluid Volume: Imbalanced, Risk for,*** related to inadequate fluid intake due to NPO status and diuretic effect of contrast medium
- ***Tissue Perfusion: Peripheral, Risk for Ineffective,*** related to mechanical reduction of arterial and venous blood flow to lower extremity

Planning and Implementation

Prepare the child for cardiac catheterization with age-appropriate information. Because the child will be sedated but arousable for the procedure, explain the sensations that will be experienced (e.g., restraints on arms, equipment noises, cold liquid cleanser for catheter site, and warm feeling of contrast injection).

Nursing care during a cardiac catheterization focuses on monitoring the child's vital signs, reassuring the child, and providing emergency care if necessary. After the catheters and guidewires are removed at the end of the procedure, direct pressure must be applied for 15 minutes. A pressure dressing is then placed over the site for several hours.

SAFETY ALERT!

Assess the pressure dressing over the catheterization site every 5 minutes for 15 minutes, every 15 minutes for 1 hour, and hourly, or as directed by the healthcare provider or facility guidelines. Do not remove or loosen the dressing to observe the site until the ordered time for the pressure dressing has elapsed. Check under the buttocks to make sure blood does not ooze out and run under the child. Seek immediate medical intervention if the leg has reduced warmth and decreased perfusion, or bleeding is noted.

The child is kept on bed rest for 4 to 6 hours with an effort to keep the leg straight for several hours. Avoid elevating the head of the bed as flexion of the hips is not permitted during this period. Activity is limited for 24 hours, and in some cases, the child is hospitalized. Provide quiet diversional activities.

Encourage the child to drink small amounts of clear liquids initially, and then progress to other fluids and food as the child tolerates them. Provide adequate fluids to maintain hydration status, especially if the child takes diuretics. The child's intake and output should be balanced.

DISCHARGE PLANNING AND HOME CARE TEACHING

Children are routinely discharged several hours after the cardiac catheterization. Teach the parents to watch the child for signs of complications and make sure they know when to notify the healthcare provider. See *Families Want to Know: Home Care After Cardiac Catheterization*.

Evaluation

Expected outcomes of nursing care include the following:

- Any potential complications (thrombosis or hemorrhage) following cardiac catheterization are rapidly identified and cared for.
- The child maintains fluid balance.

Congenital Heart Defects That Increase Pulmonary Blood Flow

The most common congenital heart defects result from a connection between the left and right side of the heart (septal defect) or between the great arteries (patent ductus arteriosus) that allows blood to flow between the left and right side of the heart.

Etiology and Pathophysiology

The pressures on the left side of the heart are higher. When a connection occurs between the left and right side of the heart, blood shunts from the left to the right side of the heart and increases the amount of blood pumped to the lungs. The size of the connection and how much blood passes through it determine how quickly the child develops signs of congestive heart failure (CHF) (see the section on CHF later in this chapter). The increased blood flow to the lungs causes increased pulmonary vascular resistance (constriction of the pulmonary vascular bed) in an effort to reduce the blood flow, and pulmonary artery hypertension (see the section later in this chapter). Right ventricular hypertrophy (RVH) develops to overcome the increasing pulmonary vascular resistance and to deliver the blood to the lungs.

Clinical Manifestations

The infant's heart rate, respiratory rate, and metabolic rate are increased because of the high pulmonary blood flow. Sucking to feed takes energy and diaphoresis often occurs. If the infant is unable to take in enough calories to support the metabolic rate and growth, poor weight gain is noted. If CHF develops, signs include dyspnea, tachypnea, intercostal retractions, and periorbital edema. Frequent respiratory infections occur as the wet environment in the lungs caused by CHF supports bacterial growth. See Table 21–5 for the pathophysiology, clinical manifestations, diagnostic tests, clinical therapy, and prognosis for the specific congenital heart defects that increase pulmonary blood flow.

Families Want to Know

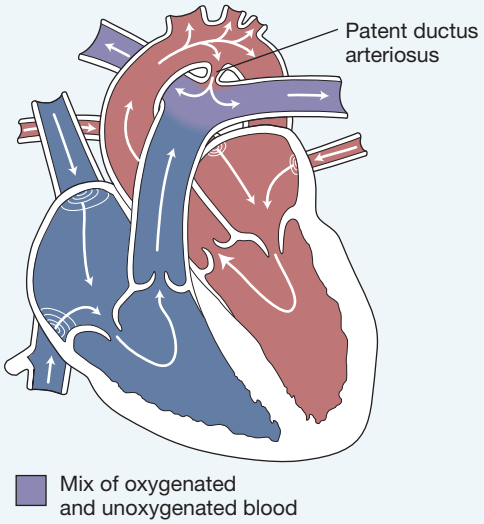
Home Care After Cardiac Catheterization

- Check for signs of complications several times in the first 24 hours after catheterization and notify the healthcare provider immediately if any of these signs are noted:
  - Bleeding or a bruise increasing in size at the catheterization site
  - Foot on side of catheterization site is cooler than other foot
  - Loss of feeling in foot on side of catheterization
  - Fever
- If the child is treated with diuretics, observe for signs of dehydration (dry mucous membranes, absence of tears, and strong urine).
- Encourage fluids to help flush the dye out of the body and to prevent dehydration.
- Permit quiet play such as computer games, puzzles, and videos for the first 24 hours after the procedure.

TABLE 21–5 Pathophysiology, Clinical Manifestations, Diagnostic Tests, Clinical Therapy, and Prognosis for Defects That Increase Pulmonary Blood Flow

ANATOMY

PATENT DUCTUS ARTERIOSUS (PDA)



Pathophysiology

A common congenital defect caused by persistent fetal circulation that accounts for 5% to 10% of all infants with congenital heart disease (Park, 2014). When pulmonary circulation is established and systemic vascular resistance increases at birth, pressures in the aorta become greater than in the pulmonary arteries. Blood is then shunted from the aorta to the pulmonary arteries, increasing circulation to the pulmonary system. It is a common problem of preterm infants who have respiratory distress syndrome or hypoxemia that work to keep the ductus arteriosus open (Park, 2014).

Clinical Manifestations

Dyspnea; tachypnea; tachycardia; full, bounding pulses; widened pulse pressure; hypotension may be noted when cardiac output is low. May be asymptomatic.

CHF, intercostal retractions, hepatomegaly, and poor growth when a large PDA exists.

A continuous "machinery" murmur during systole and diastole, and a thrill in the pulmonic area.

High risk for frequent respiratory infections and pneumonia.

Diagnostic Tests

The chest radiograph and ECG show left ventricular hypertrophy.

The PDA can be visualized, and PDA blood flow can be measured on echocardiogram.

Clinical Therapy

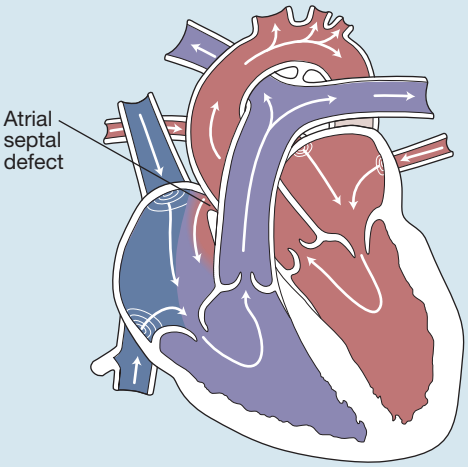
Transcatheter closure by obstructive device is the standard therapy in most centers. Video-assisted thoracoscopic surgery with clip ligation of the PDA may be performed.

Intravenous ibuprofen or indomethacin often stimulates closure of the ductus arteriosus in preterm infants, but cannot be used if CHF is present; it is not used in term infants.

Prognosis

No long-term sequelae occur if treated before pulmonary vascular disease (pulmonary hypertension or pulmonary vascular obstructive disease) develops.

ATRIAL SEPTAL DEFECT (ASD)



Pathophysiology

The opening in the atrial septum permits left-to-right shunting of blood. The opening may be small, as when the foramen ovale fails to close, or large (the septum may be completely absent). Of children with congenital heart disease, 30% to 50% have an ASD in combination with other defects, but it may occur as an isolated defect in 5% to 10% of children (Park, 2014).

Clinical Manifestations

Infants and young children with small or moderate-size ASDs usually have no symptoms. Large ASDs may cause CHF, easy tiring, and poor growth.

A soft systolic ejection murmur occurs in the pulmonic area with fixed, wide splitting of S_2 through all phases of respiration.

Diagnostic Tests

Echocardiogram identifies a dilated right ventricle due to blood overload and the shunt size.

The chest radiograph and ECG reveal little information unless the ASD is large, has excessive shunting, and right ventricular hypertrophy is present.

Clinical Therapy

Spontaneous closure of some small ASDs occurs within the first 4 years of life. No activity limitations are needed.

Secundum ASDs are usually closed by a septal occluder during cardiac catheterization. Aspirin at 81 mg per day is prescribed for 6 months after the procedure.

Surgery to close or patch the ASD is performed when significant increased pulmonary blood flow causes CHF. Arrhythmias may develop in postoperative period.

ANATOMY

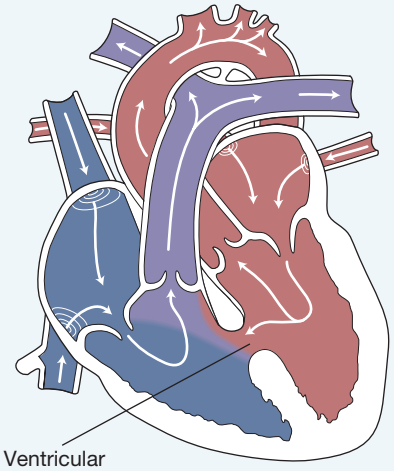
Prognosis

Middle-aged adults with uncorrected small- and moderate-size ASDs may have no symptoms but are at risk for a stroke. Small clots that commonly develop in the right atrium can pass through the ASD into the left atrium and systemic circulation. CHF, atrial arrhythmias, and pulmonary artery hypertension may develop in untreated adults.

VENTRICULAR SEPTAL DEFECT (VSD)

Pathophysiology

An opening in the ventricular septum results in increased pulmonary blood flow. Blood is shunted from the left ventricle directly across the open septum into the pulmonary artery. This is the most common congenital heart defect. It occurs as a single defect in about 15% to 20% of cases but also is found in combination with other defects (Park, 2014).



Clinical Manifestations

Infants and children with small VSDs may have no symptoms. Moderate or large VSDs may be associated with CHF, poor growth, decreased exercise tolerance, an increased number of pulmonary infections, and pulmonary hypertension.

A systolic murmur is auscultated at the third or fourth left intercostal space at the sternal border. A thrill may be present.

Diagnostic Tests

A chest radiograph and ECG reveal little when VSDs are small. An enlarged heart and pulmonary vascular markings on chest radiograph occur in cases of large VSDs with shunting. Right and left ventricular hypertrophy may be seen on ECG.

Echocardiogram identifies the size and location of the defect.

Clinical Therapy

Most small VSDs close spontaneously within the first 6 months of life. Treatment is conservative when no signs of CHF or pulmonary artery hypertension are present.

See the section on treatment of the child with CHF later in this chapter. VSD surgical closure is performed after 1 year of age unless CHF cannot be managed medically. Surgery for these infants is performed within the first 6 months of life.

Device closure of VSD during cardiac catheterization may be attempted for some VSDs that are not too close to the heart valves.

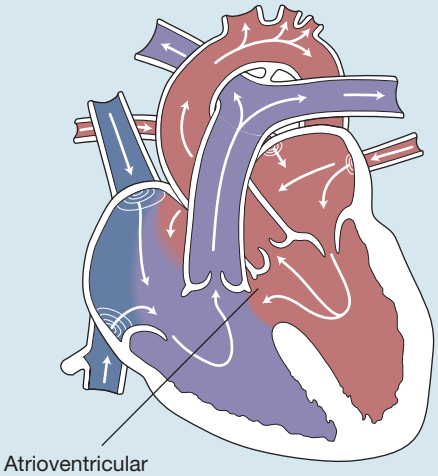
Prognosis

Highest risk associated with surgical repair is in the first 2 months of life. Children respond well to surgery and experience substantial catch-up growth. Arrhythmias, right bundle branch block, and complete heart block are possible complications. Some children need a pacemaker.

ATRIOVENTRICULAR CANAL (ENDOCARDIAL CUSHION) DEFECT (AV CANAL)

Pathophysiology

Endocardial cushions are fetal growth centers for the mitral and tricuspid valves and atrioventricular (AV) septum. The most complex AV canal defect results in one AV valve and large septal defects between both atria and ventricles. An AV canal defect occurs in about 2% of congenital heart defect cases, and 70% of these children have Down syndrome (Park, 2014).



Clinical Manifestations

Infants often develop CHF, tachypnea, tachycardia, avoidant/restrictive food intake disorder (failure to thrive), recurrent respiratory infections, and repeated respiratory failure.

S_1 is accentuated and S_2 is split. A holosystolic murmur is loudest at the left lower sternal border, and a thrill may be palpated. The murmur may be transmitted to the left axilla when mitral regurgitation is present (see Chapter 5 for a description of heart sounds).

Diagnostic Tests

On chest radiograph, cardiomegaly and pulmonary vascular markings are present.

On ECG, a prolonged PR interval and enlarged ventricles are noted.

Echocardiogram reveals dilation of the ventricles, septal defects, and details of valve malformation.

(*continued*)

TABLE 21–5 Pathophysiology, Clinical Manifestations, Diagnostic Tests, Clinical Therapy, and Prognosis for Defects That Increase Pulmonary Blood Flow *(continued)*

ANATOMY
Clinical Therapy
CHF is treated as described later in this chapter.
Surgery is performed between 2 and 4 months of age to prevent pulmonary vascular disease. Patches are placed over septal defects, and valve tissue is used to form functioning valves. The mitral valve may be replaced.
Infective endocarditis prophylaxis is required until 6 months after corrective surgery.
Prognosis
Arrhythmias and mitral valve regurgitation, a residual septal defect, and subaortic stenosis may occur postoperatively. Short-term survival rates among infants with and without Down syndrome are similar.

Clinical Therapy

See Table 21–2 for tests used to diagnose the heart condition. In addition to a chest radiograph, complete blood count, and urinalysis, coagulation studies, platelet counts, and serum electrolytes are often obtained for children having open heart surgery.

Surgery is often performed early in infancy to prevent irreversible pulmonary vascular disease. See Figure 21–3. Unless complications develop before surgery, infants and children usually make a complete recovery without limitations. The major complication of these defects is pulmonary artery hypertension, which is described later in this chapter.

Conservative treatment, such as waiting until the child is symptomatic or older, may be selected for some children with these defects. For example, a small ventricular septal defect may close spontaneously, or closure of an atrial septal defect may be postponed until preschool or early school-age years. Ibuprofen or indomethacin may be given to preterm infants with a patent ductus arteriosus when immediate closure of the ductus is needed. Interventional cardiac catheterization with a septal closing device is performed in an increasing number of cases.

Postpericardiotomy syndrome occurs as a complication in 25% to 30% of children when surgery involves an incision through the pericardium, leading to pericardial and pleural inflammation (Park, 2014, p. 364). It may result from an autoimmune response to damaged myocardium or pericardium or blood in the pericardial sac. The syndrome generally develops within a few weeks to a few months after surgery, more often in children over 2 years of age. It is characterized by a high fever up to 40°C (104°F) and sometimes severe chest pain that worsens with deep inspiration. The median duration of the condition is 2 to 3 weeks. Mild cases are treated with bed rest and NSAIDs or indomethacin. Severe cases may need corticosteroids, diuretics, or emergency pericardiocentesis.

Figure 21–3 **A newborn with a ventricular septal defect repair. Surgery is performed on this type of defect to prevent pulmonary vascular disease and pulmonary artery hypertension.**

Nursing Management

For the Child Prior to Surgery

Nursing Assessment and Diagnosis

PHYSIOLOGIC ASSESSMENT

Prior to surgery, the infant or child is seen regularly to assess growth and for signs of worsening CHF. See *Assessment Guide: The Child With a Cardiac Condition* (earlier in the chapter) for assessment guidelines. Failure to gain weight is an indication of an increased metabolic rate and inability to consume adequate calories for both metabolic function and growth. Assessment of length and head circumference helps to determine the full impact of the condition on growth.

PSYCHOSOCIAL ASSESSMENT

Assess the ability of the parents to cope with the infant's diagnosis. Parents may initially feel shock, guilt, or anxiety. They need an opportunity to express their feelings and to begin learning to manage the child's illness. The diagnosis, hospitalization, and early care of the infant at home are very stressful. Parents need special support if their infant has a life-threatening heart defect.

Examples of nursing diagnoses associated with heart defects having increased pulmonary blood flow and their complications include the following (NANDA-I © 2014):

- ***Fluid Volume: Excess*** related to heart failure and pulmonary vasculature overload
- ***Infant Feeding Pattern, Ineffective,*** related to shortness of breath and fatigue
- ***Infection, Risk for,*** related to pulmonary vascular congestion and chronic illness
- ***Family Processes, Interrupted,*** related to crisis of child's serious illness

Planning and Implementation

When the child has a large defect, CHF may be present. See the section on CHF later in this chapter for care guidelines.

FAMILY EDUCATION

Participate with members of the cardiology team to provide information and educate the family about the child's condition. Information may include the following:

- General information about the congenital heart disease, including a description of the heart's anatomy and physiology and the defect
- Information about genetic and environmental influences associated with congenital heart disease
- Signs of CHF and treatment if it develops
- Overview of the child's prognosis and timing of medical and surgical interventions, including some sample cases with good and poor outcomes

Clinical Tip

Some valuable resources for parents of a child with a congenital heart defect are as follows:

- *It's My Heart* by the Children's Heart Foundation
- *Hope for Families of Children with Congenital Heart Defects* by Lynda T. Young
- *The Heart of a Child: What Families Need to Know About Heart Disorders in Children* by C. A. Neill, E. A. Clark, and C. Clark, Johns Hopkins Press
- *Heart Warriors: A Family Faces Congenital Heart Disease* by Amanda Rose Adams, Behler Publications

PSYCHOSOCIAL SUPPORT

Parents are often anxious about an uncertain surgical outcome. Determine if parents have a support system as they learn about the infant's diagnosis and make difficult decisions about the child's surgery. Some parents may be concerned that signing consent for surgery places the child in even more danger of illness or even death. Identify some resources for support, such as social services, pastoral services, or a parent of a child with a similar heart defect.

Parents should be offered genetic counseling if planning a future pregnancy.

HOME CARE

Children are managed at home until surgery. Parents should encourage feeding to promote growth, but allow the infant to feed only for 30 minutes or as directed by healthcare providers for infants with complex heart defects or CHF. Breastfeeding or breast milk is encouraged because of its beneficial effects for the infant. Infants should be held at a 45-degree angle to reduce tachypnea. If the infant has difficulty gaining weight, formula or breast milk can be pumped and fortified with products that increase calorie density. Transpyloric, nasogastric, or gastrostomy tube feedings may also be given at night or 24 hours a day to ensure that adequate calories are ingested. See Figure 21–4. Salt intake is rarely limited in infants. When tube feedings are used, encourage the infant to take some formula orally to provide positive oral stimulation. See feeding suggestions for the infant with CHF later in this chapter.

Reduce the infant's exposure to infectious diseases, and encourage frequent hand hygiene. Respiratory infections increase hypoxemia in children with cyanosis. Fever increases the metabolic rates and oxygen demands. Vomiting and diarrhea may cause an electrolyte disturbance. Notify the healthcare provider about fever, poor feeding, vomiting, and diarrhea.

Figure 21–4 **Infants with cardiac conditions often require supplemental feedings to provide sufficient nutrients for growth and development. The parents of this infant girl have been taught how to give her nasogastric feedings at home.**

Health promotion visits are important and all immunizations are provided according to the recommended schedule. Provide monthly prophylaxis for respiratory syncytial virus (RSV) with palivizumab to infants who have complex heart defects during the peak season. See Chapter 20.

PREPARATION FOR SURGERY

When the child is preschool age or older, prepare the child for the settings, equipment, and experiences to expect before and after surgery. Follow guidelines for preoperative treatment described in Chapter 11. If an infant or toddler is having surgery, inform the parents about how the child will look, equipment that will be used, and what care will be provided in the immediate postoperative period.

Evaluation

- Nutritional intake is adequate with oral and supplemental tube feeding as necessary.
- The child maintains a growth pattern that follows the established growth curve percentile.
- The child receives all immunizations and RSV prophylaxis to reduce the potential for acute illnesses.

Nursing Management

For the Child Having Surgery for Increased Pulmonary Blood Flow

The goal of nursing management is to perform assessments, provide supportive care to the family, and meet the child's nursing care needs before and after surgery.

Nursing Assessment and Diagnosis

At the time of surgery, the child needs a careful history and physical examination to detect any acute illnesses as well as the child's physiologic status. Assess the child's behavioral patterns, cardiac function, respiratory function, weight, and fluid status. See the *Assessment Guide* earlier in this chapter.

In the immediate postoperative period, the child will be cared for in the intensive care unit. When the child returns to the general nursing unit, assessment focuses on signs of surgical complications such as infection, arrhythmias, and impaired tissue perfusion. Monitor the child's temperature and inspect the surgical incision site. Fever, excessive incisional pain, spreading erythema around the incision, and wound drainage beginning 3 to 4 days postoperatively may be early signs of infection. Assess the chest and lungs for breath sounds, respiratory effort, and signs of distress that may indicate pneumonia or fluid in the pleural space.

Monitor the vital signs, including blood pressure and SpO_2. Auscultate the apical pulse to detect an irregular heart rate or bradycardia because either finding is a sign of reduced cardiac output that requires immediate intervention. Check capillary refill, extremity warmth, pedal pulses, level of consciousness, and urine output to assess tissue perfusion. Reduced urine output is a sign of decreased cardiac output. Continue to assess the child's pain.

Examples of nursing diagnoses following cardiac surgery include the following (NANDA-I © 2014):

- ***Breathing Pattern, Ineffective,*** related to respiratory muscle fatigue
- ***Pain, Acute,*** related to surgical incision and expansion of chest with coughing and deep breathing exercises
- ***Fluid Volume: Imbalanced, Risk for,*** related to impact of surgery on heart's pumping action
- ***Infection, Risk for,*** related to surgery and chronic disease status

Planning and Implementation

PAIN MANAGEMENT

Pain management with 24-hour intravenous opioids is provided for 1 to 2 days postoperatively or until the child is taking fluids. Then give oral analgesics around the clock. Follow the guidelines for pain management provided in Chapter 15. Teach parents and caregivers to move the child without lifting under the arms to reduce stress on the incision and pain.

PROMOTE RESPIRATORY FUNCTION

Encourage the child to take deep breaths and cough or to perform spirometry exercises regularly to promote full lung expansion (see the *Clinical Skills Manual* SKILLS). Bubbles or pinwheels may help young children to take deep breaths. Splint the chest with a pillow or stuffed animal to reduce pain from coughing and deep breathing. Chest physiotherapy may be performed in children under 3 years of age.

NUTRITION AND GENERAL CARE

Encourage the infant or child to begin oral fluids and nutrition when permitted. Oral fluids are rarely limited following surgery for defects with increased pulmonary blood flow, but assess intake and output carefully. Allow parents to bring in the child's favorite foods to encourage eating when they can be tolerated. Promote bowel elimination following surgery and when opioids are used.

Administer antibiotics as prescribed. If intravenous antibiotics are continued after the child's oral intake is established, the IV line can be converted to a heparin or saline lock.

Encourage the child to increase activity gradually with longer periods out of bed every day, but ensure adequate rest periods to promote healing. Provide diversional activities and opportunities for therapeutic play so the child can better manage the stresses associated with pain and frightening procedures.

DISCHARGE PLANNING AND HOME CARE TEACHING

Infants and children may be discharged from the hospital within a few days of surgery. Parents need information spread over several days to prepare for care of the child at home. See *Families Want to Know: Care of the Child After Cardiac Surgery*.

Prepare parents for potential behavior problems of young children that may result from the stress of hospitalization, such as nightmares, separation anxiety, and overdependence on parents. Encourage parents to reassure children about their security, and to promote play and other means to deal with their feelings. If the child's behavioral symptoms continue for several weeks, referral for psychologic assessment and support may be needed for posttraumatic stress disorder. See Chapter 28.

Reassure parents of children with a complete correction of the cardiac defect that no further cardiovascular problems should occur. Provide parents with full information about the child's defect and the surgery performed to share with the child's healthcare providers. Encourage parents to allow the child to live a normal and active life.

Evaluation

Examples of expected outcomes of nursing care include the following:

- Full lung expansion is achieved with spirometry exercises or chest physiotherapy.
- The child's pain is effectively managed.
- The child's incision heals without infection.
- Catch-up growth occurs over the next few months to years.

Defects Causing Decreased Pulmonary Blood Flow and Mixed Defects

Information about these defect categories is combined in this section because the clinical therapy and nursing interventions are similar.

Etiology and Pathophysiology

DEFECTS CAUSING DECREASED PULMONARY BLOOD FLOW

Defects that obstruct the flow of blood from the right side of the heart to the lungs decrease the amount of blood that gets oxygenated by the lungs. If an atrial or ventricular septal opening exists, the obstructed pulmonary blood raises pressures on the heart's right side higher than the left, leading to right-to-left shunting. Hypoxemia and cyanosis result because of the increased amount of unoxygenated blood in the systemic circulation.

Families Want to Know

Care of the Child After Cardiac Surgery

- Place infants and children in car safety seats for travel home from the hospital. Place a small blanket over the incision to prevent the straps from rubbing.
- Sponge bathe the infant or use a tub bath with a low water level. Avoid soaking the incision until sutures are out, the Steri-Strips fall off, or the Dermabond has flaked off and the incision is healed. Clean the incision daily as directed by the healthcare provider. Do not use oils, creams, lotions, or ointments on the incision. Cover the incision with a clean shirt or bib to keep it clean and dry.
- Pick up infants and young children by placing one hand under the head and the other hand under the hips. Do not lift the child by grasping under the arms to decrease stress on the incision and sternum.
- Encourage a nutritious diet and snacks to promote healing and catch-up growth.
- Allow the child to increase activity gradually as tolerated. Report increased fatigue or decreased activity tolerance to the healthcare provider. Do not permit rough play, bike riding, and climbing for 6 weeks until the sternum incision has healed completely. The child can return to school in about 3 weeks, but no backpack should be used for several weeks.
- Report any signs of wound infection, fever over 40.3°C (101.0°F), flulike symptoms, chest pain, increased respiratory rate or respiratory distress, appetite change, or irritability to the healthcare provider.
- Give acetaminophen or ibuprofen for pain control. Use the recommended dose for the child's weight.
- When a prosthetic heart valve or material is used, give antibiotic prophylaxis for infective endocarditis for dental and invasive respiratory procedures as directed for 6 months after corrective surgery. See *Medications Used for Infective Endocarditis: Prophylaxis for Dental and Invasive Respiratory Procedures* later in this chapter. Report any unexplained fever or illness during the first 2 months following surgery.
- When blood products have been used during cardiac surgery, live virus vaccination should be delayed to ensure a full immunologic response. Check other references for the specific interval as it varies by type of blood product administered.

The bone marrow is stimulated to produce more red blood cells so more hemoglobin is available to carry oxygen. Polycythemia, an above-normal increase in the number of red blood cells, may result and place the child at risk for thromboembolism. Over time, platelet survival is reduced and clotting factors are impaired, increasing the infant's risk of bleeding with surgery. Bacteria in the unoxygenated blood (which is usually filtered out by the lung's capillaries) may cross into the systemic circulation through the septal defect, leading to a brain abscess (Park, 2014, p. 141).

When infants and children with cyanosis rise in the morning, they may experience an abrupt decrease in systemic vascular resistance. This increases the blood shunted from right to left across the VSD, and less blood flows to the lungs, leading to increased hypoxemia. Crying, feeding, increased activity, a warm bath, and straining with defecation are all events that can suddenly lower the systemic vascular resistance and trigger a hypoxic episode or spell. Hypovolemia may also trigger a hypoxic episode. The partial pressure of oxygen (Po_2) is lowered, and the partial pressure of carbon dioxide (Pco_2) rises. Hypoxemia becomes progressively worse as the respiratory center in the brain overreacts, increasing the respiratory effort. The extra respiratory effort further worsens the hypoxic episode that can become life-threatening unless rapid intervention is successful.

MIXED DEFECTS

Many complex congenital heart defects involve a combination of defects that increase and decrease pulmonary blood flow, making the newborn dependent on mixing of the pulmonary and systemic circulations for survival during the postnatal period. The mixed oxygen-saturated and oxygen-desaturated blood results in a general desaturated systemic blood flow and cyanosis. Pulmonary congestion occurs because of increased pulmonary blood flow and obstruction of systemic flow.

Clinical Manifestations

DEFECTS CAUSING DECREASED PULMONARY BLOOD FLOW

Clinical manifestations in infants initially include cyanosis shortly after birth, dyspnea, and a loud murmur. The skin may initially be ruddy or mottled before cyanosis is observed. Cyanosis that does not respond as expected to supplemental oxygen is a classic sign of decreased pulmonary blood flow. Signs and symptoms of chronic hypoxemia include fatigue, clubbing of the fingers and toes, exertional dyspnea, and delayed developmental milestones (Figure 21–5). Infants may need to stop sucking periodically during feedings to breathe, and diaphoresis may be seen with the increased work of feeding. These infants have a higher metabolic rate, and inadequate calories may be consumed, resulting in poor weight gain. See Table 21–6 for the pathophysiology, clinical manifestations, diagnostics tests, clinical therapy, and prognosis for these defects.

Figure 21–5 Clubbing of the fingers in an older child is one manifestation of a heart defect that reduces pulmonary blood flow.

TABLE 21–6 Pathophysiology, Clinical Manifestations, Diagnostic Tests, Clinical Therapy, and Prognosis for Defects That Decrease Pulmonary Blood Flow

ANATOMY

PULMONIC STENOSIS (PS)

Pathophysiology

Stenosis (narrowing of a valve or valve area) can be above, below, or at a valve. Stenosis obstructs blood flow into the pulmonary artery, increases preload, and results in right ventricular hypertrophy. PS as a single defect accounts for 8% to 12% of all congenital heart defects, but it also occurs with other defects (Park, 2014). Stenosis in the subvalvular area may develop as the heart muscle grows.

Clinical Manifestations

Children with mild stenosis may have no symptoms and grow normally.

In moderate to severe stenosis, dyspnea and fatigue occur on exertion. Signs of CHF, heart failure, and chest pain on exertion occur in severe cases.

A loud systolic ejection murmur with a widely split S_2 and thrill may be found in the pulmonic listening area. A murmur heard louder and longer indicates increased severity.

Diagnostic Tests

The chest radiograph may show an enlarged pulmonary artery with normal heart size and normal pulmonary vascularity.

The ECG may show right atrial enlargement and right ventricular hypertrophy.

An echocardiogram provides information about the thickness of the valve, the pressure gradient across the valve, and size of the valve ring.

Cardiac catheterization findings include increased right ventricular pressure and a normal or slightly lowered pulmonary artery pressure.

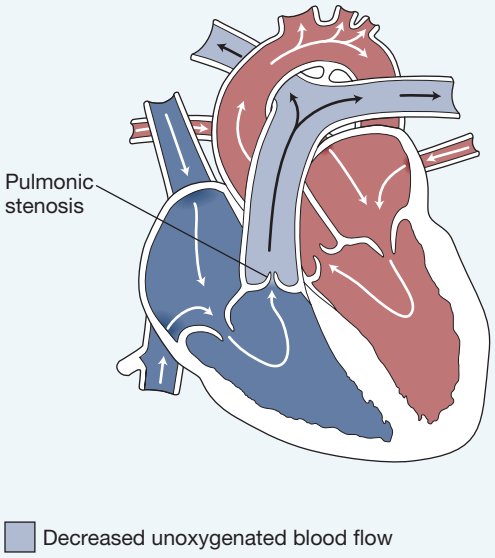
Clinical Therapy

Balloon dilation of the valve, performed during cardiac catheterization, is the preferred treatment. Pulmonary regurgitation may result but is not a significant problem.

Surgical valvotomy is performed when balloon dilation is not indicated or unsuccessful. On occasion the pulmonary valve is replaced.

Prognosis

Newborns with critical PS have a mortality rate of 10%. PS does not typically increase in severity. Lifelong infective endocarditis prophylaxis may be needed.



TETRALOGY OF FALLOT (TOF)

Pathophysiology

Four defects are involved: stenosis of the pulmonary outflow tract or valve, right ventricular hypertrophy, ventricular septal defect (VSD), and overriding of aorta. The overriding aorta and VSD allow unoxygenated blood to pass into the systemic circulation. TOF accounts for about 5% to 10% of all cases of congenital heart disease (Park, 2014).

Clinical Manifestations

The newborn becomes hypoxic and cyanotic as the ductus arteriosus closes. The degree of pulmonary stenosis determines severity of symptoms. Older infants and children have tachypnea and cyanosis.

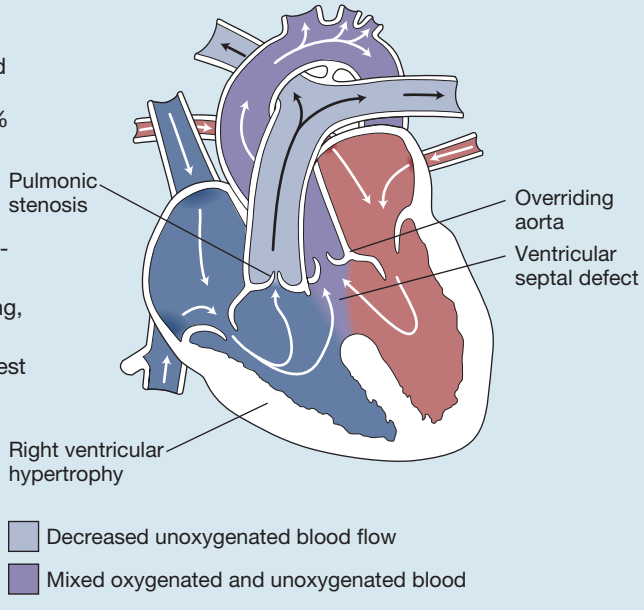
Polycythemia, hypoxic spells, metabolic acidosis, poor growth, clubbing, and exercise intolerance may develop.

Toddlers with uncorrected defects instinctively squat (assume a knee–chest position) to decrease the return of systemic venous blood to the heart.

A systolic murmur is heard in the pulmonic area and transmitted to the suprasternal notch. A thrill may be palpated in the pulmonic area.

Diagnostic Tests

A chest radiograph shows the boot-shaped heart due to the large right ventricle, decreased pulmonary vascular markings, and a prominent aorta.



ANATOMY

Diagnostic Tests (continued)

The ECG shows right ventricular hypertrophy.

The echocardiogram shows the VSD, obstruction of pulmonary outflow, an overriding aorta, and the size of the pulmonary arteries. The condition may be detected by fetal echocardiography.

Blood tests reveal an elevated hematocrit and hemoglobin and an increased clotting time. Iron deficiency may be detected.

Clinical Therapy

See the section on hypercyanotic episode management later in this chapter. Monitoring the child for metabolic acidosis or prolonged unconsciousness is critical.

Most infants have corrective surgery by 1 to 2 years of age unless a hypercyanotic spell occurs earlier. Symptomatic children have corrective surgery any time after 3 to 4 months of age. Some children need palliative surgery (modified Blalock-Taussig shunt) to delay total corrective surgery. A right bundle branch rhythm pattern may result from surgery.

If prosthetic material is used for the corrective surgery, infective endocarditis prophylaxis is required until 6 months after corrective surgery.

Prognosis

Not all children are cured by surgery, but most have improved quality of life and improved longevity. Pulmonary regurgitation may become severe and require a valve replacement 10 to 20 years after corrective surgery. Ventricular arrhythmias may occur many years after surgery and may cause sudden death (Park, 2014, p. 231).

PULMONARY OR TRICUSPID ATRESIA

In pulmonary atresia (a severe form of PS), no valve or opening exists to allow blood to flow between the right atrium and right ventricle. In tricuspid atresia, no valve or opening exists to allow blood to flow between the right atrium and ventricle. The right ventricle is **hypoplastic** (small and nonfunctional). Blood flows to the left side of the heart through the foramen ovale. The ductus arteriosus provides the only flow of blood to the pulmonary arteries and lungs. Tricuspid atresia accounts for 1% to 3% of congenital heart defects, while pulmonary atresia accounts for less than 1% (Park, 2014).

Clinical Manifestations

Cyanosis is present and severe at birth.

Tachypnea, poor feeding, CHF, pulmonary edema, hepatomegaly, acidosis, hypoxic spells, clubbing, polycythemia, and growth delays occur.

A continuous murmur from the PDA is heard in the pulmonic area. A single S_2 is heard in the aortic area, and a harsh systolic murmur may be heard at the lower left sternal border.

Diagnostic Tests

The chest radiograph may reveal a normal size or slightly enlarged right atrium and left ventricle.

The ECG may reveal left ventricular hypertrophy.

The echocardiogram shows a small hypoplastic right ventricular cavity and tricuspid valve, an absent right ventricular outflow tract, a dilated right atrium, and right-to-left shunting across the atrial septum.

Clinical Therapy

Prostaglandin E_1 is given immediately to maintain a patent ductus arteriosus. Treatment for CHF may be needed.

A balloon atrial septostomy is performed to increase the atrial opening size. Other palliative procedures may be performed, such as a Blalock-Taussig shunt or pulmonary artery banding, before a staged Fontan procedure for the single ventricle defect.

Prophylaxis for thromboembolism and infective endocarditis is recommended. Digoxin and diuretic medications may be needed long term.

Prognosis

The child has an increased risk for arrhythmia and right ventricular dysfunction. Survival after a successful Fontan procedure is greater than 95% (Park, 2014).

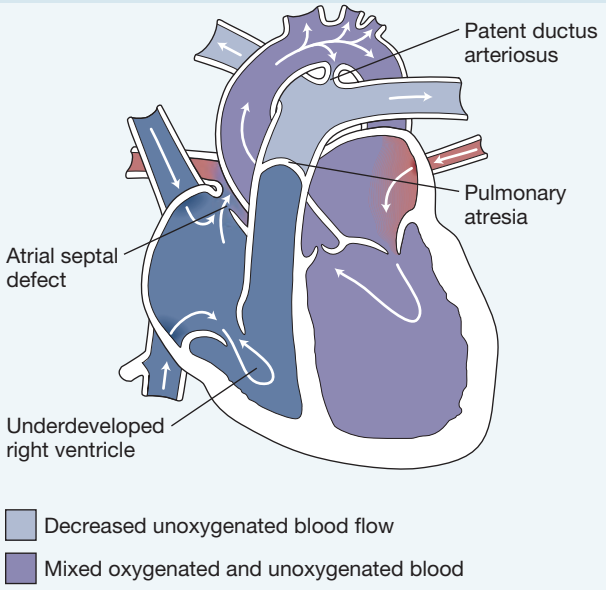


Figure 21–6 **Children compensate for inadequate blood flow. A young child with an uncorrected or partially corrected defect that reduces pulmonary blood flow may squat (assume a knee–chest position) to reduce systemic blood flow return to the heart.**

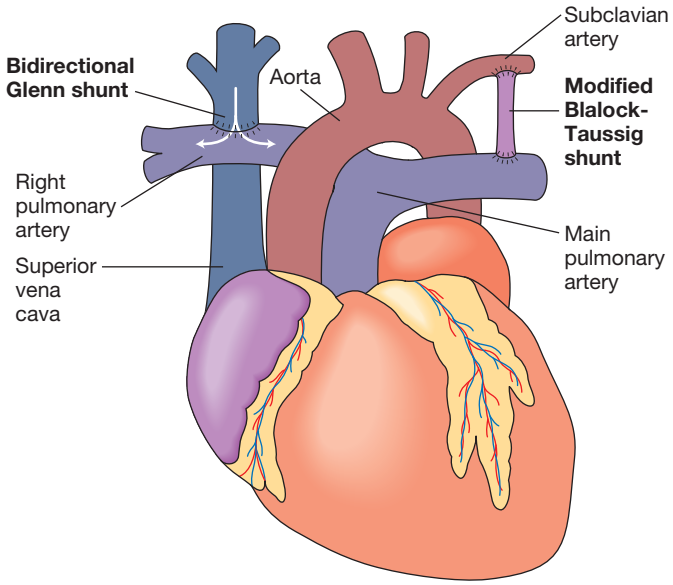

Figure 21–7 **Anatomic location of the modified Blalock-Taussig and Glenn shunts for palliative procedures.**

Toddlers with uncorrected cyanotic heart disease often squat in the knee–chest position to relieve dyspnea (Figure 21–6). This position reduces the cardiac output by decreasing the blood return from the lower extremities and by increasing the systemic vascular resistance. Blood flow to the lungs is increased. Hypoxic episodes can occur suddenly between 2 months and 2 years of age. Signs include increased cyanosis, increased rate and depth of respirations, tachycardia, poor tissue perfusion, diaphoresis, and seizures and loss of consciousness.

SAFETY ALERT!

Infants and young children respond to severe hypoxemia with bradycardia. Cardiac arrest in children often results from prolonged hypoxemia related to respiratory failure or shock rather than from a primary cardiac arrhythmia as in adults (Perkin, deCaen, Berg, et al., 2013). Bradycardia is a significant warning sign that cardiac arrest is imminent. Treating hypoxemia often reverses bradycardia and prevents cardiac arrest.

Older children may have additional symptoms such as exercise-induced dizziness and **syncope** (transient loss of consciousness and muscle tone), which are both serious signs indicating a need for medical evaluation.

MIXED DEFECTS

These complex congenital heart defects cause varying degrees of cyanosis and CHF. See Table 21–7 for the pathophysiology, clinical manifestations, diagnostic tests, clinical therapy, and prognosis for these complex mixed defects.

Clinical Therapy

Early management of these defects is important to prevent secondary damage to the heart, lungs, and brain, including the adverse effects of hypoxemia on the child's cognitive and psychomotor development. Corrective surgery is usually performed on newborns and young infants. A palliative procedure may be performed first for some potentially lethal conditions. See Figure 21–7 for various palliative shunts (surgically created channels for blood flow) that may be performed. In other cases, corrective surgery is preferred to give the newborn a better outcome. CHF is treated aggressively as described later in this chapter. See Tables 21–7 and 21–8 for clinical therapy for specific congenital heart defects.

If closure of the ductus arteriosus causes life-threatening cyanosis in newborns, prostaglandin E_1 (PGE_1) is given to reopen the ductus arteriosus and improve pulmonary or systemic blood flow. Treatment with PGE_1 provides time to transfer the newborn to a cardiac center for diagnostic evaluation and surgical intervention. Adverse effects include respiratory depression and apnea, so the infant must be closely monitored and sometimes ventilation must be assisted.

The child's hemoglobin and hematocrit values are monitored for polycythemia or anemia. If the blood viscosity becomes too high, red cell apheresis may be performed. Anemia is not well tolerated because the infant has less oxygen-carrying hemoglobin.

HYPOXIC EPISODES

Hypoxic or hypercyanotic episodes are treated aggressively. Place the infant in the knee–chest position to reduce blood return to the legs, increasing systemic vascular resistance. Reduce any irritating or painful stimuli, and try to calm the infant. Provide supplemental oxygen. If these measures do not relieve the hypoxic spell, more aggressive treatment may include IV morphine, sedation (ketamine), sodium bicarbonate to treat acidosis, or a vasoconstrictor medication such as phenylephrine. Metabolic acidosis is treated if present. Postpone all unpleasant procedures. Immediate palliative or corrective surgery is often scheduled. Propanolol may be prescribed to prevent hypoxic episodes.

INFECTIVE ENDOCARDITIS

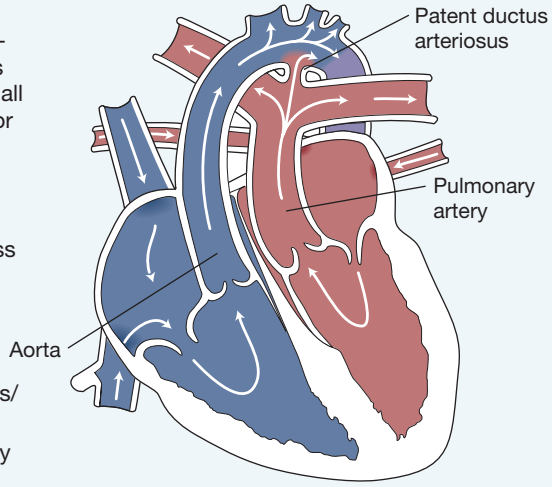
Prophylactic antibiotics for infective endocarditis are required for most children with complex cardiac defects prior to surgery and for 6 months after surgery. See *Medications Used for Infective Endocarditis: Prophylaxis for Dental and Invasive Respiratory Procedures* later in this chapter. Children whose surgery involved prosthetic valves or patches and those who have unrepaired cyanotic congenital heart disease, including palliative shunts and conduits, need lifelong infective endocarditis prophylaxis (Kharouf & Torchen, 2011).

TABLE 21–7 Pathophysiology, Clinical Manifestations, Diagnostic Tests, Clinical Therapy, and Prognosis for Mixed Defects

ANATOMY

TRANSPOSITION OF THE GREAT ARTERIES (TGA)

The pulmonary artery is the outflow tract for the left ventricle, and the aorta is the outflow tract for the right ventricle, creating parallel circulations. The condition is life threatening at birth, and survival initially depends on an open ductus arteriosus and foramen ovale. This common defect accounts for 5% to 7% of all congenital heart defects and is more common in males (Park, 2014). An ASD or VSD may also be present with TGA.



Clinical Manifestations

Cyanosis, apparent soon after birth, progresses to hypoxemia and acidosis. Cyanosis does not improve with oxygen administration. Cyanosis may be less apparent when a large VSD is present.

Infants take a long time to feed and need frequent rest periods because of rapid respiratory rate and fatigue. Growth failure may be evident as early as 2 weeks of age if corrective surgery is not performed.

CHF may develop immediately or over days or weeks. Tachypnea (60 breaths/min) is often present without retractions or dyspnea unless CHF is present.

A systolic murmur is present if a VSD is present; no other murmur is generally heard. S_2 is loud and heard as a single sound.

Diagnostic Tests

A chest radiograph may reveal a classic egg-shaped heart on a string with enlarged ventricles and increased pulmonary vascular markings.

The ECG reveals right ventricular hypertrophy.

The echocardiogram often shows the abnormal position of the great arteries rising from the ventricles and any associated defects.

Blood tests reveal an increased hematocrit and hemoglobin or polycythemia and acidosis.

Clinical Therapy

Prostaglandin E_1 is ordered to maintain a patent ductus arteriosus until a palliative procedure (balloon atrial septostomy) is performed during cardiac catheterization to permit oxygenated and unoxygenated blood to mix.

CHF is treated with diuretics and digoxin.

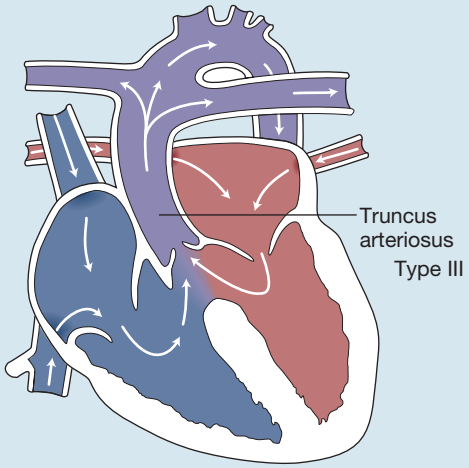
Corrective surgery (arterial switch) is usually performed in the neonatal period.

Prognosis

Survival without surgery is impossible. Complications may occur such as stenosis of the pulmonary artery or aorta in the vessels beyond the valves or coronary artery obstruction. Arrhythmias (sick sinus syndrome, atrial flutter, and atrial fibrillation), tricuspid valve insufficiency, right ventricular dysfunction or failure, and sudden death may be long-term complications associated with formerly used surgical procedures (e.g., Mustard and Senning) (Park, 2014, p. 213).

TRUNCUS ARTERIOSUS

A single large vessel empties both ventricles and provides circulation for the pulmonary, systemic, and coronary circulations. A VSD is usually present. This occurs in about 1% of congenital heart defects (Park, 2014).



Clinical Manifestations

Cyanosis develops soon after birth; however, this is also a condition of increased pulmonary blood flow. CHF develops within 2 weeks after birth with tachypnea, dyspnea, retractions, poor feeding, poor growth, clubbing, increased pulse pressure, bounding peripheral pulses, a widened pulse pressure, and frequent respiratory infections.

A systolic click may be heard in the apex and pulmonic area. The VSD produces a harsh systolic murmur in the lower sternal border.

Diagnostic Tests

The chest radiograph shows cardiomegaly, increased pulmonary vascular markings, and sometimes a right aortic arch.

The ECG reveals bilateral ventricular hypertrophy.

The echocardiogram shows a VSD, a large single great artery, and one semilunar valve.

(*continued*)

TABLE 21–7 Pathophysiology, Clinical Manifestations, Diagnostic Tests, Clinical Therapy, and Prognosis for Mixed Defects *(continued)*

ANATOMY

Clinical Therapy

CHF is treated with diuretics and digoxin.

A Rastelli procedure is performed within a week of birth to close the VSD, enabling the left ventricle to empty into the single large great artery. A conduit is created to the pulmonary arteries. Repeated surgery is necessary to enlarge the pulmonary artery conduit or to repair the truncal valve.

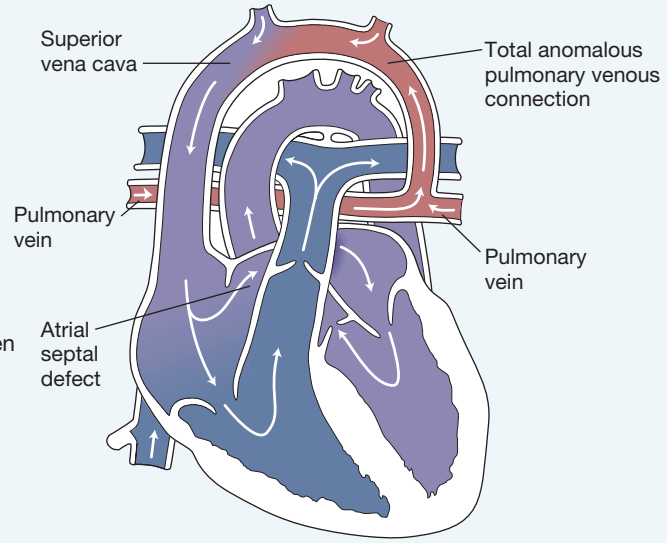
Prophylaxis for infective endocarditis is needed for life.

Prognosis

Surgical mortality varies from 10% to 30% (Park, 2014). Ventricular arrhythmias may develop. The child should not participate in competitive or strenuous sports.

TOTAL ANOMALOUS PULMONARY VENOUS RETURN

The pulmonary veins empty into the right atrium or veins leading to the right atrium rather than into the left atrium. Mixed blood must pass through the foramen ovale or an ASD to provide the systemic circulation. Any obstruction of the pulmonary veins increases the condition's severity. This accounts for 1% of congenital heart defects (Park, 2014).



Clinical Manifestations

The newborn may have mild cyanosis and tachypnea. Signs of CHF (tachypnea, dyspnea, tachycardia, and enlarged liver) and pulmonary edema develop along with poor growth and frequent respiratory infections.

A precordial bulge may be palpated. The S_2 has a wide, fixed split when there is no pulmonary vein obstruction. A systolic murmur is heard in the pulmonic area.

Diagnostic Tests

The chest radiograph shows enlargement of the right atrium and ventricle and increased pulmonary blood flow.

The ECG reveals right ventricular hypertrophy.

The echocardiogram shows a dilated right atrium and ventricle, smaller left-sided chambers, dilated pulmonary arteries, and a patent foramen ovale. It can determine the type of pulmonary drainage and if the pulmonary venous return is obstructed.

Clinical Therapy

Prostaglandin E_1 is given to maintain the patent ductus arteriosus for some newborns.

Diuretics are given to treat CHF.

Surgery is performed to move or create a conduit to connect the pulmonary veins to the left atrium.

Prognosis

Surgery is required for survival. Postoperative mortality ranges from 5% to 10% (Park, 2014). Children may develop pulmonary hypertension, pulmonary vein obstruction, or atrial arrhythmias.

OUTCOMES AND PROGNOSIS

Most children with congenital heart disease have normal IQ scores, and children with corrected simple defects can lead normal lives; however, neurologic insults can occur for many reasons. Conditions such as congestive heart failure and cyanosis can affect gross motor development. Infants with complex congenital heart defects are at risk for preoperative neurologic insult. Inadequate nutrition during the first year of life, when rapid brain development occurs, places the infant at greater risk. Some infants have structural brain abnormalities, abnormal cerebral blood flow, chromosomal abnormalities, cerebral ischemia, and other chromosomal disorders documented prior to surgery. Infants with cyanosis who also have iron deficiency anemia may develop a stroke. See *Evidence-Based Practice: Neurodevelopmental Outcomes in Children With Complex Congenital Heart Disease*.

Children with complex congenital heart defects need multiple stages of surgery, revisions of previous surgeries, valve replacements, or interventional catheterization to reopen valves or vessels that have become obstructed. However, rates of survival to adulthood have been improving for children with complex CHD. A pacemaker may be needed for children with potential life-threatening AV block or ventricular dysfunction (Park, 2014, p. 442).

EVIDENCE-BASED PRACTICE

Neurodevelopmental Outcomes in Children With Complex Congenital Heart Disease

Clinical Question

What information do parents and school officials need to plan for educational supports for children who have had surgery for complex congenital heart defects?

The Evidence

Fifty infants who had cardiac surgery at less than 8 weeks of age were assessed for gross motor performance at 4, 8, 12, and 16 months of age using the Alberta Infant Motor Scale. Infants with chromosomal abnormalities were excluded. Gross motor skill development was delayed at all ages. More than 50% of study infants had persistent delay in gross motor skills across all ages, while some showed improvement over time (Long, Harris, Elderidge, et al., 2012).

Gross motor skills were evaluated in 55 children, ages 6 to 11 years, who previously had a Fontan procedure. None had a physical activity contraindication. Each child was asked to perform locomotor skills (run, gallop, hop on one foot, standing jump, running leap, sideways slide) and object control skills (overhand throw, batting, kicking, dribbling, catching, and rolling a ball). Girls were found to have age-appropriate scores for all gross motor skills. Boys had age-appropriate locomotor skills but lower than expected object control skills. Skill mastery for running and catching were delayed at all ages. Jumping, sliding, and throwing skills were age-appropriate at younger ages but declined in older children. Lower scores were found in boys and children with more complicated medical history or who were sedentary. Children who participated on team sports or perceived family or peer expectations of activity performed better than expected for age (Longmuir, Banks, & McCrindle, 2012).

Forty children who had had corrective or palliative surgery for a significant congenital heart defect (CHD) were evaluated for behavior and competencies at school age. Children with diagnosed chromosomal abnormalities were excluded from the study. Healthy siblings closest in age to study children served as a comparison group. Parents completed the Child Behavior Checklist, while teachers completed the teacher version of the same test. Results indicated that in comparison with siblings, parents perceived that children with CHD had more behavior problems. Both teachers and parents identified reduced school competencies. Children with CHD missed more days of school, participated less in physical education, needed more remedial help, and had lower attainment than siblings (McCusker, Armstrong, Mullen, et al., 2013).

Best Practice

Children with complex CHDs and subsequent surgery often have motor and cognitive problems, such as difficulties with executive functioning skills, problem solving, and memory. These cognitive deficits may lead to learning disabilities, and poorly developed motor skills may interfere with social interactions with peers. Regular developmental screening is needed to identify the specific neurodevelopmental problems that a child could have prior to school entry. Educating families to encourage the child's participation in physical activities may help improve motor skills. Children with complex CHD may need an individualized education plan when disabilities affect learning.

Clinical Reasoning

Develop an outline of important information for a parent of a child with a complex congenital heart defect to discuss with the child's teacher and school officials when the child enters school, including physical and education issues.

Nursing Management

For the Child With Decreased Pulmonary Blood Flow

Nursing management of the hospitalized child focuses on monitoring PGE_1 therapy for newborns, treating hypercyanotic episodes, supporting families to care for the child at home, and providing postsurgical care.

Nursing Assessment and Diagnosis

PHYSIOLOGIC ASSESSMENT BEFORE SURGERY

Infants receiving PGE_1 therapy are cared for in an intensive care nursery where their cardiovascular status can be closely monitored until palliative procedures or corrective surgery is performed.

Prior to or between stages of surgery, the infant or child is seen regularly to assess growth and monitor for signs of CHF (tachycardia, tachypnea, crackles, frothy secretions, low urine output, and pulmonary edema) or worsening condition. The child's poor growth may affect weight, height, and head circumference, so plot serial measurements on the same growth curve to monitor the significance of the growth problems. Monitor physiologic status using the guidelines given in the *Assessment Guide* at the beginning of this chapter.

The child needs careful observation for signs of increased cyanosis in the morning or at other high-risk times. Observe for neurologic signs of thromboembolism due to polycythemia such as headache, dizziness, excessive irritability, and paralysis. Older children with cyanotic defects may have clubbing of the fingers and toes.

ASSESSMENT FOLLOWING SURGERY

Children are admitted to the ICU following surgery. Children undergoing video-assisted thoracostomy surgery may go to the postanesthesia unit and a short-stay unit for discharge the same day. See the nursing care guidelines in the section on nursing assessment of the child following cardiac surgery for increased pulmonary blood flow earlier in this chapter. When the child returns to the general nursing unit, monitor the child's heart functioning. Assess vital signs, pulse oximetry, skin color, and perfusion of the skin by capillary refill and distal pulses. Monitor fluid intake and output. A sudden sustained increase in pulse and respirations and a decrease in peripheral perfusion may be early signs of hemorrhage. Signs of respiratory distress may indicate the development of a pneumothorax or CHF.

PSYCHOSOCIAL ASSESSMENT

Assess the parents' need for information and emotional support. In some cases, the infant's condition is first identified at birth; however, defects are often identified by fetal sonography.

The parents will be grieving the loss of a perfect newborn and be extremely anxious about the infant's condition and prognosis.

Examples of nursing diagnoses that may apply to a child with decreased pulmonary blood flow include the following (NANDA-I © 2014):

- ***Cardiac Output, Decreased,*** related to ventricular restriction and an obstructed outflow tract
- ***Infection, Risk for,*** related to unfiltered bacteria in the blood and sites of blood shunting that promote bacterial growth
- ***Health Management, Family, Ineffective,*** related to complexity of therapeutic regimen: assessment and management of hypoxic spells, which are unpredictable events
- ***Activity Intolerance*** related to cyanosis and dyspnea on exertion
- ***Development: Delayed, Risk for,*** related to profound hypoxemia

Planning and Implementation

HOME CARE OF THE CHILD BEFORE SURGERY

Many infants with tetralogy of Fallot and other serious defects are managed at home to grow and potentially improve surgical outcome. Parents are usually anxious during the wait for surgery. They may fear that the infant will not survive until surgery or that they will be unable to manage any problems the infant may have. Provide information and teach parents how to care for the infant at home. Arrange for home health nursing and other community services if required. Many of these children require supplemental nutrition and oxygen for emergencies. Because unoxygenated and oxygenated blood mix, supplemental oxygen does not improve the child's usual oxygen saturation (SpO_2) level.

Cyanosis with or without CHF often results in delayed gross motor skills. Make referrals to community-based early intervention programs to help parents learn about realistic developmental goals and to promote the infant's development. Encourage parents to treat the infant as normally as possible.

SAFETY ALERT!

The infant with moderate to severe disease should be able to tolerate crying for a few minutes. Do not permit prolonged crying because it worsens cyanosis and causes more hypoxemia.

Hypoxic episodes become life threatening if not treated immediately. The child becomes progressively more hypoxic and limp, loses consciousness, is likely to have a seizure or stroke, and may die. Teach parents to observe for signs of worsening cyanosis, particularly in the morning, that could signal the beginning of a hypercyanotic episode. Some families use a pulse oximeter daily to monitor the infant's SpO_2 and identify a change that may indicate an emergency.

Provide guidelines for the initial care of a hypoxic episode. The parents should call for an ambulance and try to calm and reassure the infant. The infant should be placed in a knee–chest position by holding the infant facing the parent's chest, placing one arm under the knees, and folding the legs upward toward the infant's chest. Use the other arm to support the infant's head and back. Alternatively, the infant can be placed supine with knees bent up to the chest. If oxygen is available, provide it in a manner that does not further upset the infant. If none is available in the home, it will be administered in the ambulance during transport to the emergency department.

Teach parents to report signs of illness to the healthcare provider. Vomiting and diarrhea may cause dehydration, a particular risk in children with polycythemia (the blood becomes more viscous and may form thrombi). Fever increases the metabolic rate and further stresses the heart. Aggressive management with antipyretic medication and fluid volume replacement is necessary.

Signs of infective endocarditis (low-grade fever, fatigue, and malaise) occurring within 2 months of surgery or a high-risk procedure should be reported. Teach parents to request antibiotic prophylaxis for the child when appropriate.

Although parents may travel with cyanotic children, they should talk with the healthcare provider before taking them to areas of high altitude or on an airplane. Supplemental oxygen when traveling may be necessary.

Clinical Tip

Develop an emergency plan for the infant in anticipation of acute problems such as a hypoxic episode or respiratory distress. The parents should learn cardiopulmonary resuscitation. Provide the parents with a card or form that has information about the child's condition, medications, necessary emergency care, and the healthcare provider's name so emergency care providers have vital information for initial medical care.

HOSPITAL-BASED CARE OF THE INFANT AND CHILD

The newborn receiving continuous infusion of PGE_1 is cared for in the NICU. Side effects of prostaglandin E_1 treatment such as cutaneous vasodilation, bradycardia, tachycardia, hypotension, seizure activity, fever, and apnea are monitored and managed.

Avoid any unpleasant or anxiety-provoking procedures in an effort to prevent a hypoxic episode. If a hypoxic episode occurs, follow guidelines for treatment.

Following surgery, the child is initially cared for in the ICU until heart function has stabilized. Once the child returns to the general nursing unit, nursing care is the same as described for the child having surgery for increased pulmonary blood flow earlier in this chapter.

COMMUNITY-BASED NURSING CARE AFTER SURGERY

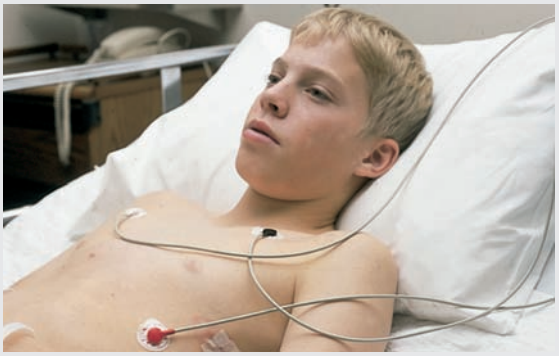
Support adolescents to transition to self-care, especially those with a complex congenital heart defect. Coordination between a primary healthcare provider and cardiologist with expertise in adults with CHD is recommended when adolescents transition to adult healthcare providers. See *Health Promotion: The Adolescent With Congenital Heart Disease.*

Evaluation

Examples of expected nursing care outcomes include the following:

- The parents recognize a hypoxic episode and initiate appropriate emergency treatment.
- The parents manage fever and medical illnesses to prevent dehydration and thromboembolism.
- The family copes with the stress of the child's condition and other family demands.
- The child demonstrates progressive development in gross motor, fine motor, and language skills following surgical repair.

Health Promotion **The Adolescent With Congenital Heart Disease**



Preventive Care

- Ensure that the adolescent has a healthcare home for general health and illness care. Perform health screening according to recommended schedules (see Chapter 9). Give all recommended immunizations, including the influenza vaccine.
- Encourage routine dental visits twice a year. Make sure the adolescent knows that regular dental care can help reduce endocarditis risk and to seek antibiotic prophylaxis if needed.
- Encourage female adolescents to initiate gynecologic care to ensure that appropriate care is provided for sexual health and contraception. For example, contraceptives containing estrogen are not recommended for individuals with cyanosis, mechanical prosthetic heart valves, or Fontan circulation because of the risk of venous thrombosis (Warnes, 2014). Educate the adolescent about the potential need for special care during pregnancy.
- Provide counseling about health risks associated with tobacco use, alcohol and drug use, and unprotected sex.

Physical Activity

- Ensure that the adolescent with complex CHD has graded exercise testing on a treadmill or bicycle to determine the sports, exercises, and physical activity recommended.
- Clearly explain the importance of physical activity for long-term health. Inquire about the adolescent's beliefs about allowable exercise and activity level, and provide education if differences in recommended and perceived activity levels are found. Explain any activity limitations, such as avoidance of body blocking if a pacemaker is used.

Nutrition

- Encourage the adolescent to eat nutritious meals and snacks, and to avoid excess weight gain that could stress the heart function.
- Educate adolescents with polycythemia to maintain hydration.

Mental and Spiritual Health

- Talk with adolescents about their self-identify, as they have scars, may be smaller than their peers, may be less physically active, and have more frequent healthcare visits.
- Discuss the adolescent's concerns for the future because there may be significant uncertainty about the disease course and outcome.
- Identify and refer adolescents as needed for counseling or to a support group of adolescents of similar age with congenital heart disease.

Education for Self-Care

- Begin the process of transitioning the adolescent to adult health care. Provide education about the congenital heart defect, surgeries that have been performed, and the types of symptoms resulting. Provide information about specific signs that require healthcare provider notification. Remember that previous education has been targeted to the parents. Correct any misperceptions that prior surgery resulted in a normal heart if that is not the case.
- Provide a written succinct summary of the adolescent's condition and medical management that can be shared with other healthcare providers.
- Provide education about infective endocarditis prophylaxis if needed. Describe situations that may increase risk, such as tattooing, acupuncture, dental care, electrolysis, and various diagnostic and surgical procedures.
- Discuss the medications needed and why. Develop plans for the adolescent to assume responsibility for self-administration. Educate the adolescent to seek guidance before using over-the-counter medications and herbal medications because of the potential for medication interaction.
- Discuss the genetic aspects of the condition and provide resources for genetic counseling if desired.
- Discuss the danger signs of the condition (such as arrhythmias, or the potential of dehydration in an adolescent with cyanosis) and how to seek urgent or emergency care.

Vocational Education

- Reassure adolescents who have had complete repairs of the congenital heart defect and have no disabilities that they have no limitations in their career or vocational selection.
- Provide career and vocational counseling to adolescents with cardiac disabilities that matches their interests, academic abilities, and clinical limitations. Encourage preparation for employment that can be maintained throughout the working career. Inform adolescents about their rights under the Americans with Disabilities Act of 1990.
- Encourage families and adolescents to identify health insurance options and policies that are a better match for the level of healthcare interventions needed.

Defects Obstructing Systemic Blood Flow

Etiology and Pathophysiology

An anatomic stenosis (narrowing of a valve, of the area around a valve, or in the great artery above a valve) causes obstruction to blood flow and results in a pressure load on the left ventricle and decreased cardiac output. The greater the narrowing, the more obstructed the blood flow is to the circulation. This results in higher pressure in the ventricle and decreased cardiac output. Newborns with severe left outflow obstruction or left ventricular dysfunction may develop decreased cardiac output and shock.

Clinical Manifestations

Low cardiac output is responsible for the following clinical manifestations: diminished pulses, poor color, delayed capillary refill

time, and decreased urinary output. The blood cannot move past the obstruction, so it backs up into the left atrium and then the lungs, causing CHF and pulmonary edema. The child with mild obstructions may have leg cramps, cooler feet than hands, and stronger pulses in the arms than the legs. Decreased blood supply to the gastrointestinal tract may lead to necrotizing enterocolitis. See Chapter 25. See Table 21–8 for the pathophysiology, clinical manifestations, diagnostic tests, clinical therapy, and prognosis for congenital heart defects that obstruct systemic blood flow.

TABLE 21–8 Pathophysiology, Clinical Manifestations, Diagnostic Tests, Clinical Therapy, and Prognosis for Defects That Obstruct the Systemic Blood Flow

ANATOMY
AORTIC STENOSIS (AS) Narrowing of the aortic valve obstructs blood flow to the systemic circulation. The valve often has two valve leaflets (bicuspid), rather than three, that may be partially fused. The left ventricle must work harder to force blood past the narrowed valve opening. Aortic stenosis accounts for up to 10% of congenital heart defects (Park, 2014, p. 188). ***Clinical Manifestations*** Most infants and children with mild AS are asymptomatic. Life-threatening AS occurs in some newborns. CHF develops in infants with significant stenosis. Peripheral pulses may be weak and thready. The child may complain of chest pain after exercise, and exercise intolerance may be noted. Fainting and dizziness (syncope) are serious signs that require intervention. The systolic blood pressure may be higher in the right arm than the left. A systolic heart murmur and thrill may be detected in the aortic area with transmission to the neck. An ejection click may be heard. Splitting of the S_2 may be noted. Interventions may result in aortic insufficiency causing a high-pitched diastolic decrescendo murmur along the left sternal border near the mitral area. ***Diagnostic Tests*** The chest radiograph may reveal a normal-sized heart, but a dilated ascending aorta may be seen. The ECG may show mild left ventricular hypertrophy in severe AS. An echocardiogram reveals the number of valve leaflets, pressure gradient across the valve, and size of the aorta. Exercise testing may be used in asymptomatic children to determine the amount of obstruction present. ***Clinical Therapy*** Newborns with life-threatening AS need PGE_1 to maintain a patent ductus arteriosus as well as dopamine and diuretics to treat CHF until the aortic valve can be dilated. Treatment involves balloon dilation during cardiac catheterization or surgical valvotomy. Surgical treatment is palliative rather than curative. Aortic valve replacement is performed when stenosis is severe or if significant regurgitation results from other interventions. ***Prognosis*** Chest pain, syncope, and sudden death can occur in symptomatic children, particularly during vigorous exercise. Untreated mild AS may progress after several decades as the valve calcifies. Stenosis may also recur after intervention. Valve replacement may become necessary, requiring lifelong anticoagulant therapy.	COARCTATION OF THE AORTA (COA) Narrowing or constriction in the descending aorta, often near the ductus arteriosus or left subclavian artery, obstructs the systemic blood outflow. This defect occurs in 8% to 10% of congenital heart defects and is found in 30% of children with Turner syndrome (Park, 2014, p. 195). ***Clinical Manifestations*** Many children are asymptomatic and grow normally. Reduced blood flow through the descending aorta causes lower blood pressure in legs and higher blood pressure in arms, neck, and head. Brachial and radial pulses are typically bounding, but femoral and leg pulses are weak or absent. Older children may complain of weakness and pain in the legs after exercise.	

ANATOMY

Clinical Manifestations

Infants with moderate constriction are pale; may have poor feeding, avoidant/restrictive food intake disorder (failure to thrive), and increased respiratory effort. They may develop CHF. Newborns with severe constriction may have cyanosis in the lower extremities, heart failure, and shock as the ductus arteriosus closes. Renal failure and necrotizing enterocolitis may develop.

On auscultation, S_2 is heard as a loud single sound. A systolic ejection murmur may be heard at the upper right and middle or lower left sternal border. A thrill may be palpated in the suprasternal notch.

Diagnostic Tests

The chest radiograph may reveal cardiomegaly, pulmonary venous congestion, and indentation of the descending aorta. Dilation of the ascending aorta may be seen. Rib notching is rarely seen before 5 years of age. MRI is preferred for imaging to see the aortic arch, site of coarctation, and collateral circulation.

ECG may be normal or show left ventricular hypertrophy.

Echocardiogram shows the size of the aorta and functioning of the aortic valve and left ventricle.

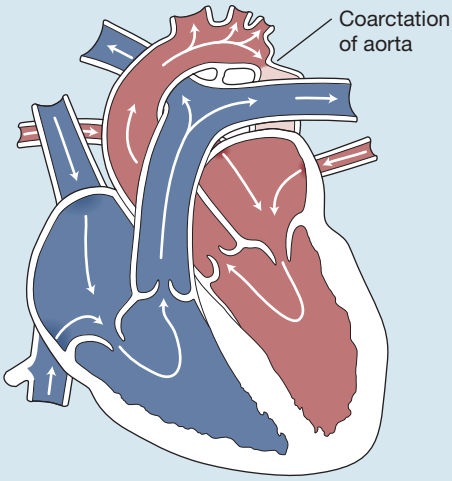
Clinical Therapy

In symptomatic newborns, PGE_1 is given to reopen the ductus arteriosus and promote blood flow to the kidneys and lower extremities. Treatment to prevent CHF may be initiated with inotropic medications, diuretics, and oxygen (Park, 2014, p. 198).

Surgical resection is often preferred to balloon dilation during cardiac catheterization to reduce the risk for recoarctation. Balloon dilation with stent placement may be performed for sick newborns who will eventually need surgical repair and stent removal (Park, 2014, p. 199). Balloon angioplasty may be performed if coarctation recurs.

Prognosis

Balloon dilation and surgical resection are palliative because coarctation may recur with either procedure. Lifelong follow-up is necessary. Persistent hypertension occurs in some children.



HYPOPLASTIC LEFT HEART SYNDROME (HLHS)

The mitral and aortic valves are absent or stenosed along with an abnormally small left ventricle and small aorta. HLHS accounts for about 1.5% of congenital heart defects (Awad & Busse, 2011). About 10% of cases are associated with Turner syndrome, trisomy 18, and other genetic disorders (Park, 2014, p. 258).

Clinical Manifestations

Within hours after birth, the newborn has progressive cyanosis and signs of CHF (tachycardia, tachypnea, dyspnea, retractions, and decreased peripheral pulses) as the ductus arteriosus closes.

Poor peripheral perfusion, pulmonary edema, and CHF lead to shock, acidosis, and death, without intervention.

On auscultation, S_2 is single and loud. No heart murmur is present.

Diagnostic Procedures

The chest radiograph shows cardiomegaly and increased pulmonary venous congestion.

The ECG shows right ventricular hypertrophy.

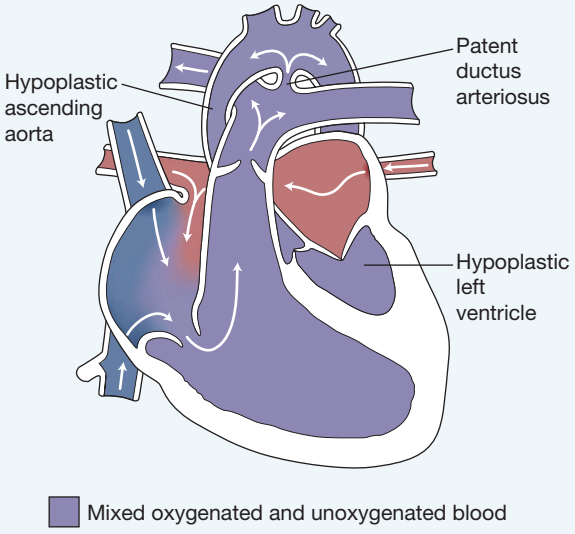
The echocardiogram shows the small left ventricle and enlarged right ventricle. This condition is often diagnosed prenatally.

Clinical Therapy

Prostaglandin E_1 is given immediately to maintain a patent ductus arteriosus.

Intubation and ventilation are performed, and supplemental oxygen is provided. Metabolic acidosis is treated.

Genetic, ophthalmologic, and neurologic evaluations are often performed before surgery.



(*continued*)

TABLE 21–8 Pathophysiology, Clinical Manifestations, Diagnostic Tests, Clinical Therapy, and Prognosis for Defects That Obstruct the Systemic Blood Flow *(continued)*

ANATOMY	
Clinical Therapy	
Treatment options include surgery or a heart transplant (see the heart transplantation section later in chapter). Comfort or palliative care is chosen less often with advances in surgery. Norwood surgery is performed in three stages. Stage 1 procedure is performed by 1 week of age. The aorta is reconstructed and the right ventricle is committed to pumping blood through the pulmonary valve to the aorta. The atrial septum is removed so blood can mix. A shunt is created to send adequate blood to the lungs. Stage 2, performed at 3 to 6 months of age, connects the superior vena cava directly to the pulmonary artery (Glenn shunt). Stage 3 Fontan procedure, performed at 1 to 2 years of age, connects the inferior vena cava to the pulmonary circulation, ending the mixing of oxygenated and unoxygenated blood. Few infant hearts are available for transplantation.	
Prognosis	
Surgery is essential for survival, and the survival rate after stage 3 Fontan is 95% after 4 years (Park, 2014, p. 261). However, some infants die during intervals between surgical stages. Heart failure, arrhythmias, and sudden cardiac death may occur in children and adolescents several years after stage 3 Fontan surgery. The child will have physical activity limitations because of a single ventricle. Approximately 50% of surviving children have significant cognitive and neurologic impairment (Paris, Moore, & Schreiber, 2012) (see *Evidence-Based Practice* earlier in this chapter).	

Clinical Tip

The systolic blood pressure is usually 10 to 15 mmHg higher in the legs than the arms in healthy children. In children with coarctation of the aorta, the systolic blood pressure in the legs may be equal to or lower than in the arms, as the defect obstructs systemic blood flow to the abdomen and lower extremities.

Clinical Therapy

Neonates with severe systemic outflow obstruction or left ventricular dysfunction may develop decreased cardiac output and shock. PGE_1 and inotrope medications may be required to support the systemic circulation until the obstruction is relieved or ventricular function improves.

Some children (e.g., after Fontan procedure or aortic valve replacement) need long-term treatment with aspirin or warfarin to prevent the development of thrombi. Caution parents of children who take warfarin (Coumadin) to avoid using herbal products because of interactions. For example, children will have an increased warfarin effect with ginkgo biloba or a decreased effect with St. John's wort (Yu, Bostwick, & Hallman, 2011).

Nursing Management

See the sections on *Congenital Heart Defects That Increase Pulmonary Blood Flow* for nursing care management of children with aortic stenosis and coarctation of the aorta earlier in this chapter and on *Defects Causing Decreased Pulmonary Blood Flow and Mixed Defects* for nursing care management of infants with hypoplastic left heart syndrome (HLHS) earlier in this chapter.

Parents of children with life-threatening defects such as HLHS are under intense pressure to make a decision about the best treatment for their newborns (palliative care, Norwood procedure, or heart transplant). Nurses have an important role in providing parent support during the decision making process as they may get conflicting recommendations by neonatologists and surgeons (Toebbe, Yehle, Kirkpatrick, et al., 2013). Share information with the parents so they are fully informed about treatment options and their associated mortality, the intense care needed by the surviving child, the potential for disabilities, and the unknown long-term survival. Identify family members, clergy, or social workers who can support the parents through this period. If parents choose comfort or palliative care, interventions such as PGE_1 are discontinued, and the infant is given appropriate pain medication and comfort (see Chapter 13). Reassure parents that they are good parents, no matter what decision they make.

Congestive Heart Failure

Congestive heart failure (CHF) occurs when heart function is impaired and cardiac output is inadequate to support the body's circulatory and metabolic needs. It may result from a congenital heart defect that either increases pulmonary blood flow or obstructs the systemic blood outflow tract. Other causes include arrhythmias, pathologic conditions that require high cardiac output (e.g., severe anemia, acidosis, or bronchopulmonary dysplasia), and acquired heart disease (e.g., cardiomyopathy or Kawasaki disease).

Etiology and Pathophysiology

Pulmonary blood volume overload associated with congenital heart defects is a common cause of CHF in infants. Many infants with this pathophysiology develop CHF within the first 6 months of life (McDaniel, 2014). Defects that allow blood to shunt from the left side of the heart to the right increase the amount of blood pumped to the lungs. The pulmonary system is overloaded, and if prolonged can lead to pulmonary artery hypertension (see the section later in this chapter). Obstructive congenital defects restrict the flow of blood, so the heart muscle hypertrophies to work harder to force blood through these structures. Eventually the heart muscle cannot keep up with the demand.

When cardiac output remains insufficient, blood pressure is decreased and hypoxia occurs in the organs and tissues. The sympathetic nervous system is activated and catecholamines are released, leading to tachycardia, improved heart muscle contraction, and improved smooth muscle tone that returns blood to the heart. The sympathetic nervous system also reduces blood flow to the kidneys, which in turn stimulates the release of rennin, angiotensin, and aldosterone. Sodium and fluid are retained to increase circulatory volume. The myocardium stretches temporarily to manage the increased blood flow and force of contraction. These physiologic responses are unable to maintain the cardiac output and maintain blood pressure as CHF progresses and the maximum myocardial stretch is reached. Progressive systemic edema and pulmonary congestion leads to right- or left-sided heart failure that may become bilateral.

Clinical Manifestations

Initial signs of CHF may be subtle and not immediately recognized. The infant tires easily, especially during feeding. Weight loss or lack of normal weight gain, diaphoresis, irritability, and frequent respiratory infections may be evident. Pallor or mottling of the skin may be present. Older children may have exercise intolerance, dyspnea, abdominal pain or distention, and peripheral edema.

As the disease progresses, tachypnea, tachycardia, pallor or cyanosis, nasal flaring, grunting, retractions, cough, or crackles may develop. A third heart sound may be auscultated. Generalized fluid volume overload is seen more commonly in toddlers and older children. Periorbital and facial edema and hepatomegaly are signs of fluid volume excess. Peripheral edema is less common in infants and young children. Jugular vein distention is seen in older children. See Table 21–9 for more detailed clinical manifestations.

Cardiomegaly, enlargement (hypertrophy) of the heart muscle, occurs in an effort to maintain cardiac output. Cyanosis, weak peripheral pulses, cool extremities, hypotension, and heart murmur are precursors of cardiogenic shock, which can occur if CHF is not adequately treated (see the section on cardiogenic shock later in this chapter).

Clinical Therapy

Diagnosis is based primarily on physical findings. A chest radiograph reveals cardiac enlargement and venous congestion or signs of pulmonary edema. Echocardiography confirms the diagnosis and severity of CHF. An electrocardiogram may identify an arrhythmia cause of CHF. Electrolytes, lactic acid, arterial blood gases, and a complete blood count are obtained. Renal function is evaluated with creatinine and blood urea nitrogen (BUN) levels. Liver function tests may be elevated.

TABLE 21–9 Clinical Manifestations of Congestive Heart Failure

PATHOPHYSIOLOGY	CLINICAL MANIFESTATIONS
Pulmonary venous congestion	Mild resting tachypnea, wheezing, crackles, retractions, cough, grunting, nasal flaring, recent onset of poor feeding, increased tachypnea and diaphoresis with feeding Tiring with play and orthopnea may be seen in older children
Systemic venous congestion	Hepatomegaly, ascites, periorbital edema, fluid retention weight gain Jugular venous distention and dependent edema in older children
Impaired cardiac output	Tachycardia, weak pulses, hypotension, capillary refill time greater than 2 sec, pallor, cool extremities, oliguria, restlessness, irritability
High metabolic rate	Avoidant/restrictive food intake disorder (failure to thrive) or slow weight gain, diaphoresis

The initial goal is to identify and treat the cause of CHF, such as an arrhythmia or surgical correction of a heart defect. Then efforts are made to decrease the work of the heart and improve systemic circulation. Diuretics, such as furosemide, thiazides, and spironolactone, are given to promote fluid excretion. Afterload-reducing agents (angiotensin-converting enzyme [ACE] inhibitors) are often prescribed to lessen the workload on the heart. Digoxin is less commonly prescribed with availability of ACE inhibitors. Inotropic medicines such as dopamine, dobutamine, isoproterenol, and epinephrine are used for critical care management. See *Medications Used to Treat: Congestive Heart Failure*.

Surgery or interventional cardiac catheterization for a congenital heart defect may become the treatment of choice. Cardiac transplantation may be performed for children with end-stage cardiomyopathy or complex congenital heart defects such as hypoplastic left heart syndrome.

Supportive medical therapies (supplemental oxygen, positioning to reduce respiratory distress, rest, and fluid and nutrition management) are part of the treatment plan. Most children improve rapidly after medication is administered.

Nursing Management

For the Child With Congestive Heart Failure

Nursing Assessment and Diagnosis

PHYSIOLOGIC ASSESSMENT

The diagnosis of CHF depends primarily on physical symptoms. Assess the child's vital signs, behavioral patterns, cardiac function, respiratory function, and fluid status using guidelines in the *Assessment Guide* earlier in this chapter. Use the age-specific heart and respiratory rates in Chapter 5 to identify tachycardia and tachypnea. Obtain a detailed history of the onset of symptoms from the parents because CHF often develops slowly.

Medications Used to Treat: Congestive Heart Failure

MEDICATIONS AND ACTIONS	NURSING MANAGEMENT
Digoxin (Lanoxin) Slows the heart rate, increases cardiac filling time, and increases cardiac output; used with increased pulmonary blood flow.	• Assess the heart rate for bradycardia for 1 min prior to giving a dose or for changes in heart rhythm or quality. • Monitor the child for digoxin toxicity. • See the CHF nursing management section for more information.
Furosemide (Lasix) Rapid diuresis; blocks reabsorption of sodium and water in renal tubules.	• Monitor patients during rapid diuresis for vital signs, intake and output, and fluid and electrolyte imbalances (e.g., hypokalemia and hypochloremia). • Assess for digoxin toxicity if hypokalemia is present.
Thiazides (Diuril) Chlorothiazide (suspension); hydrochlorothiazide (tablets). Maintains diuresis, decreases absorption of sodium, water, potassium, chloride, and bicarbonate in renal tubules.	• Monitor blood pressure and intake and output rates and patterns. • Monitor lab values for hypokalemia. Assess for digoxin toxicity if present.
Spironolactone (Aldactone) Maintains diuresis (potassium sparing).	• Assess for signs of fluid and electrolyte imbalance and digitoxicity.
ACEi (angiotensin-converting enzyme inhibitor) (e.g., Captopril, Enalapril) Promotes vascular relaxation and reduced peripheral vascular resistance, reduces afterload.	• Monitor for hypotension with initiation of therapy and dosage changes. • Assess for common side effects such as cough, hyperkalemia, and worsening renal function.
Carvedilol (Coreg) Improves left ventricular function, promotes vasodilation of systemic circulation; used for chronic heart failure and dilated cardiomyopathy.	• Give with food. • Assess the heart rate for bradycardia when the dose is increased. • Assess cardiac output by monitoring tissue perfusion, peripheral pulses, blood pressure, and urine output. • Monitor for dizziness and hypotension. • Monitor digoxin levels because drug may increase plasma digoxin concentration. • Monitor liver function periodically.

Source: Data from Wilson, B. A., Shannon, M. T., & Shields, K. M. (2016). *Pearson nurses' drug guide 2016*. Hoboken, NJ: Pearson Education; Park, M. K. (2014). *Pediatric cardiology for practitioners* (6th ed., pp. 457–464). Philadelphia: Elsevier Saunders; Satou, G. M., & Halnon, N. J. (2013). *Pediatric congestive heart failure*. Retrieved from http://emedicine.medscape.com/article/2069746-medication#1

Measure intake and output carefully. Weigh the infant's diapers before use and after changing (each 1-g difference in weight equals 1 mL of urine). Weigh the child at the same time each day. Observe for periorbital or peripheral edema and circulatory changes. If ascites is present, take serial abdominal measurements to monitor changes. (See the *Clinical Skills Manual* SKILLS for guidelines.) Turn the child frequently and assess the skin for redness and breakdown.

FAMILY ASSESSMENT

Review the child's previous hospitalizations and assess the family's knowledge about the child's condition. Families of children with CHF are anxious about the potential deterioration of the child's condition and their ability to provide ongoing care. Assess the family's anxiety level and coping strategies. Evaluate the family's economic status. Medication is crucial to treatment, and a family's inability to obtain the necessary medications jeopardizes the child's outcome. Identify the parent's ability to recognize changes in the child's condition and to provide needed care. Determine if another family member is available who could assist young parents or provide respite care.

DEVELOPMENTAL ASSESSMENT

Because fatigue limits the activities of the infant and young child with CHF, the opportunity to practice the skills needed to attain normal developmental milestones is more limited. Use a developmental assessment tool to document current status (see Chapter 6). Ask parents when the child attained expected

developmental milestones such as sitting, manipulating objects, standing, or walking; also ask about contact and play with other children and a typical day's activity schedule. Parents may limit the child's contact with other children because of frequent infections and exercise intolerance. When CHF is well controlled, the child's energy level increases and developmental skills often improve. Repeating assessments every 2 to 3 months in infants and toddlers provides useful information about development and disease management.

Several nursing diagnoses that may apply to the child with CHF can be found in the accompanying *Nursing Care Plans*. The primary nursing diagnosis is ***Cardiac Output, Decreased,*** related to cardiac anomaly (NANDA-I © 2014).

Planning and Implementation

Nursing care for the child with CHF focuses on administering and monitoring effects of medications, maintaining adequate oxygenation and myocardial function, promoting rest, fostering development, providing adequate nutrition, and providing emotional support to the child and family (Figure 21–8). (See *Nursing Care Plan: The Child Hospitalized With Congestive Heart Failure*.)

ADMINISTER AND MONITOR PRESCRIBED MEDICATIONS

Children with CHF usually receive furosemide and an ACE inhibitor, and they may receive intravenous inotropic medications while in the PICU. In some cases, digoxin is prescribed. These medications are potent and must be administered correctly.

SAFETY ALERT!

Before giving the digitalizing dose of digoxin (a higher dose to establish a blood level more rapidly), assess baseline vital signs, the quality of peripheral pulses, and clinical symptoms, and also obtain an electrocardiogram (ECG). Check the levels of serum electrolytes, and check hepatic and renal functions. Assess hydration status, and hydrate if hypovolemic. The risk for digoxin toxicity is increased when hypokalemia is present. Repeated ECGs are used for early detection of toxicity for several days after digitalization (Park, 2014, p. 461).

Before giving any dose of digoxin, take the apical pulse for 1 minute. Call for a healthcare provider's advice before administering the digoxin in the following conditions:

- The heart rate is less than 60 to 100 beats/min, depending on the age, or is higher or lower than the guideline noted in the healthcare provider's order.
- Changes in heart rhythm or quality are noted.

MAINTAIN OXYGENATION AND MYOCARDIAL FUNCTION

Oxygen therapy may be ordered. Make sure that tubing is patent, the oxygen flow rate is correct, the oxygen delivery device is working properly, and humidification is provided. Keep the child calm and quiet. Position the child in semi-Fowler or a 45-degree angle position to promote maximum oxygenation. An infant car safety seat is an option.

PROMOTE REST

Group assessments and interventions together to ensure that the child has some uninterrupted rest each hour. Rocking is restful for infants. Encourage older children to engage in quiet activities such as computer games and videos.

Figure 21–8 Jooti is receiving intravenous fluids and oxygen. Her condition is being continuously monitored for congestive heart failure.

FOSTER DEVELOPMENT

Encourage parents to play with the child, using toys to stimulate eye–hand coordination and fine motor movements. Such toys include rattles, blocks, and stuffed animals for infants and books, paper and crayons, and dolls for older children. Encourage sitting, standing, or walking for short periods with adequate rest afterward to promote the development of large muscles. Singing, talking, and playing music facilitate cognitive and language skills.

PROVIDE ADEQUATE NUTRITION

Teach parents about feeding techniques. Encourage the mother who chooses to breastfeed the infant. The antibodies in breast milk reduce infections, and the milk is naturally low in sodium. However, the sucking involved in breastfeeding or bottle feeding may cause dyspnea that forces the infant to rest frequently during feeding. Feedings should last no more than 30 to 40 minutes, but some infants should feed no longer than 20 minutes. Frequent small feedings generally work best, with burping after every half ounce of intake to minimize vomiting. Holding the infant at a 45-degree angle or positioned in an infant seat decreases venous return to the heart and decreases its metabolic demand. Make sure parents understand that changes in feeding habits (decreased intake, vomiting, sleeping through feedings, and increased perspiration with feedings) may indicate deteriorating cardiac status.

Infants with CHF need adequate nutrition to support growth because their metabolic rate is elevated. Some infants need a higher caloric formula (24 to 30 calories per ounce) to obtain adequate nutrition. For example, regular powdered formula can be prepared with less water or a human milk fortifier can be added to breast milk. In some cases, low-osmolarity glucose polymers or medium-chain triglyceride (MCT) oil is recommended for addition to standard formula (Park, 2014, p. 457). Nutritional supplementation by nasogastric, transpyloric, or gastrostomy tube may be prescribed. Parents are often advised to have the infant feed normally for a specific period to promote oral stimulation and bonding. The remainder of the formula is then given by tube feeding. (See the *Clinical Skills Manual* SKILLS.)

Nursing Care Plan: The Child Hospitalized With Congestive Heart Failure

1. Nursing Diagnosis: *Cardiac Output, Decreased,* related to cardiac anomaly (VSD) (NANDA-I © 2014)

GOAL: The child's cardiac output will be sufficient to meet the body's metabolic demands.

INTERVENTION	RATIONALE
• Administer digoxin as ordered.	• Digoxin increases contractility of the heart and force of contraction.
• Regularly count the apical pulse and listen to heart sounds, especially before each dose of digoxin. Record the apical pulse rate with each dose of digoxin.	• Digoxin may cause bradycardia. Pulse and heart sounds provide information about heart functioning.
• Use cardiac monitor if prescribed.	• Monitor notes bradycardia and arrhythmias.
• Monitor serum potassium level and for digitoxicity.	• Hypokalemia increases risk of digoxin toxicity.
• Provide for rest periods each hour.	• Rest decreases need for high cardiac output.

EXPECTED OUTCOME: Child's cardiac output will be sufficient as indicated by increased energy, adequate feeding intake, and decreased edema. Child will maintain normal serum potassium levels and therapeutic levels of digoxin. Child will rest hourly and have adequate energy to eat and play.

GOAL: The child will manifest adequate oxygenation.

INTERVENTION	RATIONALE
• Evaluate respiratory rate and breath sounds. Observe for diaphoresis, a sign of increased respiratory effort. Use pulse oximetry to determine oxygen saturation readings.	• Provides information about oxygenation and ease of respiration.
• Provide oxygen and humidification if prescribed.	• Supplemental oxygen decreases tachypnea, and humidification moistens secretions to keep airway clear.
• Place child in semi-Fowler position.	• This position facilitates lung expansion.

EXPECTED OUTCOME: Child will maintain a normal SpO_2 level and respiratory rate for age without evidence of adventitious sounds or diaphoresis.

2. Nursing Diagnosis: *Fluid Volume: Excess* related to heart failure (NANDA-I © 2014)

GOAL: Intake and output will be balanced once excess fluid is excreted.

INTERVENTION	RATIONALE
• Administer diuretics as ordered.	• Diuretics mobilize fluids and facilitate excretion.
• Measure intake and output carefully. Weigh diapers to assess output of infants. Weigh daily. Measure abdominal girth daily. Observe for peripheral edema.	• Adequate output is a good indicator of renal perfusion. Assessments demonstrate effectiveness of treatment.
• Monitor electrolytes.	• Electrolyte imbalance is common when diuretics are given.
• Maintain fluid restrictions if prescribed.	• Fluid restriction may help decrease the cardiac load.

EXPECTED OUTCOME: Child's intake and output will be proportional, and electrolyte levels will remain within normal ranges.

3. Nursing Diagnosis: *Skin Integrity, Risk for Impaired,* related to altered fluid status (NANDA-I © 2014)

GOAL: The child's peripheral and central edema will decrease.

INTERVENTION	RATIONALE
• Change child's position frequently.	• Position changes promote circulation to skin over pressure points.
• Inspect skin frequently for redness and skin breakdown over pressure points.	• Inspection identifies earliest stages of skin breakdown.

EXPECTED OUTCOME: Child will have no skin breakdown after edema resolves.

4. Nursing Diagnosis: *Nutrition, Imbalanced: Less than Body Requirements*, related to high metabolic needs and rapid tiring while feeding (NANDA-I © 2014)

GOAL: The child will receive adequate nutrition to meet metabolic needs.

INTERVENTION	RATIONALE
• Hold infant at 45-degree angle for feeding.	• Position facilitates breathing while eating.
• Record intake carefully.	• Evaluation of intake indicates whether caloric and other nutritional needs are met.
• Weigh child daily.	• Weight gain indicates growth (in absence of fluid retention).
• Give frequent small meals with rest periods in between.	• Digesting small meals requires less energy.
• Use high-calorie formula or give high-calorie snacks.	• High-calorie formulas and snacks provide calories efficiently.
• Use soothing approaches such as holding infants for feeding and having parents eat with older child.	• Restful approach facilitates intake with minimum cardiac work.
• Transition to supplemental tube feedings if the infant is not able to gain weight.	• Tube feedings provide added calories without taxing the infant's energy.

EXPECTED OUTCOME: Infant or child will gain recommended weight according to growth grids. All dietary requirements will be met, and mealtimes will be pleasant.

PROVIDE EMOTIONAL SUPPORT

The family is often anxious about the condition of the child hospitalized with CHF. Give parents a chance to express concerns about their child's condition. Explain the child's treatment regimen, and make sure family members understand the child's need for nutrition and rest. Refer parents to the appropriate support groups; talking with parents of children with cardiac conditions may be a source of emotional support.

DISCHARGE PLANNING AND HOME CARE TEACHING

Identify and address home care needs well in advance of discharge. Show parents how to prepare formula or supplement breast milk, and then offer guidance to help maximize the child's nutritional intake. While the child is hospitalized, teach the family about medication administration and signs of a worsening condition (e.g., increased feeding difficulty, irritability, lethargy, breathing difficulty, and puffiness around the eyes or extremities). Arrange for home care nursing visits to reinforce the education provided, to monitor the child's condition, and to assess the family's ability to manage the child's care. Ensure that the family has a phone contact for questions and emergency assistance. (See *Nursing Care Plan: The Child With Congestive Heart Failure Being Cared for at Home*.)

Demonstrate administration of drugs, and then supervise while the parents measure and administer medications. If digoxin is prescribed, teach parents about the signs of digoxin's toxic effects. Parents are frequently taught to take the child's pulse and to report any significant change to the healthcare provider and any signs of medication side effects. Teach parents about the potential interaction between digoxin and macrolide antibiotics so they can remind the primary care provider to prescribe safe antibiotics when they are needed.

Teach parents to take special care with an acute illness that involves a fever and diarrhea or vomiting. An acute illness could lead to dehydration more quickly when the child takes diuretics, and urgent care will be needed.

These children are evaluated frequently by healthcare providers for progression in signs and symptoms, appropriate weight gain, and developmental progress. Families are evaluated for their ongoing ability to manage the child's condition and cope with the stress of caring for a sick child.

Evaluation

Expected outcomes of nursing care can be found in the *Nursing Care Plans*.

Clinical Reasoning The Infant With Ventricular Septal Defect

Brandy, who is 1 month old, was diagnosed with a ventricular septal defect (VSD) at birth and started developing signs of respiratory distress and difficulty with feeding.

Brandy's mother had been alerted to watch for these signs as a possible indication of congestive heart failure. Brandy was quickly hospitalized so her CHF could be treated with intravenous furosemide, dopamine, and potassium. Over the next 2 days, she lost the weight she had gained as a result of fluid retention.

Corrective surgery was performed to place a patch over the septal opening. Brandy was cared for in the intensive care unit before being transferred to another unit.

- Why did Brandy develop CHF? Why was corrective surgery performed when she is so young?
- What teaching and support do Brandy's parents need to care for her at home after the heart surgery?

Acquired Heart Diseases

Cardiomyopathy

Cardiomyopathy is a serious disorder of the heart's muscle that affects chamber size, wall thickness, or contraction and leads to problems with ventricular systolic or diastolic function.

Nursing Care Plan: The Child With Congestive Heart Failure Being Cared for at Home

1. Nursing Diagnosis: *Development: Delayed, Risk for,* related to effects of physical disability (NANDA-I © 2014)

GOAL: The child will meet developmental milestones for age group.

INTERVENTION	RATIONALE
• Perform baseline developmental assessment.	• Assessment provides comparison for later assessments and basis for planning specific games, toys, and activities.
• Plan for short play periods after rest.	• Short play periods maintain energy and facilitate play.
• Introduce age-appropriate toys and activities such as rattles and blocks for infants and art projects for older children.	• Play activities facilitate learning and mastery of developmental tasks.
• Plan for interactions with healthy children.	• Social skills are learned through contact with others.

EXPECTED OUTCOME: Child will display normal language, fine motor, and gross motor activity.

2. Nursing Diagnosis: *Health Management, Family, Ineffective,* related to complexity of therapeutic regimen (NANDA-I © 2014)

GOAL: Parents will demonstrate correct administration of medications.

INTERVENTION	RATIONALE
• Have parents prepare the medication dosages and administer the digoxin, diuretics, and other medications to the child while observed by the nurse.	• Demonstrating techniques used to administer medications provides opportunities to identify dosage errors and to suggest methods to help ensure the child gets all needed medications.

EXPECTED OUTCOME: Parents will demonstrate ability to prepare correct medication dosage and administer it to the child.

GOAL: Parents will state side effects of medications and symptoms of congestive heart failure.

INTERVENTION	RATIONALE
• Describe side effects of medications. Give parents handouts with telephone number to call to ask questions or report side effects.	• If side effects are understood, serious complications can be avoided.
• Describe subtle onset of CHF symptoms (increasing weakness, exhaustion, irritability, difficulty feeding, cough or difficult respirations, edema).	• Parents can evaluate child regularly and note subtle changes requiring medical management.

EXPECTED OUTCOME: Parents will report that child continues to demonstrate improvement and adequate cardiac output without signs of congestive heart failure.

3. Nursing Diagnosis: *Nutrition, Imbalanced: Less than Body Requirements,* related to chronic illness and tiring while feeding (NANDA-I © 2014)

GOAL: The infant or child will demonstrate normal weight gain for age.

INTERVENTION	RATIONALE
• Teach parents methods to promote food intake related to positioning, size of feedings, and food choices.	• Positioning, frequency of feedings, size of feedings, and use of high-caloric foods can enhance nutritional intake.
• Observe feeding during home visit.	• Feedback can assist parents in integrating positive feeding techniques.

EXPECTED OUTCOME: Infant or child will show normal weight gain. Parents will report and demonstrate successful feedings of child.

4. Nursing Diagnosis: *Activity Intolerance* related to poor cardiac output (NANDA-I © 2014)

GOAL: The child will perform all necessary activities of daily living without undue tiring.

INTERVENTION	RATIONALE
• Suggest activities parents can alternate with rest throughout the child's day.	• Activities to promote development must be alternated with rest because of decreased cardiac output.
• Have parents limit child's exposure to persons with contagious disease.	• When the child is ill and tired, the immune system can be compromised.

- Help family plan quiet surroundings to provide for child's rest.
- Home setting may need to be altered to promote rest.

EXPECTED OUTCOME: Child will perform necessary activities and rest frequently each day.

5. Nursing Diagnosis: *Caregiver Role Strain* related to 24-hour responsibility for child's care (NANDA-I © 2014)

GOAL: Parents will express ability to meet own needs.

INTERVENTION	RATIONALE
• Assess family and community supports. Provide information related to respite care.	• Variable family and community supports are available.
• Encourage parents to seek activities to meet personal needs.	• Parents need time for own personal needs to successfully care for child.

EXPECTED OUTCOME: Parents will report some time away from the child and report renewal in caring for the child.

Dilated cardiomyopathy is the most common form, in which the four chambers dilate and systolic contraction is weakened. Clots may form as blood pools in the heart, increasing the child's risk for pulmonary or brain embolism. An estimated 20% to 35% have an inherited form with autosomal dominant, autosomal recessive, X-linked, or mitochondrial inheritance pattern (Park, 2014, p. 330). Other common causes are myocarditis, neuromuscular disease, such as muscular dystrophy, or other infections. The child usually presents with fatigue, weakness, and exertional dyspnea. Arrhythmias may develop that can cause cardiac arrest. The child is treated for CHF (diuretics, digoxin, and ACE inhibitors), including aspirin to reduce throboembolisms, antiarrhythmic medications, and beta-adrenergic medications (e.g., carvedilol). Ultimately a heart transplant may be considered. Activity is restricted.

In hypertrophic cardiomyopathy, enlargement or hypertrophy of the left ventricle and the ventricular septum occurs, making the ventricular walls rigid. About 50% of hypertrophic cardiomyopathy cases are genetically transmitted as an autosomal dominant trait involving mutations on 1 of 10 genes (Park, 2014, p. 321). Myocardial cells become enlarged with some scarring, and coronary arteries may be affected. The outflow tract may become obstructed. Because the left ventricle is stiff, diastolic filling is affected, potentially causing enlargement of the left atrium and pulmonary venous congestion. Symptoms include exertional dyspnea, fatigue, dizziness, fainting, and angina-like chest pain. Palpitations may occur because of atrial or ventricular arrhythmia. It is the most common cause of sudden unexpected cardiac death in adolescents and young adult athletes (Park, 2014, p. 321). Treatment involves beta-adrenergic blockers (e.g., propranolol or metoprolol) or calcium channel blockers (e.g., verapamil). An implantable cardioverter/defibrillator or surgical myomectomy to relieve the obstruction may be considered. Strenuous exercise and competitive sports are prohibited.

Nursing Management

Nursing management for dilated cardiomyopathy is similar to that for children with CHF unless or until a heart transplant is performed. Nursing management for cardiomyopathy involves frequent visits to assess the child's condition and to review treatments.

Heart Transplantation

Approximately 450 heart transplants are performed on children and adolescents each year in the United States (Meaux et al., 2014). The number of donor hearts available for transplantation in children is limited. Ventricular assist devices are used in some pediatric centers to maintain function in other vital organs until a heart is available for transplant. In 2010, the median survival of infants receiving heart transplants was 18.3 years and for adolescents 11.3 years (Meaux et al., 2014). The primary reasons for heart transplantation in infants and children are cardiomyopathy and congenital heart disease. The number of adults with complex congenital heart defects who seek heart transplantation is increasing as survival through childhood has increased.

Acute rejection is a leading cause of early mortality after transplantation. Signs in infants and children are often nonspecific, including low-grade fever, increasing resting heart rate, fatigue, abdominal pain, nausea, vomiting, decreasing exercise tolerance, and irregular rhythm. Endomyocardial biopsy performed during cardiac catheterization is used to diagnose rejection and may be performed frequently. Research continues for identify biomarkers that can be used to diagnose and monitor rejection in children. The immunosuppression regimen usually includes calcineurin inhibitors (cyclosporin or tacrolimus), azathioprine or mycophenolate mofetil, and corticosteroids. Selecting the correct dosage for children is essential as too much increases the risks for infection, malignancy, and toxic effects, while too little increases the risk for rejection (Andrikopoulou & Mather, 2014).

Early deaths are due to graft failure or infection. Hyperlipidemia and blood vessel thickening in the transplanted heart are leading causes of death for long-term survivors. Statin medications are prescribed to control hyperlipidemia, and hypertension is treated with calcium channel blockers.

While bacterial, fungal, and viral (i.e., cytomegalovirus) infections are a cause of mortality, more common childhood illnesses (acute otitis, colds) may be well tolerated. Antibiotics and other new medications prescribed must be carefully considered because of potential interactions with immunosuppression medications.

Nursing Management

Depending on the age at time of transplant, the child may not have had all immunizations (see Chapter 16). Live virus vaccines should be given at least 1 month prior to the heart transplant, and are usually contraindicated following the transplant (AAP, 2015, pp. 84–86). Help parents arrange for schools and childcare centers to provide early notification of cases of measles, mumps, rubella, and chickenpox. Provide preventive treatment for the child as needed. Encourage good hand hygiene to reduce the spread of infection at home and at school.

After recovery from surgery, children may have near-normal exercise capabilities, normal heart function, and be able to return to school and other activities. Immunosuppressive medications will be continued long term and can cause a variety of physical side effects such as hirsutism, gum hyperplasia, weight

gain, moon face, acne, rashes, and osteoporosis. Children and adolescents may need support to develop positive self-esteem.

Organ rejection is a major concern of families. Provide education for the parents and child about the need to adhere to the immunosuppression protocol and to keep appointments for evaluation. Adolescents need special attention to promote adherence to the immunosuppression protocol.

Pulmonary Artery Hypertension

Pulmonary artery hypertension (PAH) is a sustained increased pressure in the pulmonary artery. It is a complication of congenital heart defects that increases pulmonary blood flow in about 43% of cases (Maxwell, Nies Ajuba-Iwuji, et al., 2015). Other potential causes include pulmonary conditions (e.g., meconium aspiration, acute respiratory distress syndrome in the newborn, and prematurity-related chronic lung disease) and congenital diaphragmatic hernia.

Local mediators help the pulmonary vascular smooth muscles stay relaxed to allow blood to flow easily to the lungs. Excessive pulmonary blood flow, such as from a patent ductus arteriosus or ventricular septal defect, causes blood to back up in the lungs and pulmonary vascular constriction to decrease blood flow to the lungs. If excess pulmonary blood flow is not controlled, pulmonary vasoconstriction is maintained. Right ventricular hypertrophy develops to increase the pulmonary artery pressure and push blood across the constricted pulmonary vascular bed. Inflammation, hypertrophy of small pulmonary arteries, and fibrosis develop. The increased pressure leads to a right-to-left shunt, and right heart failure may occur. PAH may become progressive and irreversible.

The child has dyspnea with activity, retractions, fatigue, tachypnea, cyanosis with or without clubbing, diaphoresis, feeding difficulty, and avoidant/restrictive food intake disorder (failure to thrive). Cough with wheezing may occur. As right-sided heart failure occurs, signs of CHF develop. Older children also have distended neck veins, palpitations, chest pain, and syncope.

Cardiac catheterization is used to diagnose the severity of the condition. Therapy for pulmonary hypertension involves supplemental oxygen as needed. Surgery is used to treat the condition in cases of CHD that increases pulmonary blood flow. Treatments for other pulmonary conditions causing PAH, such as meconium aspiration and acute respiratory distress disorder, are initiated. Medications used to treat chronic PAH include calcium channel blockers, diuretics, and anticoagulants. Other medications used but still being tested for use in children include bosentan, ambrisentan, and sildenafil (Buck, 2013). No cure is available, but life can be prolonged with these measures.

Nursing Management

Nursing care in the community focuses on promoting rest for oxygen conservation, monitoring fluid intake and output carefully, and administering medications and oxygen. Airplane travel may be possible with supplemental oxygen. Exercise should be tailored to avoid dyspnea. Give parents needed support and information about their child.

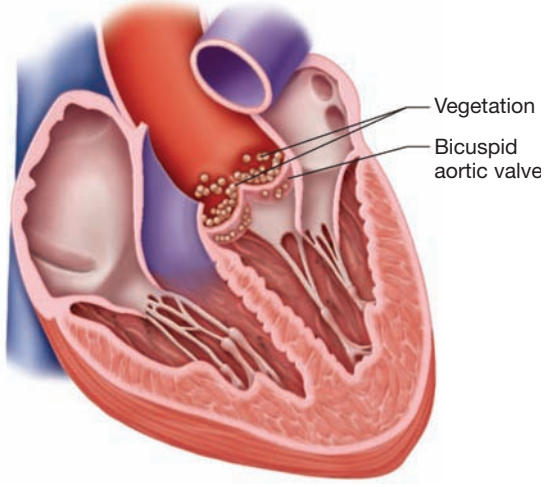
Infective Endocarditis

Infective endocarditis is a potentially life-threatening but uncommon infection in an individual with endocardial cell damage. While it is a rare condition in children, it may be associated with a congenital heart defect (CHD), rheumatic heart disease, a central venous catheter, heart surgery, or intravenous drug abuse. Among children with a CHD, those with a bicuspid aortic valve, cyanotic lesion, or cardiac surgery within the prior 6 months are at greater risk for endocarditis (Leggiadro, 2014; Park, 2014, p. 343). The rate of endocarditis has increased, potentially because of the use of medical devices and hospital-acquired infections (Bor, Woolhandler, Nardin, et al., 2013).

The endocardium may be injured by a high-velocity or turbulent blood flow due to a heart defect or an indwelling catheter in the right side of the heart. Implanted vascular grafts, patches, prosthetic valves used during cardiac surgery, or implanted devices (e.g., for dialysis) may be a site of infection. Staphylococcal and streptococcal organisms are the most commonly reported bacteria causing endocarditis (Williams & Fagan, 2014). Infectious organisms introduced into the bloodstream by dental or medical procedures adhere to the injury site and colonize (see *Pathophysiology Illustrated: Infective Endocarditis*).

The onset is often slow with symptoms such as recurrent low-grade fever, fatigue, weakness, joint and muscle aches, loss of appetite, weight loss, and diaphoresis. Other signs may include a new heart murmur, or a change in intensity of an existing murmur, and splenomegaly. Petechiae, splinter hemorrhages under

Pathophysiology Illustrated: **Infective Endocarditis**



The endocardium is injured by high velocity blood flow through a stenotic valve, by turbulent blood flow across a septal defect, or by the positioning of a central venous catheter. Fibrin and platelets migrate to the site of the endothelial damage, becoming the foundation for nonbacterial thrombotic emboli where the infective organisms settle. In some cases, a vegetation forms near the site of the injury, as in this illustration around the aortic valve.

Medications Used for Infective Endocarditis: Prophylaxis for Dental and Invasive Respiratory Procedures

ANTIBIOTIC RECOMMENDATIONS

Amoxicillin for oral use

Ampicillin for IM or IV use

If allergic to penicillin:

- Cephalexin
- Clindamycin
- Azithromycin
- Clarithromycin

NURSING MANAGEMENT

- Give 1 large dose 30–60 min before procedures, or up to 2 hr after the procedure if preprocedure dose is missed.
- Teach parents and the child to keep at least 1 dose in the home for dental visits or emergencies.
- Have parents inform each healthcare provider of the child's need for prophylaxis.

Source: Data from American Academy of Pediatrics (AAP). (2015). *Red book: 2015 report of the Committee on Infectious Diseases* (30th ed., p. 971). Elk Grove Village, IL: Author; Sabe, M. A., Shrestha, N. K., & Menon, V. (2013). Contemporary drug treatment of infective endocarditis. *American Journal of Cardiovascular Drugs*, *13*, 251–258; Park, M. K. (2014). *Pediatric cardiology for practitioners* (6th ed., p. 349). Philadelphia: Elsevier Saunders.

nails, Roth spots (exudative lesions of the retina), Osler nodes (red, painful nonhemorrhagic nodules on the pads of the fingers and toes), and Janeway lesions (nontender, blanching macular lesions on the palms and soles) may be seen in adolescents (Park, 2014, pp. 343–344). Signs of CHF may be seen in some children. Those with indwelling catheters may initially have pulmonary signs related to septic pulmonary embolism.

The Duke criteria, a positive blood culture, echocardiographic findings, and clinical signs provide guidelines for diagnosis and management of infective endocarditis. The condition is most often diagnosed by transthoracic and transesophageal echocardiography, which reveals the site of infection, valve damage, and heart function. Blood culture identifies the infective organism.

Clinical therapy consists of intravenous antibiotics such as nafcillin, oxacillin, or methacillin and gentamycin initially until blood cultures reveal the specific organism. Vancomycin is used in some cases. Once the organism is identified, the antibiotics are changed and administered for a minimum of 4 to 6 weeks depending on the infective organism. Surgery to replace an affected valve is performed in some children. The majority of children recover.

Prevention of infective endocarditis is preferred. Antibiotic prophylaxis is recommended for dental procedures and invasive respiratory procedures for selected individuals at highest risk for adverse outcomes from infective endocarditis (see the section on defects causing decreased pulmonary blood flow earlier in this chapter). See the accompanying *Medications Used for Infective Endocarditis: Prophylaxis for Dental and Invasive Respiratory Procedures*.

Nursing Management

Nursing care focuses on assessing the child's respiratory and cardiovascular status, administering medications, and teaching the parents about the child's care. Assess the child's vital signs, SpO_2, and level of consciousness because CHF and embolism may occur. The parents will be anxious about the child's condition, especially if this occurs following surgery for a congenital heart defect or in a critically ill child or newborn. Monitor the parents' coping skills and need for information.

Administer medications as prescribed and monitor serum antibiotic levels. Monitor for side effects of antibiotics and for infiltration at the infusion site. Keep invasive procedures to a minimum. Use careful aseptic technique when managing central lines and venous access devices.

The child is often lethargic and on bed rest. Encourage parents to participate in the child's care and plan quiet age-appropriate activities. Home infusion therapy is often ordered so care can continue on an outpatient basis. Instruct parents about care procedures and reinforce the importance of follow-up visits. Home schooling may be needed during the recovery period.

Nursing care also focuses on prevention of endocarditis. Good oral hygiene and regular dental care are important preventive measures. Stress the importance of telling future healthcare providers, including dentists and surgeons, about the child's infective endocarditis history so prophylactic antibiotics can be given for invasive dental and respiratory procedures.

Acute Rheumatic Fever

Acute rheumatic fever (ARF) is an inflammatory disorder of connective tissue that results from an autoimmune response to some strains of group A beta-hemolytic streptococci (GAS). This disorder may cause long-term damage to heart valves, and affects the joints, brain, and skin tissues. While ARF is a significant health problem in developing countries, the incidence is very low in the United States and developed countries because GAS infections are treated earlier.

Only a small number of individuals infected with a strain of GAS that causes pharyngitis develop ARF, but specific serotypes have not been identified (AAP, 2015, p. 733). It occurs most commonly in children between 5 and 15 years old. A genetic susceptibility to the disease may exist, such as in Pacific Islanders, predisposing children to the disorder. An estimated 60% of patients with ARF develop rheumatic heart disease (Chang, 2012).

One to 3 weeks after an untreated streptococcal infection, the major or hallmark signs of ARF may occur. Carditis involving the mitral or aortic valve may be detected by the development of a new murmur. Chest pain may be caused by pericardial inflammation. Two or more large joints become inflamed with pain, swelling, tenderness, erythema, and heat. The signs may migrate from joint to joint (migratory polyarthritis). Subcutaneous nodules may be palpated over bony prominences and along extensor tendons. A nonpruritic skin rash (erythema marginatum) with pink macules and blanching in the middle of the lesions appears on the trunk, but never on the face and hands. If the central nervous system is affected, Sydenham chorea (St. Vitus dance), characterized by aimless movements of the extremities and facial grimacing, is present.

Diagnosis is based on the Jones criteria, the presence of two or more of the major signs noted above and evidence of a recent streptococcal infection (e.g., a positive throat culture or an elevated or rising antistreptolysin-O titer of 333 Todd units). ARF is suspected when one major sign, evidence of a recent streptococcal infection and one or more minor signs (arthralgia, fever, elevated erythrocyte sedimentation rate or C-reactive protein, or a prolonged PR interval on electrocardiogram) are present (Park, 2014, p. 368). Echocardiography is used to diagnose subclinical signs of carditis that are not evident by auscultation (Gerwitz, Baltimore, Tani, et al., 2015).

Clinical therapy includes antibiotics (penicillin or erythromycin) to eradicate the streptococcal infection. Aspirin is used for fever, arthritis, and arthralgias. Corticosteroids are recommended in cases of severe carditis. Most children recover fully, but they are at risk for subsequent episodes of rheumatic fever. Children should be monitored carefully by echocardiogram for potential cardiac complications. Antibiotic prophylaxis (oral penicillin V or amoxicillin, or intramuscular benzathine penicillin G) is prescribed to children with ARF to reduce the risk for recurrent episodes until at least 21 years of age or 10 years after ARF (Park, 2014, p. 373). Persons allergic to penicillin are often prescribed azithromycin or clindamycin (Chang, 2012).

Nursing Management

An important role of the nurse is prevention of ARF. Nurses in clinics, offices, and schools need to ensure that all children with possible streptococcal infections obtain a rapid strep test or throat culture. Even if the sore throat is mild, testing is needed if family members or other contacts have had a streptococcal infection. Emphasize to the family the importance of giving all doses of the antibiotic prescribed when the test result is positive.

The child with ARF is hospitalized for a period of time. During the acute inflammatory phase, monitor temperature and vital signs at least every 4 hours. Auscultate the child's heart and note any unusual sounds. Observe the child for changes in skin, joints, or behavior. The child is on bed rest for several weeks if carditis is present, or only a week if arthritis is the major manifestation. Be sure family members obtain throat cultures to identify possible asymptomatic streptococcal carriers.

Administer antibiotics and aspirin as prescribed. The child is usually lethargic and often has joint pain. Aspirin often relieves pain dramatically after a few doses. Position and handle the child's joints carefully. Provide quiet activities, and encourage visits or telephone calls from family members and friends. Provide emotional support for the child with chorea; the purposeless involuntary movements are disturbing and can last for 5 to 15 weeks.

The child is generally cared for at home during the recovery phase. Activities may be limited, especially if heart damage is suspected. Help parents plan quiet activities, such as playing board games or computer games, watching videos, or reading. Arrange rest periods after the child returns to school. Reassure the child and parents that the effects of chorea will eventually subside.

After discharge, long-term antibiotic prophylaxis is initiated. Make sure the child and parents understand the importance of taking prescribed medication until adulthood to prevent recurrent rheumatic fever. Make sure the parents understand that the child's future sore throats may be streptococcal and a rapid strep test or throat culture should be obtained even when the child is taking daily antibiotics. The child may need a different antibiotic for the infection. Emphasize the importance of follow-up care to prevent new infections and to monitor heart function.

Kawasaki Disease

Kawasaki disease is an acute febrile, systemic vascular inflammatory disorder that affects small and midsize arteries, including the coronary arteries. It is the leading cause of acquired heart disease in children in the United States and leads to more than 5000 hospitalizations per year (O'Connell & Sloand, 2013). Children under 5 years of age account for 80% of cases, and 50% of cases occur in children under 2 years (AAP, 2015, p. 497). In the United States, Kawasaki disease has a higher incidence in children of Asian and Pacific Island origin (Park, 2014, p. 354).

ETIOLOGY AND PATHOPHYSIOLOGY

The etiology of Kawasaki disease is unknown. It is thought to be caused by or related to an infectious agent that has not yet been identified. The disorder appears to result in an exaggerated immune response to the infection in a genetically susceptible child. The inflammatory disease involves the small and midsize arteries and sometimes causes coronary artery aneurysms. Coronary artery abnormalities may occur within a week of fever onset (Rowley, 2012). Without treatment, up to 25% of children develop coronary artery aneurysms that can lead to a myocardial infarction (Park, 2014, p. 360).

CLINICAL MANIFESTATIONS

The three stages of the disease are acute, subacute, and convalescent:

- The acute stage of Kawasaki disease, lasting 1 to 2 weeks, is characterized by irritability, high fever that persists for more than 5 days, hyperemic conjunctivae, red throat, swollen hands and feet, maculopapular or erythema multiforme-like rash on the trunk and perineal area, unilateral enlargement of the cervical lymph nodes, diarrhea, and hepatic dysfunction.
- The subacute stage, lasting 2 or more weeks, is characterized by no fever, cracking lips and fissures, desquamation of the skin on the tips of the fingers and toes, joint pain, cardiac disease, and thrombocytosis (Figure 21–9).
- In the convalescent stage, 6 to 8 weeks after disease onset, the child appears normal but lingering signs of inflammation may be present. Deep transverse grooves (Beau lines) may appear across nails on the hands and feet.

Figure 21–9 **This child shows many of the signs of the subacute stage of Kawasaki disease: strawberry tongue, dry cracking lips, and buccal mucosa erythema.**

TABLE 21–10 Diagnostic Criteria for Kawasaki Disease

Kawasaki disease is diagnosed when a high spiking fever over 39.0°C (102.2°F) for 5 days or longer is accompanied by four of the five principal features not explained by another disease process. When fewer than four criteria are present, but echocardiography or angiography reveals coronary artery abnormalities, Kawasaki disease is also diagnosed.

BODY PART AFFECTED	PRINCIPAL FEATURES
Eyes	Bilateral bulbar conjunctivitis without exudate
Skin	Intense erythema of the buccal and pharyngeal surfaces with dry, swollen, cracked, and fissuring lips and a strawberry tongue Erythema of the palms and soles, edema of the hands and feet, and then desquamation after 2 or more weeks of symptoms Dermatitis of the trunk with an erythematous maculopapular rash
Lymph nodes	Cervical lymphadenopathy, frequently unilateral, with a lymph node over 1.5 cm (0.60 in.) in diameter found early in the disease

Source: Data from McLellan, M. C., & Baker, A. L. (2011). At the heart of the fever: Kawasaki disease. *American Journal of Nursing, 111*(6), 57–63; Rowley, A. H. (2012). Kawasaki disease genetics, pathology, and need for earlier diagnosis and treatment. *Contemporary Pediatrics, 29*(12), 18–24; Park, M. K. (2014). *Pediatric cardiology for practitioners* (6th ed., pp. 355–357). Philadelphia: Elsevier Saunders.

Other clinical manifestations may occur during the acute phase, such as arthralgias, abdominal pain with diarrhea, liver dysfunction, gallbladder hydrops, and aseptic meningitis. During the acute phase of Kawasaki disease, its signs and symptoms are commonly confused with other diseases.

CLINICAL THERAPY

Diagnosis is based on clinical signs using the criteria given in Table 21–10 because there is no specific diagnostic laboratory test. Blood studies may reveal elevations of the erythrocyte sedimentation rate, white blood cell count, C-reactive protein, platelet counts, bilirubin, alanine aminotransferase levels, and lipid levels (Park, 2014, pp. 356). Initial and repeat echocardiography is used to identify specific vascular changes in the heart and coronary arteries.

Kawasaki disease is treated with a single high dose (2 g/kg) IV infusion of immune globulin (IVIG) over 10 to 12 hours. Administering IVIG within 7 to 10 days of onset reduces the risk for coronary artery aneurysm. Some children receive IV diphenhydramine before IVIG to reduce the risk of allergic response. High doses of aspirin (80 to 100 mg/kg/day in 4 divided doses) are given for the high fever and to promote comfort. A lower aspirin dose (2 to 5 mg/kg once daily) is given once the child is afebrile for 2 to 3 days. Low-dose aspirin is continued to reduce clot formation until the platelet count is normal or longer term if coronary artery abnormalities occur. When the fever persists or returns within 36 hours after the first IVIG dose, a second IVIG infusion of 2 g/kg is given. If the second IVIG dose is not effective, corticosteroid therapy may be used. Infliximab, a monoclonal antibody, has been used in some U.S. children, but studies of its effectiveness have not yet been completed (Park, 2014, p. 360).

The duration of hospitalization depends on the presence of cardiac lesions and how long the fever persists. Most children recover fully, but they are monitored for cardiac disease for several months. Coronary aneurysms develop in 5% and giant aneurysms occur in 1% of children treated with IVIG, but about 50% to 67% of coronary artery aneurysms resolve within 2 years (Park, 2014, pp. 360–361). Some children with coronary artery involvement have a myocardial infarction, often within the first year after disease onset.

Nursing Management

Nursing care focuses on promoting comfort, monitoring for early signs of complications or disease progression, and supporting the family.

When the child is hospitalized, take the temperature every 4 hours and before each aspirin dose. Assess the extremities for edema, redness, and desquamation every 8 hours. Examine the eyes and the mucous membranes for inflammation. Monitor the child's dietary and fluid intake, and weigh the child daily. Carefully assess heart sounds and rhythm.

Administer aspirin and monitor for side effects such as bleeding and gastrointestinal upset. Administer IVIG as a blood product. Start the infusion rate at a rate of 0.5 mL/kg/hr for 30 minutes and gradually increase the rate to 2 mL/kg/hr. Carefully monitor the child and stop the infusion immediately if a reaction occurs (see Chapter 22).

Promote the child's comfort. Assess pain and provide analgesics and complementary therapies to manage pain. Keep the child's skin clean and dry, and lubricate the lips. Use cool compresses and tepid sponges to make the feverish child more comfortable. Change the child's clothes and bed linens frequently. Give the child frequent small feedings of soft foods and liquids that are neither too hot nor too cold.

Use passive range-of-motion exercises to facilitate joint movement. Because the child with Kawasaki disease is often lethargic and irritable, plan rest periods and quiet age-appropriate activities. Encourage the parents to participate in their child's care to promote comfort and reassure the child. Give the parents information about the disease and the child's treatment.

Before the child is discharged, teach the parents to administer aspirin as ordered and to watch for side effects. Have them measure the child's temperature daily for the first 2 weeks and record it on a log. Any fever above 38.3°C (101.0°F) should be reported to the healthcare provider. Advise the parents that the child needs to avoid contact sports or other activities that could cause bleeding when aspirin or warfarin is prescribed long term. The child who recovers without cardiovascular complications is encouraged to live an active lifestyle without exercise limitations. Limitation of strenuous activity is recommended for all children with coronary aneurysms or stenoses.

Emphasize the need for follow-up care to monitor for cardiac complications, hypertension, and hyperlipidemia. Postpone needed live virus vaccines (measles and varicella) for 11 months after IVIG administration, but other immunizations may be given on schedule.

Cardiac Arrhythmias

Cardiac **arrhythmias** (abnormal heart rhythms or dysrhythmias) occur frequently in children, but less often than in adults. Three categories of arrhythmias are tachyarrhythmias (sinus tachycardia), bradyarrhythmias (sinus bradycardia), and no pulse (ventricular tachycardia, ventricular fibrillation, pulseless electrical activity, or asystole). Less common arrhythmias are often

associated with postoperative complications of congenital heart disease, Kawasaki disease with coronary artery involvement, rheumatic heart disease, cardiomyopathy, and electrolyte abnormalities. Arrhythmias may cause decreased cardiac output and CHF. More serious arrhythmias may result in syncope or sudden death.

BRADYCARDIA

Bradycardia is a heart rate less than the lower limit of normal for the child's age (usually a heart rate less than 80 in infants and less than 60 in children and adolescents). Some athletes may normally have a heart rate of 60. It is associated with beta-adrenergic medications and conditions such as hypothermia, hypoxia, hyperkalemia, and increased intracranial pressure. See Chapter 5 for normal heart rate ranges by age.

General symptoms of bradycardia include fatigue, exercise intolerance, dizziness, and syncope. The underlying cause is treated. Other treatment may include supplemental oxygen and medications (epinephrine, atropine, isoproterenol, glucagon). Chronic bradycardia may require a pacemaker.

SUPRAVENTRICULAR TACHYCARDIA

Supraventricular tachycardia (SVT), the most common pathologic tachycardia, is the abrupt onset of a rapid, regular heart rate, often too fast to count. The presenting heart rate with SVT will be greater than 220 beats/min in infants and greater than 180 beats/min in children. Potential causes include Wolff–Parkinson–White syndrome, congenital heart defects (e.g., single ventricle and corrected transposition of the great arteries), and postoperative cardiac surgery. Often no heart disease is present. Cardiac output is affected because diastolic filling cannot occur with such a rapid heart rate. Prolonged episodes of continuous SVT (more than 6 to 12 hours) can progress to CHF or cardiogenic shock if untreated.

Early signs in infants include poor feeding, irritability, and pallor. Older children may have palpitations, chest pain, dizziness, shortness of breath, decreased exercise tolerance, and syncope. Palpitations felt in the neck may be present. Recurrent attacks are common.

Treatments focus on reducing the heart rate. Initial steps involve vagal stimulation (applying ice-water bag to the face for 10 seconds or rectal stimulation with a thermometer) or having the child perform a Valsalva maneuver (e.g., holding the breath and straining, or blowing forcefully on the thumb to increase intrathoracic and venous pressures). Amiodarone by IV bolus is the preferred medication to lower the heart rate. Synchronized cardioversion is used for life-threatening episodes unresponsive to medications. Recurrent episodes of SVT are common, and propranolol, verapamil, or atenolol may be prescribed long term to reduce the frequency of episodes. **Radio-frequency ablation**, the use of radio energy (heat) to destroy a very small section of the myocardium through which an accessory conduction pathway passes, may be performed during cardiac catheterization.

LONG QT SYNDROME

Long QT syndrome (LQTS) is an inherited rhythm disturbance of ventricular tachycardia with a prolonged QT interval and abnormal T waves that puts children at risk for ventricular fibrillation and sudden death. Electrolyte disorders and certain drugs may trigger long QT arrhythmia in some children genetically predisposed to the disorder. In some children, arrhythmia is triggered by demanding physical exercise (e.g., swimming), a strong emotional reaction, or an abrupt loud noise (e.g., doorbell or alarm clock). In some genetic forms, the arrhythmia more often occurs during rest or sleep. Arrhythmia may occur without warning and result in sudden death. Presenting signs include episodic dizziness, palpitations, syncope, seizure, or cardiac arrest.

Professionalism in Practice **Sports Preparticipation Screening**

The American Academy of Pediatrics recommends sports preparticipation screening to identify children and youth at risk for sudden cardiac death (American Academy of Pediatrics Section on Cardiology and Cardiac Surgery, 2012). Nurses can play an important role in identifying children and youth at risk by asking questions during the history for any child symptomatic of an arrhythmia or presenting for a physical assessment to play sports. Important questions include the following:

- Has the child passed out or had a seizure suddenly and without warning, either during exercise or in response to a loud noise (e.g., doorbell, alarm clock)?
- Has the child ever experienced chest pain or shortness of breath when exercising?
- Has any family member died suddenly and unexpectedly before age 50 years?
- Has any family member been diagnosed with an enlarged heart (cardiomyopathy) or rhythm disorder like long QT syndrome?

If the child is resuscitated or evaluated because of presenting signs or family history, the arrhythmia is commonly detected by electrocardiogram. The disorder is treated by beta-blockers (e.g., propranolol). A cardioverter/defibrillator (ICD) may be implanted in children and adolescents considered at high risk for sudden death. Do not permit the child to participate in competitive sports and supervise the child when swimming. Other triggers and medications that prolong the QT interval are avoided.

Nursing Management

Children with severe arrhythmias are treated in the emergency department or intensive care unit. The child is placed on a cardiac monitor and pulse oximeter. Frequently assess the vital signs and keep the healthcare provider informed about continuing abnormal rates or rhythms. Observe and record changes in level of consciousness, color, weakness, irritability, and feeding patterns. Administer medications as ordered. Have emergency drugs and resuscitation equipment available at the bedside. When sedation is ordered for invasive procedures such as synchronized cardioversion, follow the institution's guidelines for frequent assessment and intervention.

Episodes of arrhythmia and the potential for future episodes are frightening for both the child and parents. Provide written information about the danger signs indicating an arrhythmic episode and how to obtain emergency care. Educate the child and parents about the home treatment plan, including the importance of medication adherence that may prevent or reduce the frequency of episodes. Encourage parents to obtain cardiopulmonary resuscitation training. Help the child and family to avoid medications that can trigger another episode: for SVT, cardiac stimulant drugs such as decongestants; and for

LQTS, medications that prolong the QT interval (e.g., antihistamines, antidepressants, and macrolide antibiotics). An updated list of these medications can be found online. If the child has an ICD, parents need education about signs of defibrillation discharges (crying, grabbing chest, chest pain) and when to notify the healthcare provider.

Dyslipidemia

Dyslipidemia is an abnormal concentration of one or more lipids (total cholesterol, low-density lipoproteins [LDL], triglycerides, high-density lipoproteins [HDL]) in the blood. Children who have a genetic history or lifestyle that makes them more susceptible to future coronary heart disease (atherosclerosis) should be identified so preventive health measures can be implemented. A high LDL level, reduced HDL level, elevated blood pressure, type 1 or 2 diabetes mellitus, cigarette smoking, and obesity are major risk factors (National Heart Lung and Blood Institute [NHLBI], 2012).

Abnormalities in the lipid levels may be the result of excessive production, lack of clearance of the lipoprotein particles, a genetic defect in lipid metabolism, or other defects such as enzyme deficiencies. Some children have dyslipidemia due to genetic factors that cause abnormalities in lipid-metabolizing enzymes or abnormal cellular lipid receptors. Obesity is another leading cause of dyslipidemia. Examples of other causes include hypothyroidism, diabetes, nephritic syndrome, and certain drugs such as corticosteroids, beta-blockers, and isotretinoin (Brashers, 2014). More commonly, children have mild lipid abnormalities due to a combination of heredity and lifestyle factors. The child with dyslipidemia has no clinical manifestations of the condition.

A blood test for total cholesterol, HDL, and triglycerides identifies the condition. The LDL level is calculated from the triglyceride, HDL, and total cholesterol levels. See Table 21–11. Children between 2 and 8 years of age with the following risk factors should be screened for hyperlipidemia with a fasting lipid panel: a positive family history of dyslipidemia or cardiovascular disease (e.g., myocardial infarction, angina, stroke, coronary bypass surgery, or angioplasty) before 55 years in men or 65 years in women, parent with total cholesterol of 240 mg/dL or higher, or the child has cardiovascular risk factors (body mass index greater than 95th percentile, hypertension, cigarette smoking, diabetes mellitus, or a condition that causes secondary dyslipidemia). All children should have lipid screening once between 9 and 11 years of age and again between 17 and 21 years of age (NHLBI, 2012).

The primary management of dyslipidemia in most children includes dietary modifications, exercise, and other changes in lifestyle. The child's diet is carefully analyzed and changes are made to satisfy the dietary guidelines so that saturated fats are less than 7% and monosaturated fats are 20% of total caloric intake, cholesterol intake is less than 200 mg/day for treatment of elevated LDL levels, and trans fats are avoided (NHLBI, 2012). A healthy total fat intake is 20% to 35% of daily calories. High dietary fiber is encouraged. If the child is obese, weight loss is encouraged.

If a child age 10 years or older continues to have high serum lipid levels after dietary changes and increased physical activity, medications may be prescribed. Cholestyramine or colestipol, which bind bile acid in the intestine, niacin, statins, and fish oil may be prescribed. The goal is to lower LDL concentration to less than 130 mg/dL or a 50% level reduction (Giddings, 2012). Children and adolescents taking statins should have periodic creatine kinase and liver transaminase monitoring.

TABLE 21–11 Laboratory Values for Assessment of Dyslipidemia in Children Between 2 and 19 Years Old

TEST	RECOMMENDED LEVEL	LEVELS OF HIGHER RISK
Total cholesterol	Under 170 mg/dL	Borderline: 170–199 mg/dL Abnormal: 200 mg/dL or higher
LDL-C	Under 110 mg/dL	Borderline: 110–129 mg/dL Abnormal: 130 mg/dL or higher
Triglyceride		
0–9 years	Under 75 mg/dL	Borderline: 75–99 mg/dL Abnormal: 100 mg/dL or higher
10–19 years	Under 90 mg/dL	Borderline: 90–129 mg/dL Abnormal: 130 mg/dL or higher
HDL-C	45 mg/dL or higher	Borderline: 40–45 mg/dL Abnormal: Under 40 mg/dL

Nursing Management

Nursing care focuses on identifying children at risk for dyslipidemia, providing education about diet and exercise, and monitoring eating patterns. Identification and management of dyslipidemia takes place in many community settings. Office and clinic nurses identify children who need to have serum lipid measured. Nurses in schools provide education on ways to reduce risk factors. The child's history of exercise patterns, weight percentile, and dietary intake provides important information. Obtain information on familial heart disease, hypertension, diabetes, and smoking to determine risk factors.

Work with nutritionists to provide dietary teaching and monitor family eating patterns. The food plan for the child and entire family should consist primarily of fruit, vegetables, whole grain breads and cereals, low-fat and nonfat dairy products, lean meat and fish, legumes, and nuts. Processed foods, juices, sugar-sweetened drinks, and simple carbohydrates (foods with sugar and white flour) should be limited. Help parents understand that modeling food choices helps children learn to select and eat better food choices and reduce lipid levels. For children with familial hypercholesterolemia, lifelong dietary management is essential.

Healthy People 2020

(NWS-18) Reduce consumption of saturated fat in the population aged 2 years and older

Help the child select an enjoyable moderate to intense activity for daily participation, and then perform 30 minutes of aerobic exercise (e.g., jogging, swimming, biking, roller blading, soccer) at least 3 to 4 times a week to promote cardiovascular

fitness. Discourage smoking by the child or the parents to reduce the risk for cardiovascular disease.

Educate children and adolescents taking statin medications to report any adverse effects to their healthcare provider: myalgia, muscle soreness, weakness, tenderness, or dark-colored urine. Include the entire family in the treatment plan; it is difficult for a single family member to change eating and exercise patterns.

Hypertension

Hypertension in children and adolescents is defined as a systolic or diastolic blood pressure reading that is equal to or greater than 95th percentile for age, gender, and height percentile. Normal blood pressure is defined as a systolic or diastolic reading that falls below the 90th percentile for age, gender, and height percentile. An estimated 3% to 5% of children and adolescents have hypertension (Hylick, Grubbs, Johnson, et al., 2014). Detection during childhood is important as it is a major risk factor for heart disease and stroke during adulthood.

Healthy People 2020

(HDS-5) Reduce the proportion of persons in the population with hypertension

Primary hypertension occurs in about 5% of the pediatric population and is related to the increasing rate of obesity in children (Dennison, 2012). The most common causes of secondary hypertension in children include coarctation of the aorta, renal disorders, neurofibromatosis, obstructive sleep apnea, and endocrine disorders (Daniels, 2012).

Because children rarely have symptoms of hypertension, the condition is detected during a health examination. Symptoms of severe hypertension may include headaches, epistaxis, dizziness, and visual changes.

CLINICAL THERAPY

Hypertension is diagnosed after three or more separate blood pressure readings a week apart or when ambulatory blood pressure monitoring shows systolic or diastolic readings at the 95th percentile or higher for gender, age, and height. Initial evaluation includes a urinalysis, serum creatinine, electrolyte levels, blood urea nitrogen, and a complete blood count. A urine culture and renal ultrasound are performed if an initial test is positive. Serum lipid studies, fasting glucose, and serum insulin are obtained to identify dyslipidemia or diabetes. Other potential testing may include thyroid and adrenal hormone levels to identify hyperthyroidism and an echocardiogram to assess for coarctation of the aorta or left ventricular hypertrophy. Polysomnography may be performed to identify a sleep disorder.

Developing Cultural Competence **Blood Pressure**

A recent study investigated the blood pressure readings of 199,513 children between 3 and 17 years of age along with height, weight, and body mass index (BMI). The sample was well represented by the following racial and ethnic groups: White, Black, Asian, and Hispanic. The rate of prehypertension (90th to less than 95th percentile) was 12.7%, whereas 5.4% were in the hypertension range (95th percentile or greater). The highest prevalence of hypertension was found among the Black and Asian children in the study (Lo et al., 2013).

Nonpharmacologic measures for reduction of blood pressure include weight reduction and increased exercise (30 to 60 minutes a day). The Dietary Approaches to Stop Hypertension (DASH) diet is recommended for children and adolescents with elevated blood pressure. It is low in sodium and encourages fruits, vegetables, low-fat or fat-free dairy products, whole grains, fish, poultry, beans, seeds, and nuts (NHLBI, 2012). Discourage the child from smoking and the use of alcohol or drugs.

Medications are used for children with persistent, severe hypertension that is not resolved with dietary changes and exercise. Medications prescribed may include diuretics, beta-blocking agents, angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers (ARB), and calcium channel blockers (Daniels, 2012).

Nursing Management

Children should have their blood pressure measured annually beginning at 3 years of age. Take a complete history for the child with persistent high blood pressure to identify potential risk factors such as family history for hypertension, smoking, or a systemic disease. Is the child obese? Assess the diet for salt intake and servings of fruits and dairy products eaten daily. What are the child's daily exercise routines? Review any medications or other potential agents used by the child or adolescent.

Assess the child's blood pressure and consistently use the right arm and an appropriately sized cuff (see the *Clinical Skills Manual* SKILLS). Compare the leg blood pressure to that in the arm. Compare readings to the blood pressure values for gender, age, and height percentile (see Appendix B). Monitor the child with borderline hypertension every 3 to 6 months. Take at least two readings during the visit and average them if they differ.

Teach both the child and the parents how to improve the diet and develop exercise routines. Provide suggestions about seasoning substitutes for salt and a list of salty foods to avoid. Increasing intake of low-fat dairy products and fruits can contribute to blood pressure control.

Discuss ways to increase activity and reduce time watching television or playing computer games. Provide suggestions for the management of stress and stressful situations. Emphasize the need to avoiding smoking, alcohol, and drugs. Teaching that involves the entire family is usually the most effective. Instruct the family on correct administration of prescribed medications when used.

Injuries of the Cardiovascular System

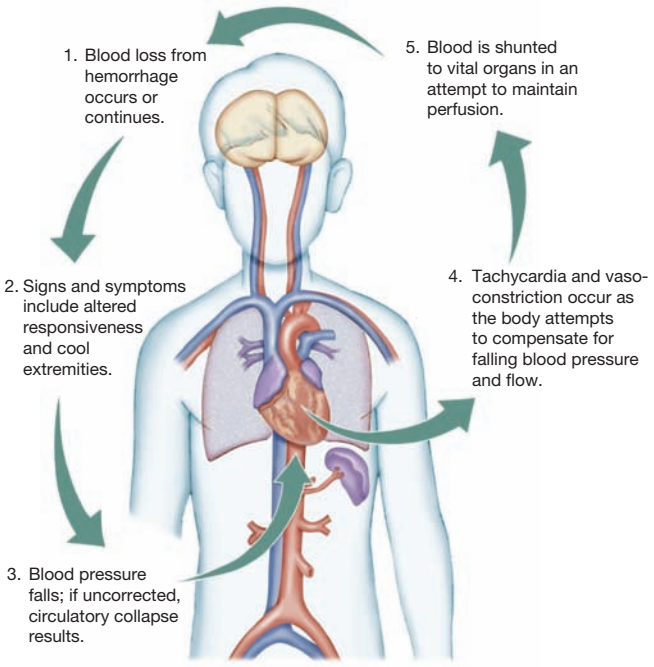
Shock

Shock is an acute, complex state of circulatory dysfunction resulting in failure to deliver sufficient oxygen and other nutrients to cells and tissues. It can be caused by a variety of conditions such as hemorrhage, dehydration, sepsis, obstruction of blood flow, and cardiac pump failure.

Hypovolemic Shock

Hypovolemic shock is a clinical state of inadequate tissue and organ perfusion resulting from inadequate blood or plasma volume in the vascular space (see *Pathophysiology Illustrated: Hypovolemic Shock*). The blood or plasma in the vascular space may be decreased because of hemorrhage or fluid movement into the interstitial spaces.

Pathophysiology Illustrated: **Hypovolemic Shock**



If hemorrhage reduces the circulating blood volume, the body compensates by increasing the heart rate and constricting the peripheral blood vessels. This allows the remaining blood to be circulated to the vital organs. When blood loss exceeds 20% to 25%, the child's body can no longer compensate; blood pressure falls, and circulatory collapse is imminent.

ETIOLOGY AND PATHOPHYSIOLOGY

Major causes of decreased intravascular blood volume include the following:

- Hemorrhage from significant injury
- Plasma loss from burns, nephrotic syndrome, and sepsis
- Fluid and electrolyte loss associated with dehydration, diabetic ketoacidosis, and diabetes insipidus

Decreased blood volume results in inadequate delivery of oxygen and nutrients to cells and accumulation of toxic wastes in the capillaries. Less blood returns to the heart to fill the ventricles, resulting in a lower stroke volume. Decreased cardiac output and mean arterial pressure then occur. The kidneys receive less blood, leading to decreased ability to filter toxins. Cellular hypoxia (reduced oxygenation of the tissues) and acidosis develop simultaneously. The accumulation of toxins and inadequate tissue oxygenation cause cellular damage.

When the child's brain senses inadequate oxygen, adrenergic and renal mechanisms help compensate:

- Catecholamine and cortisol levels rise to increase the heart rate, blood pressure, and heart muscle contractions to improve cardiac output.
- The renin–angiotensin–aldosterone system works to retain sodium and fluid in the vascular space when kidney perfusion is decreased.
- Antidiuretic hormone is secreted when the atria have reduced blood volume leading to water retention.
- Glucagon is released to provide energy for life-preserving functions.
- An increased respiratory rate improves oxygenation and decreases waste accumulation in the cells.
- The hydrostatic pressure falls, permitting fluid to shift into the vascular space and increase circulating blood volume.
- Peripheral vessels constrict to maintain systemic vascular resistance and increase perfusion to vital organs as long as possible.

When the child can no longer compensate (20% to 25% of volume loss), hypotension results. Life-threatening end-organ failure occurs without immediate therapy.

CLINICAL MANIFESTATIONS

Signs of early hypovolemic shock in children are nonspecific as the child is compensating for decreased blood volume. The blood pressure may be normal for age. The child has sustained tachycardia (usually higher than 130 beats per minute), increased respiratory effort, delayed capillary refill (greater than 2 seconds), weak peripheral pulses, pallor, and cold extremities (signs of decreased perfusion). Urine output decreases (to less than 0.5 to 1 mL/kg/hr in infants and young children) when renal blood flow drops. In cases of dehydration, dry mucous membranes and poor skin turgor are also present. See Table 21–12.

CLINICAL THERAPY

Clinical signs are used to diagnose the condition as no laboratory tests detect the blood volume deficit quickly enough. After hypovolemic shock is diagnosed or suspected, treatment is initiated. The hematocrit and hemoglobin, arterial blood gases, serum electrolytes, glucose, osmolality, blood urea nitrogen, and urinalysis are obtained during initial care.

Emergency care focuses on improving tissue perfusion. An open airway is established, oxygen is administered, and ventilation is assisted if necessary. Bleeding is controlled, and an IV or intraosseous line is inserted to provide large volumes of crystalloid fluids (normal saline or lactated Ringer). A fluid bolus of 20 mL/kg is administered rapidly over 5 minutes. The same amount of fluid is given in 5 minutes if the child's physiologic condition does not improve after the first fluid bolus. When the child is injured and no improvement is seen after the second fluid

TABLE 21–12 Clinical Manifestations of Hypovolemic Shock

SYSTEM	EARLY COMPENSATED SHOCK	MODERATE UNCOMPENSATED SHOCK	SEVERE UNCOMPENSATED SHOCK
Cardiac	Mild tachycardia, weak distal pulses, strong central pulses, normal blood pressure	Moderate tachycardia, thready distal pulses, weak central pulses, decreasing systolic blood pressure	Extreme tachycardia, hypotension, narrow pulse pressure, absent distal pulses, thready central pulses
Respiratory	Mild tachypnea	Moderate tachypnea	Severe tachypnea
Neurologic	Normal, anxious, irritable, or combative behavior	Confusion, agitation, combativeness, lethargy, decreased pain response	Comatose state
Skin	Mottled appearance; capillary refill time greater than 2 sec; cool, clammy extremities	Pallor; capillary refill time greater than 3 sec; cold, dry extremities; sunken eyes	Pale, cold skin; cyanosis; capillary refill greater than 5 sec
Renal	Decreased urine output; increased specific gravity in older infants and children (newborns cannot concentrate urine)	Oliguria; increased specific gravity	No urine output

F., Mondozzi, M. A., & Baker, R. A. U. (2014). Shock, multiple organ dysfunction syndrome, and burns in children. In K. L. McCance, S. E. Huether, V. L. Brashers, & N. R. Rote (Eds.), *Pathophysiology: The biologic basis for disease in adults and children* (7th ed., pp. 1699–1727). St. Louis, MO: Mosby Elsevier; Steffen, K. M. (2011). Trauma, burns, and common critical care emergencies. In M. M. Tschudy & K. M. Arcara (Eds.), *The Harriet Lane handbook* (19th ed., p. 109), Philadelphia, PA: Elsevier Mosby.

bolus, blood is often administered. Once the child's physiologic condition is stabilized, the cause of the hypovolemic shock becomes the focus of examination and treatment.

Nursing Management

For the Child With Hypovolemic Shock

Nursing Assessment and Diagnosis

Ask the parent (or child, if appropriate) about possible injuries or the duration and severity of acute illnesses. If no external bleeding is evident, determine whether an injury may be causing internal bleeding. For example, the liver and spleen are highly vascular organs and if injured could bleed enough to cause hypovolemic shock without evidence of bleeding. An acute illness such as gastroenteritis with prolonged vomiting and diarrhea can also result in dehydration and hypovolemic shock.

If external bleeding is apparent, determine the amount of blood lost. Although children lose the same amount of blood from a laceration as adults, the total volume of blood lost is proportional to their weight.

Growth and Development

The child's total blood volume varies by weight. The child has approximately 80 mL of blood for every kilogram of body weight.

- Newborn: 3 kg × 80 mL = 240 mL (1 cup)
- 5-year-old child: 25 kg × 80 mL = 2000 mL (2 quarts)
- 13-year-old child: 50 kg × 80 mL = 4000 mL (1 gallon)

Frequently assess the child's heart rate, respiratory rate, blood pressure, capillary refill time, level of consciousness with the Glasgow Coma Scale (see Chapter 27), color, and skin temperature to identify any changes that indicate improvement or deterioration in the child's condition. Monitor urine output and specific gravity hourly. Signs of the child's improved status include:

- A decrease in heart rate, respiratory rate, and capillary refill time
- An increase in systolic blood pressure and urine output
- Improved color, level of consciousness, and skin temperature
- Regaining of lost weight

Assess the parents' response and coping mechanisms to the child's potentially life-threatening injury. Families are unprepared for the abrupt change in the child's condition because of the unpredictability of the injury. See Chapter 13.

Examples of nursing diagnoses that may apply to the child with hypovolemic shock include (NANDA-I © 2014):

- ***Cardiac Output, Decreased,*** related to hypovolemia
- ***Fluid Volume: Deficient*** related to active fluid volume loss
- ***Tissue Perfusion: Peripheral, Ineffective,*** related to impaired transport of oxygen across alveolar and capillary membrane
- ***Coping: Family, Compromised,*** related to life-threatening condition of the child

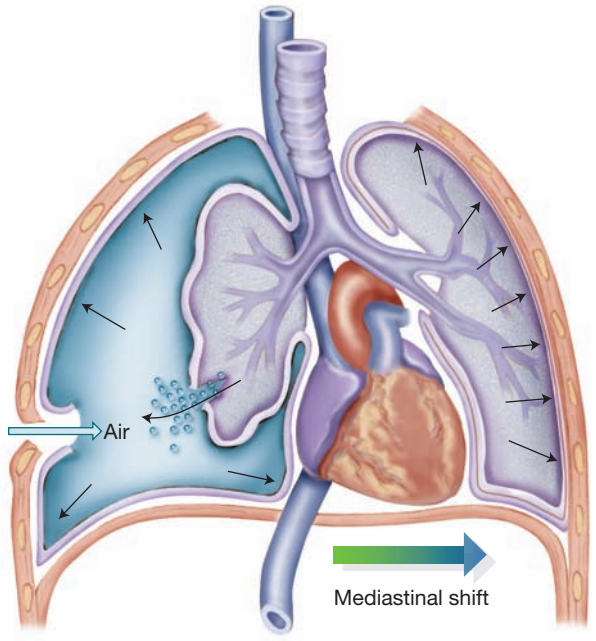
Planning and Implementation

Nurses in the emergency department, operating room, and intensive care unit more commonly participate in the resuscitation of the child in hypovolemic shock, often using guidelines or protocols for nursing actions. Assist with the child's assessment and establish IV access. Calculate and prepare the amount of IV fluid needed for the child's weight (20 mL/kg). The IV fluid is often warmed because hypothermia interferes with the child's response to treatment. Ensure rapid fluid administration by IV push or pressure bag. Monitor the child's physiologic response to the fluid bolus within 5 minutes. Prepare a second and third fluid bolus. Keep the child covered or use heat lamps to reduce body-heat loss.

When packed red blood cells are administered, verify that the correct blood has been obtained for the child. Ensure that the IV fluid is normal saline to prevent clotting during blood administration (see the *Clinical Skills Manual* SKILLS). Assess the child carefully for a transfusion reaction (see Chapter 23). Monitor the child's physiologic circulatory responses for improvement or deterioration in status. Notify the healthcare provider of any deterioration.

Parents and children with hypovolemic shock resulting from injury are usually apprehensive. The child may be fearful because of the sudden hospitalization or agitated because of an

Pathophysiology Illustrated: **Obstructive Shock Due to Mediastinal Shift**



Obstructive shock can occur when a tension pneumothorax obstructs blood flow to and from the heart (see Chapter 20). Here, the great vessels are compressed during the mediastinal shift, obstructing blood return to the heart.

altered level of consciousness. Because parents often fear for the child's life in cases of severe injury, update them about the child's condition frequently. Provide support and explain the care being provided and how it helps the child. Listen to their concerns and correct any misconceptions.

Evaluation

Examples of expected nursing care outcomes include the following:

- The child receives adequate fluid resuscitation or blood to prevent progression to severe uncompensated shock.
- The family copes with the stress of the child's injury.

Distributive Shock

Distributive shock is an abnormal distribution of blood volume, usually resulting from a decrease in systemic vascular resistance. The blood accumulates in the extremities because of vasodilation and capillary permeability. Less blood is returned to the heart, so **preload** (amount of blood in the ventricle at the end of diastole that stretches the heart muscle before contraction) drops and cardiac output falls. Blood flow is inadequate to all tissue beds. Causes of distributive shock include anaphylaxis, sepsis, and spinal cord injury. See Chapter 16 for a discussion of sepsis and septic shock.

Nursing Management

The child with distributive shock is cared for in the intensive care unit. Nursing care focuses on detecting and managing subtle changes in the child's physiologic status to improve the child's condition. Parents are supported as described in Chapter 13.

Obstructive Shock

Obstructive shock occurs from a mechanical blockage of blood flow into and through the heart and great vessels (see *Pathophysiology Illustrated: Obstructive Shock Due to Mediastinal Shift*). Causes in children include compression of the vena cava, pericardial tamponade, pulmonary embolism, tension pneumothorax, pleural effusion, and congenital heart defects with outflow obstruction (e.g., severe aortic stenosis, coarctation of the aorta). Management is focused on treatment of the underlying condition to relieve the obstruction.

Nursing Management

The child is usually cared for in the intensive care unit with nursing care focused on supporting the child's respiratory and cardiovascular functioning. See Chapter 20 for care of the child with a tension pneumothorax.

Cardiogenic Shock

Cardiogenic shock is an impairment of myocardial function that causes low cardiac output and poor tissue perfusion even though blood volume is adequate. Causes of cardiogenic shock in children may include pump failure, severe obstructive congenital heart disease such as hypoplastic left heart syndrome, cardiomyopathy, myocarditis, severe electrolyte or acid–base imbalance, a complication of shock, and early septic shock (Hazinski, Mondozzi, & Baker, 2014).

Compensatory responses divert blood to the heart and brain; however, reduced blood flow to the kidneys, liver, and intestines can lead to ischemia and end-organ failure. Increased systemic vascular resistance puts more stress on the failing heart. Each contraction causes more blood to accumulate in the

heart and pulmonary vessels, eventually leading to CHF, metabolic acidosis, and circulatory collapse.

Clinically, cardiogenic shock resembles hypovolemic shock with low cardiac output. Tachycardia, tachypnea, decreased oxygen saturation, hypotension, diminished peripheral pulses, and cool, mottled extremities are common signs. Disorientation and restlessness occur as the compensatory mechanisms fail. Signs of respiratory distress associated with CHF and pulmonary edema are often present.

An enlarged heart and pulmonary congestion may be seen on a chest radiograph. The goals of medical treatment are rapid restoration of myocardial function. Diuretics and vasodilators are given along with adequate ventilatory support, sedatives, analgesics, and antipyretics. Inotropic agents may be used in some cases.

Nursing Management

The child will be cared for in the intensive care unit. Nursing care focuses on monitoring and supporting the respiratory and cardiovascular status, fluid management, and medication administration. See Chapter 13 for care of the child with a life-threatening condition.

Myocardial Contusion

Myocardial contusion, a rare injury in children, results from a strong, blunt force against the chest wall that injures the heart muscle in the right ventricle. Blood flow to areas of the heart muscle is disrupted, or myocardial cells are directly destroyed. This potentially life-threatening condition most often occurs with striking the steering wheel of a motor vehicle during a crash, a crush injury, or a fall.

A myocardial contusion should be suspected in cases of injury to the anterior chest. The child has chest wall tenderness or pain because of fractured ribs or chest wall contusion. An electrocardiogram reveals arrhythmias or signs of myocardial infarct. A two-dimensional echocardiogram may show an abnormality in heart wall movement. Cardiac troponin I levels may be elevated.

Because of the risk of sudden arrhythmias, the child is admitted to the intensive care unit for cardiac monitoring.

Commotio Cordis

Commotio cordis, also known as a cardiac concussion, is a blunt, nonpenetrating blow to the precordium that causes ventricular fibrillation and sudden death. The majority of victims are healthy children and youth without an underlying cardiovascular disease participating in sports such as baseball, softball, ice hockey, and lacrosse. In some cases, the event is triggered by physical contact with another person, such as a fist, elbow, knee, or head. The impact timing on the precordium is believed to coincide with the period of vulnerable cardiac repolarization.

The most common arrhythmias recorded after the victim's collapse include ventricular fibrillation and ventricular tachycardia. Survival improves if prompt cardiopulmonary resuscitation or defibrillation is provided.

Nursing Management

The role of the nurse is to implement rapid cardiopulmonary resuscitation and to facilitate defibrillation. Nursing care is then focused on monitoring for cardiac arrhythmias, often in the intensive care unit.

Chapter Highlights

- Congenital heart defects occur in approximately 1% of all live births, making them the most common birth defect.
- Infants and children under 5 years of age increase their cardiac output by increasing the heart rate. After that age, the muscle fibers in the myocardium are developed enough to stretch and increase stroke volume.
- Most congenital heart defects develop during the first 8 weeks of gestation, often the result of genetic and environmental factors.
- Congenital heart defects are categorized by pathophysiology and hemodynamics:
  - Defects that increase pulmonary blood flow include the following: patent ductus arteriosus, atrial septal defect, ventricular septal defect, and atrioventricular canal.
  - Defects that decrease pulmonary blood flow include the following: pulmonic stenosis, tetraology of Fallot, pulmonary atresia, and tricuspid atresia.
  - Defects that decrease systemic blood flow include the following: aortic stenosis, coarctation of the aorta, and hypoplastic left heart syndrome.
  - Transposition of the great arteries and truncus arteriosus are examples of mixed defects that require mixing of the pulmonary and systemic circulations for survival during the neonatal period.
- Cardiac catheterization is more commonly used in children to intervene or repair some heart defects rather than to evaluate the hemodynamics and pressure gradients within the heart.
- Infants with congenital heart defects that increase pulmonary blood flow are at high risk for development of congestive heart failure.
- The child with a congenital heart defect that decreases pulmonary blood flow may have life-threatening hypoxic episodes requiring emergency treatment.
- Congenital heart defects that obstruct systemic blood flow cause signs and symptoms associated with low cardiac output: diminished pulses, poor color, prolonged capillary refill time, and decreased urinary output.
- Infants are at risk of heart failure as they are more sensitive to volume or pressure overload.

- Signs of congestive heart failure may include tachypnea, tachycardia, pallor or cyanosis, nasal flaring, grunting, retractions, cough, crackles, periorbital and facial edema, jugular vein distention, and hepatomegaly.
- Cardiomyopathy during childhood occurs most often in infancy and adolescence.
- Heart transplantation is performed in infants and children for complex heart defects or cardiomyopathy. Rejection and infection are the major causes of mortality and morbidity during the first year following the transplant.
- Pulmonary artery hypertension is a life-threatening complication of congenital heart disease with excessive pulmonary blood flow. Irreversible pulmonary vascular changes include inflammation, hypertrophy of pulmonary vessels, and fibrosis.
- Infective endocarditis is a risk for children who have some congenital heart defects, following heart surgery with patching or artificial valves, rheumatic heart disease, or a central venous catheter. Not all cases of infective endocarditis are preventable.
- Rheumatic fever is an inflammatory connective tissue disease following a streptococcal infection that may affect the heart, joints, skin, or central nervous system.
- Kawasaki disease is an acute febrile, systemic inflammatory illness with an unknown etiology. Coronary artery inflammation or aneurysms may be a significant complication.
- Two potentially life-threatening cardiac arrhythmias are supraventricular tachycardia and long QT syndrome.
- Some children have familial or lifestyle-related dyslipidemia that causes undesirable levels of cholesterol or triglycerides. These children need dietary intervention and exercise regimens as initial therapies.
- All children with systolic or diastolic blood pressure at the 95th percentile for age, gender, and height percentile have hypertension.
- Hypovolemic shock is an acute, complex state of circulatory dysfunction resulting in failure to deliver sufficient oxygen and other nutrients to meet cell and tissue demands.
- Signs that a child is in compensated hypovolemic shock include tachycardia, increased respiratory effort, prolonged capillary refill time, weak peripheral pulses, pallor, and cold extremities.
- Distributive shock is an abnormal distribution of the blood volume that results from a decrease in vascular resistance. It may be caused by anaphylaxis, sepsis, or spinal cord injury.
- Obstructive shock occurs when circulation is impeded by conditions such as compression on the vena cava due to tension pneumothorax, aortic stenosis, or coarctation of the aorta.
- Myocardial contusion results from a strong, blunt force against the chest wall that injures the heart muscle and causes an arrhythmia.

Clinical Reasoning in Action

You are working in the hospital when Samantha, a 2-day-old newborn, is diagnosed with a continuous, systolic, grade 3 heart murmur in the pulmonic area of the chest. This is the parents' first child and they are extremely worried about their 6-week-premature baby. Samantha has full, bounding pulses and weighed 5 lb 6 oz at birth, but has lost 3 oz in the past 2 days. The mother's pregnancy was healthy until her water broke suddenly. The day after Samantha was born, the parents were told about the heart murmur. After an echocardiogram and chest radiograph are performed, Samantha is diagnosed with a patent ductus arteriosus (PDA). The healthcare provider prescribes 3 doses of a medication to aid in the closure of the duct. You explain that her vital signs and urine output will need to be monitored closely for decreases while she is on this medicine.

Several days later, the heart murmur is still heard; the medicine did not work. The parents want to avoid surgery if possible and the doctor explains that if the ductus closes by the time she is 9 to 12 months old, and she is without symptoms, surgery could be avoided. If the PDA is not corrected, her life span will be shortened. She is discharged from the hospital, thriving and breastfeeding well. The parents are educated to observe for poor weight gain, swelling, intercostal retractions, and breathing more than 60 times per minute. A follow-up appointment is made for 1 week later.

1. How would you explain a PDA to the parents?
2. What was the most likely cause of Samantha's initial weight loss? Is it the PDA that caused the weight loss?
3. What is the physiologic reason Samantha's life span would be shortened if the PDA does not close or get surgical correction?
4. How would you describe congestive heart failure to the parents?

Chapter 22
Alterations in Immune Function

Barbara Penoyar/Getty Images

We knew that Raymond might have AIDS—my sister was HIV positive. But we have taken him in as our own child and cared for him. Somehow we thought he would be fine. Now, to find out that he does have AIDS is devastating, especially since my sister is also very ill. We need to learn a lot about how to help him. Can we send him to a preschool next year as we had planned? How will we get money to pay for his medicines? What do we tell other people? How do we get him to eat better? We just don't know where to turn right now.

—Aunt of Raymond, 2 years old

Learning Outcomes

22.1 Describe the structure and function of the immune system and apply that knowledge to the care of children with immunologic disorders.

22.2 Summarize infection control measures needed for children with an immunodeficiency.

22.3 Develop a nursing care plan in partnership with the family for a child with human immunodeficiency virus (HIV infection).

22.4 Plan nursing care for the child with an autoimmune condition such as systemic lupus erythematosus or juvenile arthritis.

22.5 Identify exposure prevention measures for the child with latex allergy.

22.6 Determine nursing interventions and prevention measures for the child experiencing hypersensitivity reactions.

Signs and symptoms of immunologic disorders in children are often nonspecific. The immune system is one of the few body systems that regulate, either directly or indirectly, all other body functions. Thus a problem with the immune system can result in multisystem consequences and may be life threatening. The child with recurring infections may have an undiagnosed immunologic disorder. Congenital abnormalities sometimes signal a defect in cellular immunity. This chapter will examine some of the more common disorders of immune function and discuss nursing care of children and families who have these diseases.

Immunodeficiency Disorders

Immunodeficiency, a state of decreased responsiveness of the immune system, can occur to varying degrees in response to any number of events. Children with congenital immune deficiency, or **primary immune deficiency**, are born with a failure of humoral antibody formation (B-cell disorder), a deficient cellular immune system (T-cell disorder), or a combination of both defects. In congenital disorders, the immune deficiency is not caused by another condition. However, immunodeficiency may also be acquired, as in human immunodeficiency virus (HIV) infection. Acquired immune deficiency is also called **secondary immune deficiency**.

Text continues on page 566

FOCUS ON:
The Immune System

Anatomy and Physiology

The function of the immune system is to recognize any foreign substances within the body—in simple terms, to distinguish "nonself" from "self"—and to eliminate foreign substances as efficiently as possible. When the body recognizes the presence of a substance that it cannot identify as part of itself, the body protects itself through the immune response. Normally, the immune system responds to an invasion of foreign substances, or antigens, in numerous ways. It produces **antibodies**, or proteins that work against **antigens**, the foreign substances that trigger the immune response. There are many types of antibodies, which are described later in this section. The immune system also produces other types of cells, such as T lymphocytes and natural killer (NK) cells.

Immunity is either natural or acquired. **Natural immunity** comprises the defenses present at birth, such as intact skin, body pH, natural antibodies from the mother, and inflammatory and phagocytic properties. **Acquired immunity** consists of humoral (antibody-mediated) and cell-mediated immunity and is not fully developed until a child is about 6 years of age.

Humoral immunity is responsible for destroying bacterial antigens. B lymphocytes, produced in the bone marrow, gut, and other lymphoid tissue, are the central factor in humoral immunity and develop into plasma cells that produce antibodies. Antibodies are a type of protein called **immunoglobulins**, of which there are five types: IgM, IgG, IgA, IgD, and IgE (Table 22–1). IgM, IgG, and IgA act to control a number of body infections, whereas IgE is useful in combating parasitic infections and is part of the allergic response. The role of IgD is unknown (Orduño, Grimaldi, & Diamond, 2013).

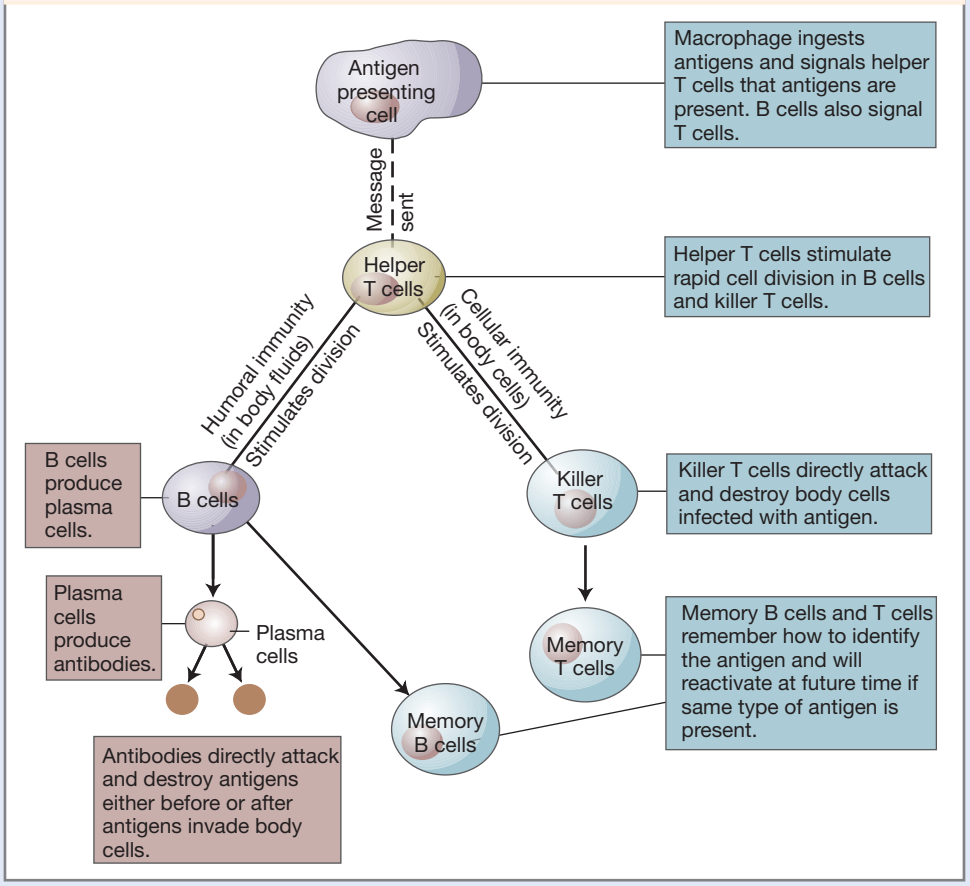
Antibodies are found in serum, body fluids, and certain tissues. When a child is first exposed to an antigen, the B-lymphocyte system begins to produce antibodies that react specifically to that antigen (see *Pathophysiology Illustrated: Primary Immune Response*). It takes approximately 3 days for this process, known as a **primary immune response**, to occur. Subsequent encounters with the antigen trigger memory cells, resulting in a **secondary immune response** within 24 hours.

Cellular immunity or *cell-mediated immunity* uses T lymphocytes, produced mainly in the thymus, to provide cellular

TABLE 22–1 Classes of Immunoglobulins

IMMUNOGLOBULIN	LOCATION	ACTION
IgM	Present in intravascular spaces (blood and lymph)	Mediates cytotoxic response and activates complement First antibody produced with primary immune response
IgG	Present in all body fluids	Active against bacteria, bacterial toxins, and viruses Activates complement Only immunoglobulin to cross the placenta
IgA	Present in secretions of gastrointestinal, respiratory, and genitourinary tracts	Prevents binding of viruses to cells of the respiratory and gastrointestinal tracts
IgD	Present in blood, lymph, and surfaces of B cells	Function not fully understood
IgE	Present in internal and external body fluids	Releases chemical mediators responsible for immediate hypersensitivity response

Pathophysiology Illustrated: **Primary Immune Response**



immunity and protect against most viruses, fungi, slowly developing bacterial infections such as tuberculosis, and tumors. In addition, they control the timing of the response in delayed hypersensitivity reactions, such as the purified protein derivative (PPD) test, and they are responsible for the rejection of foreign grafts, such as transplants. Specialized types of T lymphocytes include killer T cells, suppressor T cells, and helper T cells. Suppressor T cells inhibit B lymphocytes from differentiating into plasma cells. Helper T cells aid in the proliferation and immunologic function of other cells. T lymphocytes have proteins on their surfaces that attract and trap receptors; these proteins can be used to measure the immune activity of these cells. For example, some of the common proteins are CD2, CD3, CD4, CD5, CD7, and CD8. Natural killer (NK) cells (also known as non-B/non-T lymphocytes) originate in the bone marrow and thymus and migrate to the blood and spleen. They play a role in control of viral infection, tumors, and autoimmune diseases.

Complement is a component of blood serum consisting of 11 protein compounds. It is an inactive enzyme that activates in response to antigen–antibody functions, resulting in a generalized inflammatory reaction that kills foreign cells. It also plays a role in causing some autoimmune diseases.

Immune cells also secrete proteins called cytokines that carry messages for immune system function. Lymphocytes, monocytes, and macrophages all secrete cytokines that have a variety of effects on the target cells. Effects may include stimulation of growth through proliferation of cells, differentiation of cellular actions, production of inflammation, sensitization to pain, and other actions. Interleukins, a type of cytokine, were first identified in white blood cells but now are known to be present in many cells. Many types of interleukins have been identified, and some are known to influence the function of the immune system.

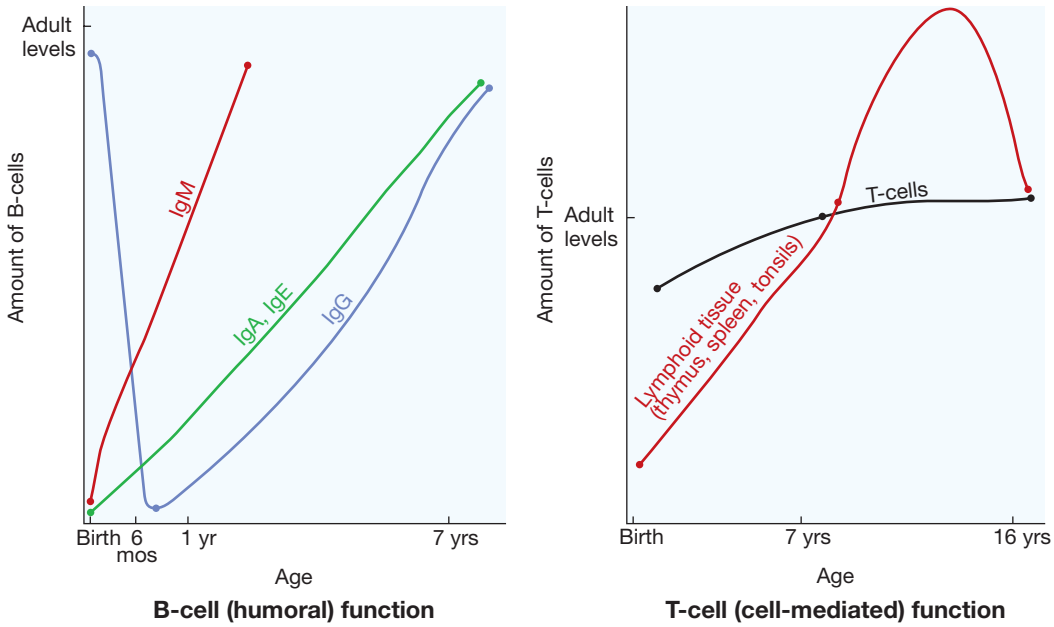
Pediatric Differences

Immune system development is a complex and multifactorial process. Early in-utero experiences, environmental exposures after birth, and other factors influence this important feedback system. It protects children from harmful diseases but also leads to conditions such as asthma (Chapter 20), food allergy (Chapter 14), or skin atopy (Chapter 31).

Infants and children have differing amounts of some immunoglobulins. IgG is the only immunoglobulin that crosses the placenta; as a result, a newborn's levels are similar to those of the mother (Buckley, 2016a). This maternal IgG disappears by 6 to 8 months of age. The infant's IgG then increases gradually until mature levels are reached at 7 to 8 years. IgM levels are low at birth, rise markedly at 1 week of age, and continue to increase until adult levels are reached at about 1 year. IgA and IgE are not present at birth. Manufacture of these immunoglobulins begins by 2 weeks of age; however, normal values are not achieved until 6 to 7 years. Thus it is easy to see why children under 6 years of age become ill so often—they do not have a full complement of immunoglobulins.

In contrast, cell-mediated immunity achieves full function early in life. Early in fetal life, the thymus begins producing T cells. By birth, many of these cells are present. The thymus is large at birth, grows during childhood, reaches peak size just before puberty, and then decreases in size (Buckley, 2016a). Other lymphoid tissues, such as the spleen and tonsils, are also comparatively large in young children. Because of the well-developed cellular immunity, any blood infused into newborns is generally irradiated to prevent **graft-versus-host disease** (a series of immunologic reactions in response to transplanted cells) from transfused

As Children Grow: **Immunoglobulins Throughout Childhood**



(*continued*)

lymphocytes (see *As Children Grow: Immunoglobulins Throughout Childhood*).

Newborns have somewhat lower numbers of NK cells than older children and adults, decreasing their ability to respond to certain antigens. The levels of some complement proteins are lower in newborns than in older children and adults, thus delaying and hampering response to certain infections.

Growth and Development

Newborns are most prone to development of infection, particularly when born prematurely, because they have lower levels of their own immune protections. Human milk contains immunologic components that can influence the immune response in the infant and protect against infection (Hassiotou et al., 2013).

Table 22–2 provides examples of diagnostic and laboratory tests used to evaluate immune system function. Use *Assessment Guide: The Child With an Immune System Alteration* to perform a nursing assessment of the immune system.

TABLE 22–2 Diagnostic Tests and Laboratory Procedures for the Immune System*

DIAGNOSTIC TEST	LABORATORY TEST
Intradermal skin testing	Complete blood count
	Complement
	Immunoglobulins
	HIV tests—see information later in the chapter

*See Appendices D and E for information about these diagnostic procedures and tests.

ASSESSMENT GUIDE | The Child With an Immune System Alteration

Assessment Focus	Assessment Guidelines
Family history	• Does a family member have a history of allergy? • Does the mother or other family member have a history of HIV or other immune system disorder? • Has the child been treated prophylactically for HIV due to the mother's positive status?
Growth and development	• Is growth regular? Is the child meeting developmental milestones? • What is the child's food intake and appetite?
Skin and mucous membranes	• Is the skin intact? Are there lesions of the mucous membranes? • Do lesions heal quickly without additional infection?
Evidence of disease	• Does the child have a history of recurring or unusual infections?

B-Cell and T-Cell Disorders

In B-cell disorders, immunoglobulins may be present in inadequate numbers or nearly absent. X-linked agammaglobulinemia, selective IgA deficiency, and common variable immunodeficiency are examples of such disorders (Michaels & Green, 2016). Because newborns are protected from infection by maternal antibodies in the first months after birth, symptoms of B-cell disorders usually become apparent after 3 months of age once the infant loses maternal antibodies. Infants with these disorders have frequent recurrent bacterial infections and failure to thrive. With treatment, consisting of intravenous immunoglobulins and antibiotics, most children survive into adulthood. Prognosis depends on the degree of antibody deficiency.

T-cell disorders are characterized by inadequate numbers of T lymphocytes or absence of T-cell functions. Isolated T-cell disorders are rare, are usually accompanied by a B-cell disorder, and may be associated with congenital abnormalities (as in DiGeorge syndrome) or of unknown cause. DiGeorge syndrome, a T-cell disorder caused by chromosome deletion at 22q11.2, is usually diagnosed soon after birth. The syndrome is characterized by the absence (complete DiGeorge) or hypoplasia (partial DiGeorge) of the parathyroid glands or thymus gland, hypocalcemia with tetany within 24 to 48 hours after birth, cardiac defects, low-set ears, hypertelorism (widely set eyes), and viral and bacterial infections in the neonatal period (Buckley, 2016b; Fernandez, 2013). There is generally a mild to moderate decrease in T-lymphocyte counts (McDonald-McGinn & Sullivan, 2011). Prophylactic antibiotics are used to prevent bacterial infections. Children with partial DiGeorge are treated with calcium and vitamin D supplements. Those with complete DiGeorge need thymus transplantation in order to survive (Fernandez, 2013).

Immunodeficiency with hyper-IgM is a T-cell disorder that primarily affects males and causes decreased T-cell function, variable abnormal levels of immunoglobulins, and high titers of some antibodies. It is usually X linked but may be autosomal in some cases. Infections caused by viruses, bacteria, fungi, and opportunistic infections are common in children with this disorder. Intravenous immune globulin (IVIG) therapy is helpful in decreasing the frequency of lower respiratory tract infections and severe infections but does not affect the frequency of upper respiratory infections or other infections. Bone marrow or stem cell transplantation with cord blood has been used as an aspect of treatment in some patients with varying outcomes (Park, 2012). Table 22–3, shown later, compares laboratory values for selected congenital immunodeficiency disorders.

Severe Combined Immunodeficiency Disease

Severe combined immunodeficiency disease (SCID) is a congenital condition characterized by the absence of both humoral and cellular immunity that is manifested by lack of appropriately functioning T cells and B cells (Schwartz & Sinha, 2013). SCID occurs in X-linked recessive and autosomal recessive forms. In some cases, SCID may be the result of chromosomal abnormalities. The disorder is estimated to occur in 1 per 50,000–100,000 live births (Pai & Notarangelo, 2013). Without appropriate treatment, children born with SCID usually do not survive more than 1 year (Buckley, 2016c)

ETIOLOGY AND PATHOPHYSIOLOGY

Severe combined immunodeficiency disease is caused by genetic mutations that lead to absence of immune function and, in some cases, absence of natural killer (NK) cells (Buckley, 2016c). The B lymphocytes are also generally defective, but even if they are normal, their function is compromised because of the severe T-cell deficiency (Kwan et al., 2014).

CLINICAL MANIFESTATIONS

Symptoms of SCID develop early in life. The infant often demonstrates a susceptibility to infection, presenting during the first few months of life with persistent respiratory infections and diarrhea (Buckley, 2016c). Recurrent oral candidiasis, failure to thrive, and skin infections are also frequently seen in affected children. Additionally, failure to recover completely from infection, frequent reinfection, and infection with viruses such as cytomegalovirus and the bacterium *Pneumocystis jiroveci* (formerly called *P. carinii*) are common in the child with SCID (Buckley, 2016c). Children are also highly susceptible to serious infections such as meningitis, skin or organ infection, osteomyelitis, or sepsis.

CLINICAL THERAPY

Refer to Table 22–3 for laboratory findings in SCID. Diagnosis is usually made only after extensive laboratory testing. In addition to a complete blood count, erythrocyte sedimentation rate, and B- and T-cell lymphocyte counts, other studies including IgA, IgG, and IgM antibody titers to immunizations received, and neutrophil count, may be performed (Table 22–4). A chest radiograph is conducted to assess thymus size.

TABLE 22–3 Laboratory Findings for Selected Congenital Immunodeficiency Disorders

DISORDERS	LABORATORY FINDINGS
B CELL	
X-linked hypogammaglobulinemia	Reduced IgA, IgM, IgE, IgG (<100 mg/dL), absence of B cells in peripheral blood, normal T cells
Selective IgA deficiency	IgA less than 10 mg/dL
Common variable immunodeficiency	Reduced IgG, IgA, and IgM
T CELL	
DiGeorge syndrome	Lymphopenia; absent T-cell functions, decreased T cells, normal B cells
X-linked immunodeficiency with hyper-IgM	Reduced IgG, IgA; elevated IgM; mutations in T-cell surface proteins
COMBINED	
Severe combined immunodeficiency syndrome (SCID)	Complete absence of T- and B-cell and NK immunity
Wiskott-Aldrich syndrome	Thrombocytopenia, low platelet volume, nonfunctional B-cells, normal IgG, decreased IgM, increased IgA, increased IgE; inability to respond to polysaccharide antigens

The standard therapy for severe combined immunodeficiency disease is the administration of intravenous immune globulin (IVIG), which is administered to provide protection until humoral immunity is established. Hematopoietic stem cell transplantation (see Chapter 23) offers the best hope for children with SCID. T-cell function is restored with the transplantation, and new cells appear 3 to 4 months after infusion of the donor stem cell. Gene therapy may also be used to treat SCID. Prognosis for the child is poor without aggressive therapy and transplant.

Prevention and prompt treatment of infection are essential. Antibiotic therapy is targeted at infectious agents. Antibiotic

TABLE 22–4 Cells Evaluated in Laboratory Studies for Immune Conditions

TEST AND TYPE OF CELL EVALUATED	ACTION	IMPLICATION OF INCREASED OR DECREASED LEVELS
WHITE BLOOD CELL (WBC) COUNT		
Neutrophil (54%–62%)	Phagocytic cell that defends against bacteria	Increased in bacterial infection, inflammatory processes, and some malignancies
Eosinophil (1%–3%)	Associated with antigen–antibody reaction	Increased in allergic reaction; decreased in children receiving corticosteroids
Basophils (0%–3%)	Phagocytic cell; involved in immediate hypersensitivity reaction; stores histamine and has receptor sites for IgE	Increased in leukemia; decreased in allergy, acute infection, collagen, and chronic diseases
Monocytes (4%–9%)	Phagocytic cell active in chronic infection	Increased in tuberculosis, protozoan infection, monocytic leukemia
Lymphocytes (T, B, non-B/non-T [NK]) (25%–33%)	Major components of immune system	Increased in many infections; decreased in children with immune deficiency
IMMUNOGLOBULINS		
(IgM, IgG, IgA, IgD, IgE) (See Appendix D for age-specific values.)	Many roles in a number of immunologic reactions	Increased in presence of infection or allergic response; decreased in children with immune deficiency

prophylaxis and special immunization recommendations are needed. Children with T-cell deficiencies should receive lymphocyte-depleted and irradiated blood products because of the risk of infection and graft-versus-host disease from lymphocytes in the donor blood (Schwartz & Sinha, 2013).

Nursing Management

For the Child With SCID

Nursing Assessment and Diagnosis

Obtain a thorough history of infections, including age of onset, type of causal organism, frequency, and severity. Assess family history, and determine if the child has had any unusual reactions to vaccines, medications, or foods. Measure the child's height and weight and plot on a growth chart to identify failure to thrive. Assess the child's nutritional intake and fluid and electrolyte balance. Assess for evidence of infections involving the skin, subcutaneous tissues, respiratory system, and mucous membranes. Palpate the abdomen for hepatomegaly and the lymph nodes for lymphadenopathy. Perform a developmental assessment and assess for delays in achievement of developmental milestones. Assess family support systems and coping mechanisms when a child is diagnosed with the disorder.

The primary nursing diagnosis for a child with SCID is ***Infection, Risk for,*** related to immunodeficiency. Other nursing diagnoses may include the following (NANDA-I © 2014):

- ***Nutrition, Imbalanced: Less than Body Requirements,*** related to illness
- ***Skin Integrity, Risk for Impaired,*** related to immunologic deficit
- ***Caregiver Role Strain, Risk for,*** related to a child with a chronic, life-threatening illness
- ***Development: Delayed, Risk for,*** related to physical disability and chronic illness

Planning and Implementation

Nursing care of the immunodeficient child focuses on preventing infection (see *Families Want to Know: Reducing Risk of Infection in the Child With Immunodeficiency Disease*). However, even with the use of environmental controls, such as keeping children inside special units (positive-pressure rooms) to maintain a sterile environment, these children are prone to **opportunistic infections** (those caused by normally nonpathogenic organisms in persons who lack normal immunity).

PREVENT SYSTEMIC INFECTION

Frequent and thorough handwashing is important. Standard precautions are always used and transmission-based precautions are established when indicated. Implement sterile aseptic technique when caring for all sites where needles, catheters, central lines, endotracheal tubes, pressure-monitoring lines, and peripheral intravenous lines, or other invasive equipment enter the child's body (see the *Clinical Skills Manual* SKILLS). The child should be placed in a positive-pressure isolation room, and contact with infectious individuals should be avoided. Inform parents that because of the risk of infection to the child, live vaccines are avoided for the child as well as siblings, parents, and other household members. Refer to the current recommendations for immunizations for the immunocompromised child. (See Chapter 16.)

PROMOTE SKIN INTEGRITY

The skin is the only intact defense that many immunodeficient children have. Provide thorough and frequent skin care, and observe all possible pressure areas closely for signs of breakdown or infection. Reposition the child frequently and encourage range-of-motion exercises.

PROMOTE NUTRITIONAL BALANCE

Encourage adequate fluid and nutritional intake. Provide foods that the child prefers and those with high nutritional value. Offer small frequent feedings of high-calorie, protein-rich foods. Refer to a dietitian as needed to plan with parents for the best individualized diet for the child.

MANAGE MEDICATION THERAPY

Many medications used long term in the treatment of children with SCID have numerous side effects. Monitor closely for side effects of antibiotics, such as overgrowth of resistant organisms (e.g., thrush infections in the mouth, *Clostridium difficile* infections of the gastrointestinal tract) and administer IVIG safely.

PROVIDE EMOTIONAL SUPPORT AND REFERRALS

SCID is a life-threatening and devastating disease. Even with aggressive therapy, the prognosis is poor for children who do not receive a hematopoietic stem cell transplant. Evaluate the family's knowledge about the disease and provide education about infection control measures and signs of infection. The parents may experience guilt because of the genetic nature of the disease and the difficulties of treatment. Listen closely to their concerns and encourage them to discuss their fears. Refer them to an appropriate support group or counselor if needed. Encourage genetic counseling if the parents plan to have more children. Evaluate the family's ability to care for the child at home. Offer financial resource information and other referrals as needed.

Families Want to Know

Reducing Risk of Infection in the Child With Immunodeficiency Disease

Teach family members the following practices to reduce the risk of transmission of infection:

- Wash all bottles, nipples, and pacifiers with hot water and soap, or in the dishwasher.
- Do not allow child to share utensils, cups, bottles, or pacifiers.
- Use safe food preparation practices such as peeling fruit and vegetables and using different surfaces and utensils for preparing meats versus other foods.
- Change diapers frequently and cleanse skin with mild soap and dry thoroughly.
- Wash hands before handling child, after changing diapers, and before feeding child.
- Maintain clean pets and keep the pet's environment clean.
- Avoid exposing the child to other family members' illnesses, such as colds.

The family of a child who undergoes hematopoietic stem cell transplantation requires additional support and referrals. The transplantation procedure involves surgery for both the ill child and the donor, often another child in the family. After the transplant the ill child will be hospitalized for several months until T-lymphocyte levels are sufficient to provide resistance to infection. During this period, parents may need to rely on social services to help manage the family situation, particularly if the child is hospitalized at a medical center far from the family's home. Assess the family's situation and make appropriate referrals to social services and support groups. Introduce parents to other families undergoing hematopoietic stem cell transplantation. (See Chapter 23 for discussion of hematopoietic stem cell transplantation.)

Evaluation

The success of nursing care for the child with SCID is measured by outcomes such as the following:

- The child is free of infection.
- The child has adequate nutritional status as determined by normal growth patterns.
- The child's skin remains intact.
- The family adapts to and copes with the demands of a chronic illness.
- The child performs developmentally within normal level for age.

Wiskott-Aldrich Syndrome

A combined congenital immunodeficiency syndrome, Wiskott-Aldrich syndrome (WAS) is an X-linked disorder that causes mutation in the *WAS* gene and changes in the WAS protein. The gene resides on Xp11.22–11.23 (Buckley, 2016c). The incidence is 1 in 250,000 live male births (Schwartz & Siperstein, 2013). The IgM levels are low, IgG levels are normal or slightly low, and IgA and IgE levels are elevated (Buckley, 2016c).

The diagnosis is made in the early neonatal period on the basis of the thrombocytopenia, which leads to bleeding as evidenced by petechiae, hematuria, bloody diarrhea, and hematemesis. In addition to thrombocytopenia and related symptoms, Wiskott-Aldrich syndrome is characterized by eczema and recurrent infections in infancy and childhood. Infections including otitis media, bacterial pneumonia, and skin infections are common (Albert, Notarangelo, & Ochs, 2011; Schwartz & Siperstein, 2013).

Treatment is supportive and includes antibiotic prophylaxis, platelet transfusions, and intravenous gamma globulin (IVIG). Splenectomy may reduce the risk of bleeding; however, this is done sparingly because of the risk of life-threatening infection following the procedure. The treatment of choice and the only cure for Wiskott-Aldrich syndrome is hematopoietic stem cell transplantation (HSCT). Following HSCT, the child is at risk for both rejection and graft-versus- host disease (Albert et al., 2011; Schwartz & Siperstein, 2013).

Nursing Management

Nursing care is similar to that for the child with SCID. Refer the parents for genetic counseling to help them understand the disease transmission and the probability of having another child with the same disorder. Arrange for psychologic support for parents overwhelmed with guilt from learning that the illness is inherited.

Help the parents and family cope with the knowledge that the child has a chronic and potentially fatal illness (see Chapters 12 and 13). Referral to family counseling may be appropriate. Expected outcomes are the child's return to normal immunologic function, absence of hemorrhage, and successful coping with a life-threatening illness.

Human Immunodeficiency Virus and Acquired Immune Deficiency Syndrome

Acquired immune deficiency syndrome (AIDS) is caused by the human immunodeficiency virus (HIV-1 primarily; HIV-2 less commonly) (American Academy of Pediatrics [AAP], 2015, p. 453). Because HIV destroys the body's ability to fight infection, opportunistic infections that would normally not affect healthy people destroy the immune system. AIDS is the advanced stages of HIV infection.

Most cases of HIV in children are the result of perinatal transmission. The Centers for Disease Control and Prevention (CDC) (2014a) estimates that 162 infants were born with HIV infection in the United States in 2010. The incidence of perinatally acquired HIV infection in the United States has declined by an estimated 90% since the early 1990s. This improvement is primarily due to more effective identification and treatment of mothers who are infected with HIV (CDC, 2014a). The leading cause of newly acquired HIV infection in teens is unprotected sexual intercourse, while intravenous substance use is responsible for most other cases. In many cases, both of these factors are involved.

ETIOLOGY AND PATHOPHYSIOLOGY

Children can acquire HIV in a form of **vertical transmission** from their mothers transplacentally or during delivery. Transmission can occur during birth from blood, amniotic fluid, and exposure to genital tract secretions, and after birth through breast milk from HIV-infected mothers. However, risk for perinatal transmission has been significantly reduced since mothers identified as being infected receive antiretroviral therapy (ART) during pregnancy, undergo a cesarean section, and are advised not to breastfeed (CDC, 2014a). If the mother is not treated during pregnancy, labor, or delivery, there is a 25% chance that the newborn will be infected (U.S. Department of Health and Human Services [USDHHS], 2012). Prenatal testing is essential for identifying mothers who are HIV positive so that treatment can be started and decrease the infant's chances of acquiring the infection to less than 1% (CDC, 2014a).

The virus affects multiple systems and eventually destroys the ability of the child's immune system to respond to infection. An understanding of the natural history of HIV disease is still evolving, and there are several important differences in the disease progression and clinical manifestations of pediatric and adult HIV infections.

The virus selectively targets and destroys T cells, thereby decreasing and eventually eliminating cellular immunity. HIV destroys CD4 T cells (helper cells), which are crucial to normal function of the immune system. HIV selectively targets T cells, decreasing cellular immunity, and affecting humoral immunity as well. Thus the untreated child is left unprotected against a myriad of bacterial, viral, fungal, and opportunistic infections, which are ultimately fatal. Every organ system can be affected. (See *Pathophysiology Illustrated: Human Immunodeficiency Virus.*)

CLINICAL MANIFESTATIONS

The neonate is asymptomatic at birth. The time period for the development of opportunistic infections varies; however, the interval from HIV infection to the onset of overt AIDS is shorter in children than in adults. See Table 22–5.

Early clinical signs for children with HIV infection are nonspecific findings, including lymphadenopathy, hepatosplenomegaly, oral candidiasis, failure to thrive and weight loss, delayed development, swelling of the parotid gland, and chronic diarrhea (AAP, 2015, p. 457; Kronman & Smith, 2015). Recurrent bacterial infections, lymphoid interstitial pneumonitis (LIP), and progressive neurologic deterioration are more common in children than adults. *Pneumocystis jiroveci* (formerly known as *P. carinii*) pneumonia is also common and may present early in infancy (Kronman & Smith, 2015).

CLINICAL THERAPY

There is no cure for HIV or AIDS. Care focuses on the prevention of HIV transmission, the detection of the presence of HIV, aggressive therapy to reduce progression to AIDS, and promotion of the infant's or child's growth and development and survival.

Most children with HIV infection are diagnosed early in life. Virologic tests for detection of the virus are monitored in infants born to mothers infected with HIV. Testing is recommended at 14 to 21 days, 1 to 2 months, and 4 to 6 months. The preferred tests are the HIV DNA polymerase chain reaction (PCR) or the HIV RNA assay (viral load). Any positive result is confirmed by retesting. In addition, CD4 cell counts and percentages should be performed at least every 3 to 4 months to evaluate the child's immune status. This monitoring may change to every 6 to 12 months in children and adolescents who are compliant with therapy and have stable CD4 values and clinical status for over

Pathophysiology Illustrated: **Human Immunodeficiency Virus**

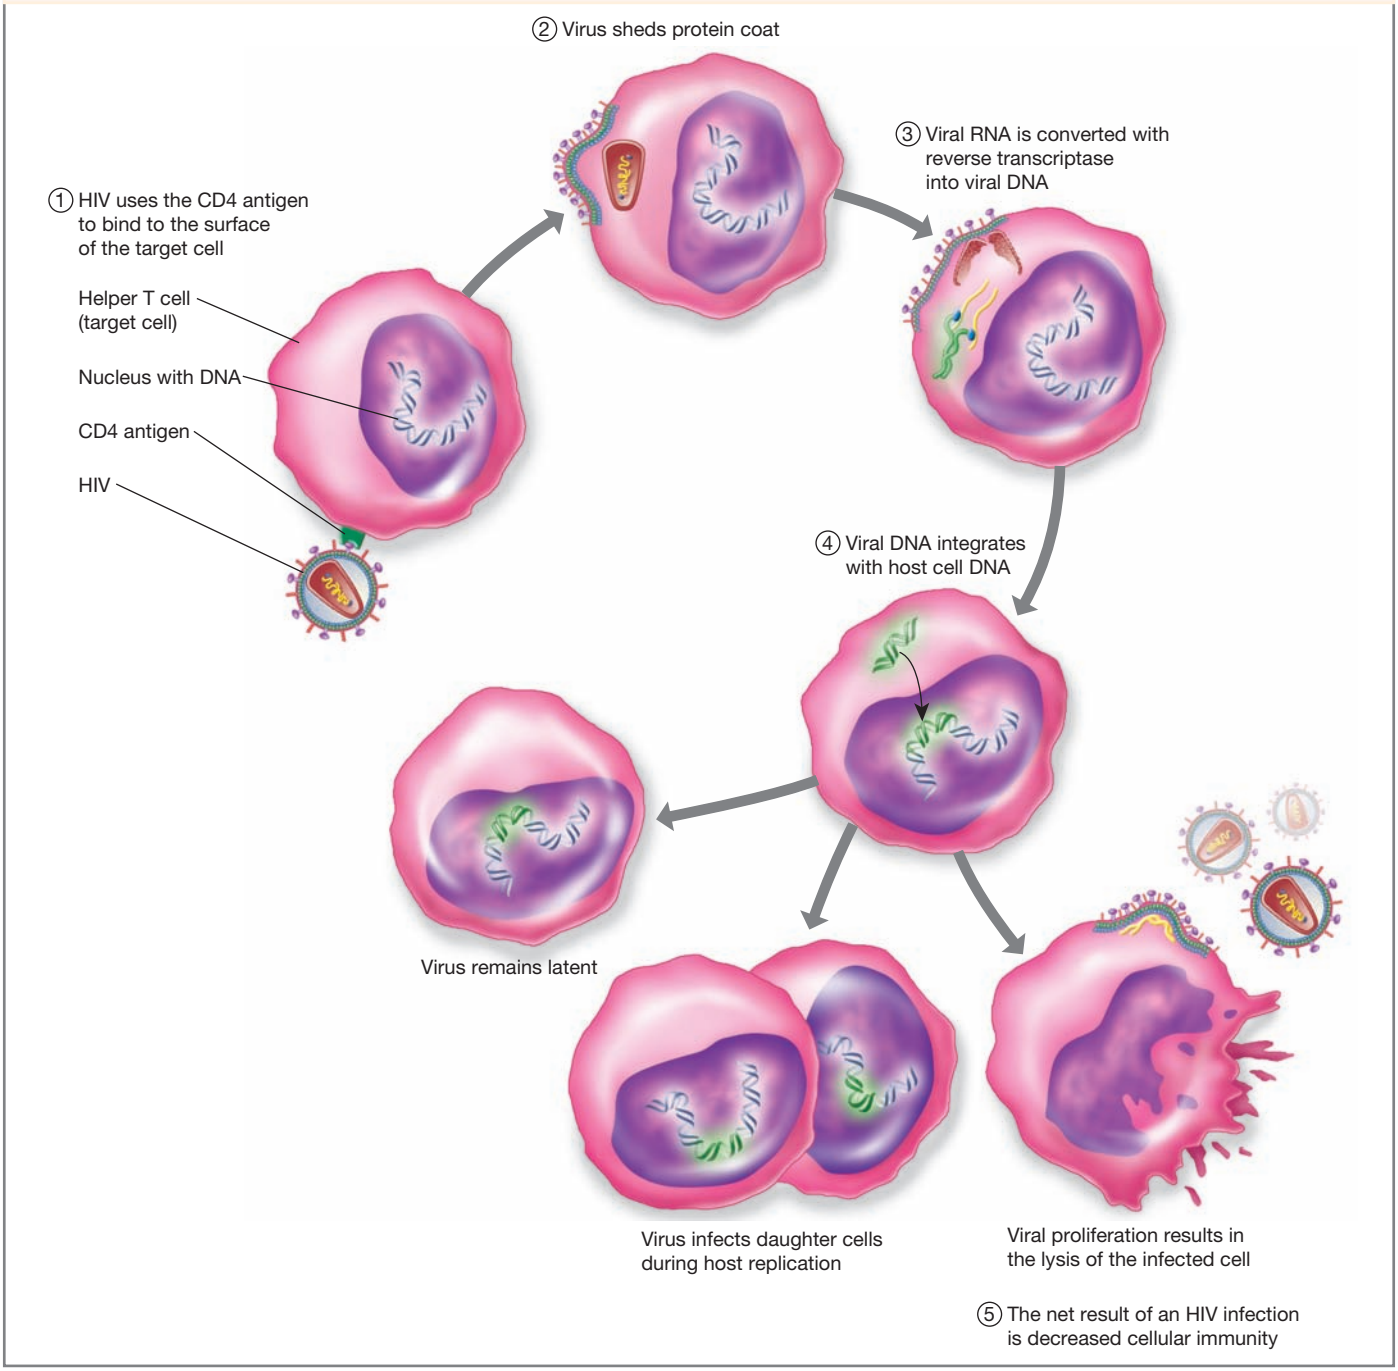


TABLE 22–5 Clinical Manifestations of Human Immunodeficiency Virus in Children

ETIOLOGY	CLINICAL MANIFESTATIONS	CLINICAL THERAPY
Frequent, chronic, or unusual infections due to poor immune response	Chronic bilateral otitis media Oral candidiasis *Pneumocystis jiroveci* pneumonia Skin disorders Fever Parotitis	Antimicrobial therapy for treatment of infections Recommended immunizations Limit exposure to groups of people or to individuals with known infections of any kind
Poor nutritional intake due to lack of appetite caused by disease and medications	Failure to thrive (eating disorder of childhood) Weight and body mass index below 10th percentile Chronic diarrhea Skin irritation	Monitor growth Supplemental intake such as enteral feedings at night, and total parenteral nutrition (TPN) if needed Meticulous skin care to prevent breakdown
Immune system overgrowth to compensate for lack of proper immune response	Hepatosplenomegaly and lymphadenopathy	Assess abdomen frequently Teach about safe transport to avoid injury to liver and spleen

Note: Be alert for the possibility of HIV infection in infants with combinations of listed clinical manifestations, especially in infants known to be at risk.

Source: Data from American Academy of Pediatrics (AAP). (2015). *Red book: 2015 report of the Committee on Infectious Diseases* (30th ed.). Elk Grove Village, IL: Author; Kronman, M. P., & Smith, S. (2015). Infectious diseases. In K. J. Marcdante & R. M. Kliegman, *Nelson essentials of pediatrics* (7th ed., pp. 315–416). Philadelphia, PA: Elsevier Saunders.

2 to 3 years (Panel on Antiretroviral Therapy and Medical Management of HIV-Infected Children, 2014).

Antibody tests are performed in children with no clinical signs or virologic evidence of HIV infection to see if the maternal HIV antibodies have disappeared. A diagnosis of HIV infection is definitively excluded in children with two negative antibody tests at age 6 months or older. Repeat testing is recommended between 12 and 18 months of age in children who have not yet had two negative antibody tests (Panel on Antiretroviral Therapy and Medical Management of HIV-Infected Children, 2014). See Table 22–6.

Medical management begins with prevention of the spread of HIV from mother to newborn. Because of the rapidity of disease progression in perinatally transmitted HIV infection, early identification of infected infants is important to ensure the most effective treatment. Mothers infected with HIV should be identified during pregnancy, and their infants should undergo periodic laboratory testing, as described earlier. All infected mothers should receive zidovudine antiretroviral therapy after the 14th week of pregnancy (AAP, 2015, p. 472). Early identification of mothers infected with HIV and implementation of antiretroviral therapy will lead to a decrease in the numbers of infants and children with HIV infection.

Clinical Tip

Many people who are at risk of HIV infection may not have HIV testing readily available. To reduce barriers to early detection of the virus, rapid HIV tests have been made available. Specimens are obtained from saliva or fingerstick for blood sample. Oral fluids are obtained by gently swabbing both the upper and lower outer gums of the mouth. Results are available in 20 minutes. Follow-up testing is performed to confirm positive rapid HIV tests (CDC, 2014b). Health professionals must be prepared to offer counseling during the same visit as when the test is administered.

All infants of infected mothers with indeterminate HIV infection status should start prophylaxis against *P. jiroveci* pneumonia by the age of 4 to 6 weeks and continue to 1 year of age unless the diagnosis of HIV infection is excluded. Prompt therapy with anti-infectives is used for bacterial and viral opportunistic infections. The need for prophylaxis after 1 year of age is dependent on the child's degree of immunosuppression (AAP, 2015, p. 641).

Treatment for the child diagnosed with HIV involves combination antiretroviral therapy (cART). Initial medication therapy should include a combination of several antiretroviral (AVR) drugs. At least three drugs from a minimum of two different categories should be used. See *Medications Used to Treat: Human Immunodeficiency Virus in Children* for information related to antiretroviral drugs that may be used in children. Families should be advised that these drugs neither cure HIV nor prevent transfer from the person infected to others.

Children on antiretroviral therapy should be monitored closely for side effects and toxicity related to the medications. A complete blood count and blood chemistry along with a clinical history should be evaluated prior to beginning treatment, 4 to 8 weeks later, and then every 3 to 4 months. In addition, CD4 cell counts and HIV RNA levels are recommended at the same time intervals to evaluate compliance with the medication regimen and effectiveness of the treatment. A lipid panel is also recommended prior to initiating treatment and every 6 to 12 months to monitor for signs of elevated cholesterol and triglyceride levels. Additional testing may be recommended depending on the particular drug regimen (Panel on Antiretroviral Therapy and Medical Management of HIV-Infected Children, 2014). With rapid advances in the treatment of HIV infection, HIV is thought of more as a chronic illness as opposed to a terminal disease (Mawn, 2012).

TABLE 22–6 HIV Pediatric Classification System: Clinical Categories

WHEN INFECTED, THE CHILD WITH HIV IS CLASSIFIED AS:

- Category N (not symptomatic)
- Category A (mildly symptomatic)
- Category B (moderately symptomatic)
- Category C (severely symptomatic; multiple, recurrent serious bacterial infections)

Source: Adapted from Panel on Antiretroviral Therapy and Medical Management of HIV-Infected Children. (2014). *Guidelines for the use of antiretroviral agents in pediatric HIV infection*. Retrieved from http://aidsinfo.nih.gov/contentfiles/lvguidelines/pediatricguidelines.pdf

Medications Used to Treat: Human Immunodeficiency Virus in Children

MEDICATION AND ACTION/INDICATION	NURSING IMPLICATIONS
Nucleoside and nucleotide analog reverse transcriptase inhibitors	
Inhibits action of viral reverse transcriptase, an enzyme in the conversion of RNA to DNA. Abacavir Didanosine Emtricitabine Lamivudine Stavudine Tenofovir Zidovudine (AZT)	Common side effects include fever, headache, insomnia, myalgia, nausea, vomiting, diarrhea, anorexia, bone marrow suppression with resulting granulocytopenia and anemia, dyspnea, cough, skin rash. Teach signs and symptoms of infection.
Protease inhibitors	
Blocks the function of the enzyme protease needed for viral formation and growth. Atazanavir Darunavir Fosamprenavir Lopinavir/Ritonavir Nelfinavir Ritonavir Tipranavir	Side effects include CNS, CV changes, life-threatening hematologic changes, respiratory distress, and allergy; monitor for specific side effects of the particular drug administered. Take oral forms within 2 hr of a full meal.
Nonnucleoside reverse transcriptase inhibitors (NNRTIS)	
Binds to viral reverse transcriptase and disrupts the conversion of RNA to DNA. Efavirenz Etravirine Nevirapine	Side effects include fever, headache, nausea, diarrhea, hepatitis, altered liver function, anemia, neutropenia, drowsiness and fatigue, altered mental status, rash, Stevens–Johnson syndrome. Teach the family to notify healthcare provider immediately if rash appears.
Fusion inhibitors	
Prevents viral entry. Enfuvirtide	Requires subcutaneous injection twice a day. There is a high incidence of local reaction at the injection site, limiting the use of this medication in children.
Integrase inhibitors	
Blocks the action of the viral enzyme integrase. Raltegravir	Side effects include rash, nausea, diarrhea, headache, insomnia, fever, and muscle weakness. Give orally without regard to food intake.

Nursing Management

For the Child With HIV Infection

Nursing Assessment and Diagnosis

For infants at risk of HIV infection, obtain the HIV test results of the mother if available. When the mother's results are positive, the infant will need to be screened for HIV infection according to CDC guidelines as described in the previous section. Facilitate the screening and explain its necessity to the family.

PHYSIOLOGIC ASSESSMENT

Assessment centers on observation and evaluation of potential sites of infection. Assess breath sounds, respiratory status, arterial blood gases, level of consciousness, and mental status, and report any abnormal findings. Assess the child's height and weight frequently. Observe for signs of failure to thrive and assess for anemia. Assess for *Candida* infections in the mouth and the diaper area. Note any developmental delays in motor skills or intellectual functioning, which could result from encephalopathy and poor nutrition, and can signal an increasing severity in

symptom level. These findings should be reported immediately so that further medical evaluation can be implemented.

PSYCHOSOCIAL ASSESSMENT

Assess family support systems and coping mechanisms because the stress of caring for a child with HIV infection may overwhelm the parents. Assess the family's ability to care for the child. Inquire about the extended family's ability to provide daily care as well as emotional support. Support the family when they decide to inform a school-age child or adolescent of the diagnosis. When assessing an adolescent with HIV infection, evaluate the teen's understanding of how HIV is transmitted and the response to the diagnosis.

The accompanying *Nursing Care Plan* includes common nursing diagnoses that may apply to a child hospitalized with HIV infection. Other nursing diagnoses may include the following (NANDA-I © 2014):

- ***Diarrhea*** related to gastrointestinal infection, malignancy, or drug reactions
- ***Mucous Membrane: Oral, Impaired,*** related to infection
- ***Development: Delayed, Risk for,*** related to chronic infection and poor nutrition
- ***Coping: Family, Compromised,*** related to life-threatening illness
- ***Caregiver Role Strain*** related to anxiety about child's condition and demands of providing care

Planning and Implementation

The first step in managing HIV infection is prevention. Nurses must be active in instituting measures to prevent vertical transmission of HIV to the infants of infected mothers. Measures advised include adequate testing, prophylaxis for HIV-exposed infants and opportunistic infections, and follow-up visits for evaluation of general health and development for all infants at risk of the disease.

Education related to HIV infection, transmission of the disease, and testing should be a routine part of anticipatory guidance provided to adolescents. Adolescents who are sexually active should be offered HIV testing. Nurses can be instrumental in developing educational programs related to HIV prevention in school settings.

If the child is diagnosed with HIV, close health supervision is needed to ensure that medications are taken and examinations are carried out. When HIV progresses to clinical AIDS, nursing care is similar to that of a child with any serious, chronic, life-threatening disease. Nursing care focuses on preventing infection, managing pain, promoting respiratory and other organ function, promoting adequate nutritional intake, and providing emotional support to the parents and child, while promoting the child's growth and development. The accompanying *Nursing Care Plan* summarizes nursing care for the child hospitalized with AIDS.

PREVENT INFECTION

Immunosuppressed children become infected with bacteria as well as other organisms that are common in the environment. Protect the neonate from HIV-infected maternal secretions. Bathe the newborn as soon as possible after delivery and wash the eyes and face before administering prophylactic eye drops or ointment. Avoid invasive procedures in the newborn and encourage the mother to formula-feed the baby rather than breastfeed.

Proper disposal of needles and contaminated materials or equipment is essential to reduce the transmission of HIV (Figure 22–1). Standard precautions (see the *Clinical Skills Manual* SKILLS) are implemented to prevent exposure to HIV.

Frequent hand hygiene and limiting exposure of the child to individuals with upper respiratory or other infections are the best interventions to protect the child with HIV from acquiring other infections. Vaccines are administered to children with HIV infection following guidelines that have been established (see Chapter 16). Benefits and risks of vaccines are weighed and the child should receive the immunization if appropriate. The live measles-mumps-rubella and the varicella vaccines can be administered to children and adolescents with HIV infection who are asymptomatic and have adequate T-lymphocyte and CD4 values (AAP, 2015, p. 469). See Chapter 16 for further immunization recommendations for the child who is immunocompromised. Educate sexually active adolescents on the importance of practicing safe sex and the ramifications of high-risk sexual behaviors and intravenous drug abuse.

Clinical Tip

Older school-age children and adolescents with HIV should be informed of their diagnosis and counseled appropriately regarding sexual transmission. Telling the child is difficult for parents and they often avoid doing so. Because parents usually want to be the ones to tell the child, they need help to plan how to discuss the issue and ongoing support in the process of communication. Nurses can assist in the following ways:

- Help parents understand the need to discuss the diagnosis with the child.
- Provide information about how to tell the child. Role-play with the parents how to tell the child and use information at the child's developmental understanding to assist parents to be honest.
- Provide sources of hope—the success of treatment, children living with HIV, and maintaining an active life.
- Assist the family to join support groups or web-based groups.
- Help the family plan for respite care as needed.
- Provide emotional support for this difficult task and allow for ongoing opportunities to express concerns, fears, and anxieties.

Figure 22–1 Biohazard disposal. This nurse is disposing of a needle and syringe in a biohazard container, a necessary practice to avoid the transmission of HIV through needlesticks with contaminated needles. Standard precautions provide protection even when the immune status of the patient is not known.

Nursing Care Plan: The Child With Acquired Immunodeficiency Syndrome

1. Nursing Diagnosis: *Infection, Risk for,* related to immunosuppression (NANDA-I © 2014)

GOAL: Risk factors for infection will be reduced as evidenced by absence of signs of infection.

INTERVENTION	RATIONALE
• Assess the child every 2–4 hr for fever; lesions in the mouth; and redness, inflammation, soreness, and lesions on the skin or around intravenous lines.	• Fever is one of the few signs of infection in the immunosuppressed child who does not have a sufficient number of white blood cells.
• Auscultate for changes in breath sounds every 2 hr. Perform pulmonary toilet (coughing, deep breathing, incentive spirometry) every 2–4 hr.	• Pneumonia is a likely infection in the child HIV infection.
• Enforce good hand hygiene. Allow no fresh flowers, fruits, or vegetables in child's room. Screen visitors for colds or recent exposure to varicella. Use blood and body fluid precautions (refer to the *Clinical Skills Manual* SKILLS). Practice strict asepsis for dressing changes and suctioning.	• Control of environmental factors helps prevent infection.
• Coordinate patient care assignments to avoid exposing the child to individuals with recent infections or immunizations.	• Planning minimizes chances for infection.
• Organize patient care activities to allow for adequate periods of rest.	• Rest periods allow the child to regain energy.
• Follow recommendations of CDC and AAP for immunizing immunosuppressed children. Avoid varicella vaccine. Perform annual TB testing.	• Special recommendations consider the child's decreased immune response and the danger of acquiring disease from certain live virus vaccines.

EXPECTED OUTCOME: Child will have no fever and show no other signs of infection.

2. Nursing Diagnosis: *Nutrition, Imbalanced: Less than Body Requirements,* related to loss of appetite and decreased absorption of nutrients (NANDA-I © 2014)

GOAL: The child will demonstrate adequate nutritional status to meet metabolic needs as evidenced by adequate weight gain for age.

INTERVENTION	RATIONALE
• Encourage frequent small meals to promote nutritional and fluid intake.	• Additional nutrition is required to rebuild the immune system.
• Maintain nasogastric tube feeding, if ordered. Total parenteral nutrition may be necessary to ensure adequate nutrition.	• Supplementation may be needed to ensure adequate calories.
• Eliminate unpleasant stimuli and odors from the environment during meals.	• Unpleasant stimuli decrease the desire for food.
• Monitor skin turgor every shift.	• Skin turgor reflects hydration status.
• Weigh daily.	• It is important to monitor weight status.
• Involve a nutritionist in planning a diet for the child that includes favorite foods.	• Including favorite food encourages intake.

EXPECTED OUTCOME: Child will eat frequent meals of adequate nutritional content. Child's weight will stay within normal limits.

3. Nursing Diagnosis: *Skin Integrity, Risk for Impaired,* related to skin infection, immobility, or diarrhea (NANDA-I © 2014)

GOAL: The child will have intact skin.

INTERVENTION	RATIONALE
• Observe all pressure areas closely for signs of infection or breakdown.	• Skin care is important in the immunocompromised child. The skin may be the only intact defense the child has.
• Keep skin clean and dry. Provide perineal care to minimize irritation from diarrhea.	• Prevents breaking or cracking of skin.

EXPECTED OUTCOME: Child will be free of preventable skin breakdown.

4. Nursing Diagnosis: *Knowledge, Deficient (Parent),* related to home care of child with AIDS (NANDA-I © 2014)

GOAL: The parent(s) will demonstrate knowledge about home care including medication regimen, measures to prevent infection, and signs and symptoms to report to healthcare providers.

INTERVENTION	RATIONALE
• Explain the importance of optimizing the child's health status and reducing risk of complications through diet, rest, and meticulous personal hygiene. Be sure that parents and other family members understand how HIV infection is spread and take appropriate precautions.	• Knowledge about the disorder and preventive measures is necessary to provide safe and effective home care for the child.
• Be sure that parents understand the need for adherence to the medication regimen and understand how to administer medications.	• Knowledge of rationale increases compliance.
• Inform the family about signs and symptoms of infection that should be reported promptly to the healthcare provider or nurse (fever, chills, cough, mild erythema).	• Prompt treatment increases outcome.

EXPECTED OUTCOME: Parent will describe appropriate home care and preventive measures for a child with AIDS.

Clinical Tip

Work with the family of the child with HIV infection to establish a plan for medication administration. Assist them to establish a time schedule that limits the administration of several large amounts of medication at the same time. Stress the importance of disguising the taste of bitter medications to increase the child's willingness to take the medication.

PROMOTE MEDICATION REGIMEN ADHERENCE

The treatment regimen with the use of antiretroviral therapies for the child with HIV infection may be complex, time consuming, and costly, presenting an overwhelming challenge to the child and the family. Adherence to the prescribed antiretroviral regimen is imperative as nonadherence will likely result in disease progression (Buchanan et al., 2012). Some common reasons for nonadherence include frequent dosing, restrictions on daily schedules, pill taste, side effects, and dietary restrictions (Malee et al., 2011). Strategies for achieving optimal management of the treatment regimen include educating the parent or childcare provider, and the affected child when doing so is developmentally appropriate, about the purpose of the medication, the benefits of adhering to the regimen, and the potential consequences of failure to adhere to the regimen. Behavior modification techniques, using positive reinforcement, can be very effective in promoting the child's adherence. Provide support to the family, and tailor the medication regimen to the family's routine when possible. Offer praise to the child and parent for adhering to the regimen. If problems exist in managing the treatment regimen, carefully listen to the family to help determine the cause. Collaborate with the family in establishing goals to help meet the prescribed treatment regimen. If further intervention is required, options include direct observational therapy or home visits. Consider the effect of cultural beliefs on medication adherence (see *Developing Cultural Competence: HIV/AIDS and African Americans* and *Evidence-Based Practice: Adolescents With HIV Infection and Medication Regimen Adherence*).

Developing Cultural Competence HIV/AIDS and African Americans

HIV affects African Americans more than any other racial/ethnic group. The incidence of HIV in African Americans is 8 times greater than that of Whites. According to 2010 data, African Americans accounted for approximately 44% of new HIV infections in adults and children over 13 years of age. The CDC has implemented programs focusing on maximizing the effectiveness of HIV prevention methods (CDC, 2015). It is essential that efforts are focused on high-risk populations so that they receive education regarding prevention, testing, and resources.

PROMOTE RESPIRATORY FUNCTION

Because many children with HIV infection develop pneumonia, encourage the child to cough and deep breathe every 2 to 4 hours. In the community, regular physical activity encourages lung aeration. When in the hospital, blowing cotton balls with a straw, blowing bubbles, or other games may engage the interest of a younger child. Reposition infants frequently so all areas of the lungs can aerate. The plan of care should include rest periods to conserve energy and lower the body's demand for oxygen.

PROMOTE ADEQUATE NUTRITIONAL INTAKE

Because many children with HIV infection fail to thrive, nutrition is an important part of their care. (See Chapter 14 for information to include in a detailed nutritional assessment.) A nutritionist should be involved in planning an appropriate diet for the child that provides necessary calories, protein, and other nutrients. Vitamins may be especially lacking in the diets of infected children. Antioxidants (vitamin A, vitamin E, zinc, and selenium) are known to enhance general immune system function; children should consume these nutrients at recommended levels. It is important, however, to verify that there are no interactions between specific vitamins and the child's prescribed antiretroviral medications. Periodic dietary analysis and teaching are needed. Adequate nutrition is sometimes provided through total parenteral nutrition or through nasogastric or gavage feeding.

Diarrhea resulting from gastrointestinal infection and lactose intolerance is a common finding in children with HIV infection, and it complicates other nutritional disturbances. Alternative formulas may be recommended. Although antidiarrheal medications are not generally used in infants, they may be prescribed for older children. Carefully monitor hydration status, skin turgor, and urine output. Provide careful perineal skin care to prevent infection.

The frequency of *Candida* infections leads to blisters, cracking, and discharge involving the oral mucous membranes. To keep the child's lips and mouth moist, mouth care should be performed every 2 to 4 hours with a non–alcohol-based solution such as normal saline. The child may need a prescription mouthwash.

PROVIDE EMOTIONAL SUPPORT

The family of the child with HIV infection is under emotional stress, and this is compounded if others in the family are infected. The infected teen may see progression of disease in the parent and lose hope. Integrate social services and support groups into the care of the child as soon as the diagnosis is made. Spend time talking with the family to provide them with an opportunity to discuss their fears and feelings. In many parts of the United States, HIV infection still carries a tremendous stigma, and the family may not be able to discuss their feelings outside the healthcare environment. Safeguard the family's wishes about the privacy of the diagnosis.

Clarify any misconceptions the older child with HIV infection may have about transmission of the disease. Routes of transmission and the need for safe sexual practices must be discussed openly and clearly with adolescents. Providing support for adolescents is particularly important because the dependence on family or other caregivers that this chronic and terminal disease brings can make it difficult to meet the

EVIDENCE-BASED PRACTICE | Adolescents With HIV Infection and Medication Regimen Adherence

Clinical Question

What factors are associated with medication adherence in the adolescent with HIV infection?

The Evidence

MacDonell, Naar-King, Huszti, et al. (2013) utilized a cross-sectional multisite sample to examine barriers to antiretroviral medication adherence in behaviorally and perinatally HIV-infected youth. The subjects for the study were 484 youth, ages 12 to 24, who were prescribed medication for HIV. The most common barriers reported were forgetting to take the medication, not feeling like taking the medication, and not wanting to be reminded of their disease. While the top barriers were similar for behaviorally and perinatally infected participants, those infected perinatally reported significantly more barriers. There was a significant correlation in those with perinatally acquired infection between the number of barriers and percentage of doses missed, psychologic distress, and viral load. For those with behaviorally acquired infection, there was a significant correlation between number of barriers and number of doses missed, psychologic distress, and substance use. Forgetting to take the medication was the top barrier listed for the full study sample. Other top barriers included not feeling like it/needing a break, medicine reminded them of the disease, medication made them sick to their stomach/tasted bad, and running out of the prescription.

A qualitative study by Udomkhamsuk, Fongkaew, Grimes, et al. (2014) examined the concerns and needs related to adherence to treatment for HIV infection. Data were collected using participatory activities and interviews with 25 youth ages 14 to 21. Five themes emerged from the interviews: Lack of drug knowledge; boredom, discouragement, and denial; fear of disclosure; not managing medication; and risk taking. Some of the subthemes included not knowing about side effects of antiretroviral therapy (ART), being bored with repeatedly taking medications, feeling discouraged by having an incurable disease, denial, fear of losing friendships, disclosure of their infection, forgetting to carry the medicine with them, not taking medicine on time, lack of negotiation skills, curiosity, and poor safe sex planning skills. The study concluded that lack of full adherence to the ART regimen was related to cognitive and psychosocial factors and that youth with HIV infection lack knowledge related to ART.

Navarra, Neu, Toussi, and colleagues (2014) used a cross-sectional descriptive survey design to evaluate the relationship between functional literacy (the ability to read and write), health literacy (the skill to access and understand health information), beliefs about antiretroviral therapy (ART), media use, and adherence to ART. Fifty youth ages 13 to 24 participated in the study. The instruments used in the study included The Test of Functional Health Literacy in Adults (TOFHLA), the Rapid Estimate of Adult Literacy in Medicine-teen (REALM-teen), the Media Use Questionnaire, and the Beliefs About Medication Scale (BAMS). The BAMS assessed intent regarding oral medication adherence, perceived threat of illness, negative outcome expectancy, and positive outcome expectancy. Data from these instruments were collected during a clinic visit using face-to-face interviews after the investigator asked the youth to recall how many doses of their antiretroviral medication had been missed in the past 3 days. While health literacy was not a predictor of adherence in these subjects, higher positive outcome expectancy scores were associated with increased adherence. Subjects with below-grade level reading were associated with a lower level of adherence. This study indicated the importance of a comprehensive care model that includes assessing both health beliefs and reading skills in HIV-infected youth.

Best Practice

Adherence to antiretroviral therapy is a concern in the adolescent population. Concerns and knowledge related to the disease and the treatment plan should be assessed. It is essential that adolescents have adequate medical care and receive comprehensive education related to the importance of adherence to their medication regimen and the positive effects of adhering to antiretroviral therapy. Regimens that are simple, palatable, and with the fewest side effects possible are important in order to increase adherence (MacDonnell et al., 2013). Measures that increase adolescents' confidence in their ability to comply with the treatment plan should be implemented. Discuss strategies with adolescents that will assist them in remembering to take their medication.

Clinical Reasoning

What barriers does your health center address in its care of children with HIV that may lead to medication nonadherence in the HIV-infected adolescent? What support does the adolescent need to improve medication adherence? What measures can the nurse take to improve medication adherence in the adolescent?

developmental task of independence. Adolescents may benefit from contact with other infected peers.

Clinical Tip

Disclosure of client information is a breach of confidentiality that may subject the nurse to legal action. HIPPA guidelines must always be followed. Disclosure of confidential information occurs whenever a client's condition—for example, a diagnosis of HIV infection—is discussed inappropriately with any third party.

DISCHARGE PLANNING

The diagnosis of HIV infection is surrounded by strong emotions and fears. Be honest and direct. Education is essential. Explain that there is no evidence that casual contact among family members can spread the infection. For the child who has been hospitalized, home care needs should be identified in advance of discharge.

Discuss the family's finances as well as health insurance coverage for the child's care. Assess the family's ability to provide nutritious food, pay for required medications, and to provide a supportive environment. Refer to services as needed to ensure provision of quality care after discharge.

Support groups, home healthcare nursing services, financial assistance, and psychologic counseling are usually needed at some point during the child's illness, and the family should be aware that such services are available. Assist the family with coping mechanisms to deal with feelings of guilt and/or fear about the child's condition.

Clinical Reasoning The Toddler With HIV Infection

Raymond, a 2-year-old child, has had recurrent infections since he was born. After a recent illness with fever, vomiting, and diarrhea, blood tests were done to evaluate his immune function. He was diagnosed with HIV infection and admitted to the hospital for children.

- What physical needs does Raymond have at this time?
- What information does Raymond's family need?
- What can you do to provide emotional support to Raymond's family?

COMMUNITY-BASED NURSING CARE

Much of the care of the child with HIV infection takes place in the community. With the continued success of aggressive therapy, the majority of children infected with HIV can be expected to attend child care and school. Additionally, a substantial number of these children will reach adolescence, and some will reach adulthood. Assess the family and community support systems and provide resources and referrals as needed to help parents provide adequate care for their child and to assist adolescents as they transition to adulthood. Many children with HIV infection are placed in foster homes, and these families need careful instruction to manage this multifaceted illness.

School attendance guidelines recommend unrestricted school attendance and/or childcare center attendance for children with HIV infection. In addition, children should be allowed to participate in all activities to the extent that their health and other recommendations for management of infectious diseases permit (AAP, 2015, pp. 158–159). Contraindications to school attendance include lack of control of body secretions, biting, and open wounds that cannot be covered. CDC guidelines for standard precautions should always be followed in the school, child care, and home settings. The nurse or assigned school personnel may be responsible for providing medicines or other care at school for children infected with HIV.

Assist the family in altering the home environment to provide standard precautions during care. To reduce the likelihood of transmission of HIV, make sure the child and family understand that the virus is transmitted through blood, urine, stool, and other body fluids. Instruct parents to use recommended precautions when handling body fluids. Explain that they should wear gloves when changing diapers; disposing of urine, stool, and emesis; or treating the child's cuts and scrapes. In addition, teach them to wash their hands immediately after contact with blood or other body fluids. To reduce the risk of spread of infectious organisms to the child with HIV, educate family members about the importance of proper hand hygiene. Instruct parents to use a bleach solution for disinfection of objects when necessary and to avoid contact with people with infectious illnesses.

Precautions to guard against foodborne illness are particularly important for the child with HIV infection. Parents also need instruction on correct administration and side effects of any medications the child is taking. Giving a child a complicated combination of drugs can be challenging for all families; therefore, teaching should be tailored to the particular family and should be followed by repeated evaluation of the family's success with medication administration.

SAFETY ALERT!

When a child has been diagnosed with HIV, even common childhood infections are a cause for concern. Conditions such as respiratory infection, fever, chickenpox, or gastrointestinal illness can progress rapidly to a life-threatening stage. Teach families to seek prompt treatment at the first sign of illness.

The parent's close observation and feeling that something is not right should be cause for concern and medical evaluation.

Emphasize the importance of promoting the child's development. Perform frequent developmental screenings. Teach the parents how to support the child in achieving developmental milestones. Encourage contact with other children and adults, provide for appropriate toys, teach parents how to encourage the child's communication, and praise the family for what the child has already accomplished. Children who manifest decreasing achievement of developmental milestones or other neurologic symptoms should be assessed by the primary healthcare provider for HIV-induced encephalopathy. The nurse's record of development will be of great importance in this situation. The child needs regular health maintenance care, such as child health supervision visits, immunizations, and care for any other health conditions.

Evaluation

There are many desired outcomes of care for the child with HIV infection or AIDS. Expected outcomes of nursing care include the following:

- The numbers of cases of pediatric HIV due to vertical transmission from known infected mothers decrease.
- Infectious diseases in children with HIV infection are prevented.
- The child has adequate respiratory function and perfusion.
- The child has adequate nutritional intake to support normal growth patterns and prevent malnutrition.

Families Want to Know

Food Safety

The child with HIV infection is more prone to foodborne disease. Instruct parents to practice the following:

1. Use a separate cutting board for meats, and wash it with hot soapy water after use.
2. Wash all utensils with hot soapy water between any uses.
3. Wash and peel fresh fruits and vegetables. Consider use of canned varieties to limit exposure to microorganisms.
4. Use a disposable cloth or cloth that is washed after each meal to clean dishes. A sponge can harbor microorganisms and should not be used.
5. If well water is the source of drinking water, have it checked for contaminants regularly.
6. Do not allow the child to eat raw or undercooked meats, fish, eggs, or cookie dough. Avoid natural honey.
7. Bleach solution (2 tablespoons liquid chlorine bleach added to 1 quart cold water) is a good low-cost sanitizer for cleaning surfaces in the kitchen.

- The family adequately copes with the stress of a chronic disease.
- The child attends school and is supported in the educational process.

Autoimmune Disorders

In an immune system damaged by pathologic changes, an immune response may occur to some of the body's own proteins, resulting in the production of autoantibodies. These pathologic conditions in which the body directs the immune response against itself—identifying "self" as "nonself"—are called *autoimmune disorders*.

The primary feature of autoimmune disorders is tissue injury caused by a probable immunologic reaction of the host with its own tissues. Structural or functional changes occur as immune cells attack other cells in the body. Autoimmune disorders are grouped into systemic and organ-specific diseases. Systemic diseases, which generally involve more than one organ, include systemic lupus erythematosus and juvenile arthritis, which are discussed in this chapter. Organ-specific diseases, which primarily affect a single organ, include type 1 diabetes (see Chapter 30) and thyroiditis. Immune thrombocytic purpura is an immune disease affecting blood platelets and clotting and is discussed in Chapter 23. Psoriasis is a T-cell–mediated autoimmune disease of the skin and is discussed in Chapter 31.

Systemic Lupus Erythematosus

Systemic lupus erythematosus (SLE) is a chronic inflammatory, autoimmune disease of unknown origin that involves many organ systems (Silverman & Eddy, 2011). Although it is primarily diagnosed in adulthood, approximately 15% to 20% of cases are diagnosed in childhood (Fortuna & Brennan, 2013). SLE affects 1.5 million people in the United States. It is more common among African Americans, Native Americans, Hispanics, and Asians than Whites. More severe disease and higher morbidity and mortality are seen in African Americans with SLE (Mattingly, 2011). SLE is 9 times more common in females than males (Ferenkeh-Koroma, 2012).

ETIOLOGY AND PATHOPHYSIOLOGY

The exact etiology of SLE is unknown. A genetic component is suspected because the disease is often more prevalent in members of the same family. It is believed that in those genetically predisposed, an outside environmental agent causes the body to initiate an abnormal immune system response to its own tissues (Lupus Foundation of America, 2014; Silverman & Eddy, 2011). The body produces autoantibodies and combines with antigens to form immune complexes. These antigen–antibody complexes are deposited in the connective tissue, triggering an inflammatory response. The chronic inflammation then destroys connective tissue. The tissue damage varies according to the organ involvement, although the tissues most likely to be affected are the small blood vessels, glomeruli, joints, spleen, and heart valves. Because many systems can be affected simultaneously, organ damage with subsequent multisystem failure may occur.

CLINICAL MANIFESTATIONS

Manifestations of SLE may be acute, with onset of nephritis, arthritis, or vasculitis, or may be noted as a gradual onset with nonspecific symptoms. Symptoms depend on the organ involved and the amount of tissue damage that has occurred and include fever, fatigue, malaise, and weight loss. Other clinical manifestations include rash, arthritis, and nephritis (Defendi, 2011; Mattingly, 2011). A butterfly rash on the face, consisting of a pink or red rash over the bridge of the nose extending to the cheeks, is a characteristic finding (Ferenkeh-Koroma, 2012) (Figure 22–2). Children with SLE may have anemia, leukopenia, and thrombocytopenia (Mattingly, 2011). Renal disease, the leading cause of morbidity and mortality in children with SLE, is evident at diagnosis in 50% of these children and in 80% to 90% within the

Figure 22–2 **This child displays a "butterfly" rash across the cheeks and bridge of the nose. It is often seen in the child with SLE.**

SOURCE: BSIP/Science Source.

first year of diagnosis. Central nervous system disorders may occur in children with SLE and include headaches, mood disorders, seizure disorders, and cerebrovascular disease (Silverman & Eddy, 2011). See Table 22–7.

Systemic lupus erythematosus is characterized by periods of remission and exacerbation (flares). Flares are triggered by a variety of causes, including sun exposure, an upper respiratory infection or other infection, and stress. The child or family may be able to identify other triggers to flares, such as particular events, activities, or situations.

CLINICAL THERAPY

Blood tests reveal anemia, an elevated blood urea nitrogen (BUN), abnormal plasma proteins, abnormal erythrocyte sedimentation rate (ESR), presence of antinuclear antibodies, and a positive LE (lupus erythematosus) cell reaction, which indicates nonspecific inflammation. The Coombs test is positive. Radiologic examinations include chest radiographs and computed tomography (CT) scans, as well as magnetic resonance imaging (MRI) of affected joints. A 24-hour urine collection and imaging studies, as well as renal biopsies, may be performed to evaluate lupus nephritis. Urinalysis may reveal proteinuria.

The goals of medical management are to create a remission of symptoms and to prevent complications. Corticosteroids, such as prednisone or methylprednisolone, are prescribed to control inflammation. Antimalarial preparations, such as hydroxychloroquine, are used to treat symptoms associated with skin lesions and renal and arthritic problems. Although the exact action of these drugs on SLE is not known, they often permit continued remission with a lowered dose of steroids. Nonsteroidal anti-inflammatory drugs (ibuprofen, naproxen) are used to relieve muscle and joint pain. Immunosuppressant drugs, such as cyclophosphamide, azathioprine, mycophenolate mofetil, cyclosporine, and methotrexate, have been used to help control SLE (Klein-Gitelman, 2013; Mattingly, 2011; Silverman & Eddy, 2011). Patients with SLE who are on corticosteroids or those who have arthritis are at increased risk for osteopenia. Vitamin D_3 and calcium carbonate improve bone health in these patients (Klein-Gitelman, 2013). Diet may be restricted if the child has excessive weight gain or fluid retention from steroids and renal damage. Prognosis depends on the severity of the internal organ involvement. Whereas SLE was once considered a fatal disease, 5-year survival rates for SLE are 92% or as high as 100%, and 10-year survival rates of 85% have been cited (Defendi, 2011). Survival rates decrease to 80% at 15 years after diagnosis (Mattingly, 2011). Kidney failure is managed by hemodialysis or peritoneal dialysis. Renal transplantation has been very successful for treatment of renal failure secondary to lupus nephritis.

TABLE 22–7 Clinical Manifestations of Systemic Lupus Erythematosus

SYSTEM	CLINICAL MANIFESTATIONS
Integumentary	A butterfly rash on the face, consisting of a pink or red rash over the bridge of the nose extending to the cheeks, is a characteristic finding Photosensitivity Alopecia Mouth or nose ulcers
Hematologic	Fatigue Fever Easy bruising Nosebleeds
Musculoskeletal	Joint pain Swollen inflamed joints Myalgias Muscle weakness
Neurologic	Headache Peripheral neuropathy Psychosis Seizures Mood disorder Cognitive disorder Stroke
Pulmonary	Chest Pain Dyspnea Pulmonary hypertension Pulmonary embolism
Cardiac	Arrhythmias Chest pain Friction rub Raynaud phenomenon (fingers turning white and/or blue in the cold)
Renal	Hematuria Hypertension Proteinuria Edema
Gastrointestinal	Abdominal pain (may radiate to the shoulder) Diarrhea

Source: Adapted from Mattingly, E. (2011). Lupus in adolescents. *Advance for NPs & PAs, 2*(4), 27–32; Klein-Gitelman, M. S. (2013). *Pediatric systemic lupus erythematosus*. Retrieved from http://emedicine.medscape.com/article/1008066-overview; Silverman, E., & Eddy, A. (2011). Systemic lupus erythematosus. In J. T. Cassidy, R. E. Petty, R. M. Laxer, & C. B. Lindsley (Eds.), *Textbook of pediatric rheumatology* (6th ed., pp. 315–343). Philadelphia, PA: Elsevier Saunders.

Growth and Development

The side effects of the corticosteroids, immunosuppressants, and antimalarial drugs used in the treatment of children with SLE include hair loss, susceptibility to infection, "moon face," retinal damage, and bone loss. These are significant side effects for the adolescent, who is commonly concerned about appearance. Teens with SLE may need special teaching, guidance, and support. Support groups or Internet chat rooms may be helpful.

Nursing Management

For the Child With SLE

Nursing Assessment and Diagnosis

PHYSIOLOGIC ASSESSMENT

Assess the child's nutritional status, including comparison of prior and current weight for evidence of recent weight loss or weight gain. Assess the skin for rashes, ulcers, photosensitivity, ecchymosis, petechiae, cyanosis, and hair loss. Respiratory assessment includes breath sounds, respiratory rate, and assessing for extra sounds associated with pleural effusion or pleuritis. Cardiovascular assessment includes vital signs as well as assessing heart sounds and for signs of pericarditis or friction rub. Musculoskeletal assessment includes joint pain, joint swelling, joint deformity, pain, weakness, and ability to perform activities of daily living. Assess the neurologic system for changes in affect or cognitive abilities and seizure activity. Palpate the spleen to detect splenomegaly.

PSYCHOSOCIAL ASSESSMENT

Because SLE is a chronic disease that primarily affects adolescents, psychosocial assessment is indicated. Assess family interactions, exploring stressful situations such as divorce or trauma. Treatment-related restrictions associated with medications and changes in appearance such as weight gain, cushingoid appearance, and skin rashes can lead to withdrawal, depression, and risk for suicide. Perform psychosocial assessments periodically as the child grows and adapts to the disorder or faces new developmental challenges with a chronic disease.

Several nursing diagnoses may apply to the child with SLE. These include the following (NANDA-I © 2014):

- ***Skin Integrity, Risk for Impaired,*** related to photosensitivity
- ***Activity Intolerance, Risk for,*** related to joint pain and fatigue
- ***Body Image, Disturbed,*** related to side effects of medications and skin alterations
- ***Infection, Risk for,*** related to immunosuppressive medications
- ***Pain, Acute,*** related to joint inflammation and injury
- ***Health Management, Family, Ineffective,*** related to complexity of therapeutic regimen

Planning and Implementation

The goals of nursing care are to assist the child to manage and cope with a chronic disease, prevent infection, maintain fluid balance, promote adequate nutrition, promote skin integrity, promote rest and comfort, manage side effects of medication, avoid triggers for disease flares, and provide emotional support.

PREVENT INFECTION

Infections are a leading cause of death for those with SLE. Prophylactic antibiotics may be required for dental work and surgical procedures. Instruct the patient and family to inform all healthcare providers of the disease to plan for prophylactic measures. Emphasize the importance of receiving recommended immunizations including pneumococcal, meningococcal, and influenza. Instruct the family on hand hygiene and infection control measures in the home. Warn adolescents about the dangers of tattooing and body piercing because of the risk of infection.

MAINTAIN FLUID BALANCE

Because most children with SLE have renal involvement, nursing care includes maintaining accurate intake and output measurements and frequent evaluation of the child's fluid and electrolyte status and weight.

PROMOTE ADEQUATE NUTRITION

Currently, there are no specific dietary plans for the child with SLE; however, the diet may be restricted according to renal involvement, weight gain, weight loss, or other complications. The child is at risk for weight gain associated with treatment with steroids and a decreased activity level during exacerbations of this disease. A well-balanced, nutritious diet with calcium and vitamin D supplements to support bone density as well as appropriate fluid intake for age should be encouraged.

PROMOTE SKIN INTEGRITY

The presence of ulcers on mucous membranes can cause weakening of the tissues, placing the child at increased risk for infection. Provide instructions on oral care to maintain intact oral mucosa. Encourage the use of good hygienic measures and a mild soap for the skin. Recommend that adolescents limit their use of cosmetics, especially oil-based ones. Reinforce the importance of avoiding sunlight as much as possible and the use of sun protection factor (SPF) of 30 or higher at all times when in the sun. Encourage the child to wear protective clothing to limit exposure to sunlight (see Chapter 31 for discussion of sun exposure). Additionally, avoidance of unprotected fluorescent lighting is recommended since exacerbations of systemic lupus erythematosus have been reported following this type of exposure. Advise adolescents with lupus to avoid the use of tanning beds since these devices produce ultraviolet light and can cause or worsen lupus skin lesions (Lupus Foundation of America, 2014). Provide instructions on oral care to maintain intact oral mucosa. Provide instructions on the care of the head if alopecia occurs.

PROMOTE REST AND COMFORT

The child with SLE experiences fatigue and joint pain, leaving little energy reserve during acute episodes of the disease. Encourage frequent rest periods and a nutritious diet to maximize energy stores. A physical therapist can plan a program to encourage mobility and increase muscle strength. Implement measures such as application of heat to painful areas.

MANAGE SIDE EFFECTS OF MEDICATIONS

Observe for side effects of medications used for treatment, and teach the child and family about these effects. For example, immunosuppressant drugs can reduce the body's resistance to infection, and nonsteroidal anti-inflammatory drugs commonly cause gastric distress and bleeding of the gastrointestinal tract. The antimalarial drug hydroxychloroquine increases the risk of retinopathy and blindness; therefore, eye examinations should be performed every 6 months (Ilowite & Laxer, 2011). Corticosteroid side effects include cushingoid effects, weight gain, and hypertension. Sulfa drugs should be avoided because they increase photosensitivity.

AVOID TRIGGERS FOR DISEASE FLARES

Many children and their parents can recognize the signs of an impending flare and the triggers that precede them. Some of the triggers that might cause a flare include sunlight, stress, illness, and medications. Partner with the parents and child to implement measures to avoid these triggers. Discuss preventive behaviors such as avoiding sun exposure and avoiding stressors. Stress-reducing techniques such as guided imagery, reading, yoga, and quiet games can benefit the child or adolescent and reduce exacerbations of SLE. It may be necessary to discontinue a sport, music lesson, or other activity temporarily to provide a chance for the child to relax each day. Adolescents should be warned that alcohol, smoking, and drugs also pose an increased risk due to the potential to stimulate flares. Female adolescents who are sexually active should avoid birth control pills that contain the hormone estrogen, since the extra estrogen may exacerbate symptoms. Alternative birth control methods should be discussed with the adolescent.

PROVIDE EMOTIONAL SUPPORT

Adolescents may have an altered body image as a result of rash, alopecia, arthritic changes in the joints, and chronic disease. Referral to a lupus support group, social services, or counseling may be helpful. The Lupus Foundation of America can provide information to help parents and children adjust to the disease. Internet support groups are also available for those with SLE.

Evaluation

Successful outcomes of nursing care involve management of this chronic disease. Expected outcomes of nursing care include the following:

- The child has absence of pain.
- The child has absence of infection.
- The child has adequate intake and output levels, with demonstrated fluid and electrolyte balance and renal function.
- The child maintains intact skin.
- The child has a positive body image.

Juvenile Idiopathic Arthritis

Arthritis in children has long been referred to as *juvenile rheumatoid arthritis (JRA)* in the United States. The International League of Associations for Rheumatology now uses the term *juvenile idiopathic arthritis (JIA)* to describe arthritis with an unknown cause in children (Wedderburn & Nistala, 2013).

Juvenile idiopathic arthritis refers to inflammation involving one or more joints, lasting more than 6 weeks, and diagnosed prior to 16 years of age (Wedderburn & Nistala, 2013). This disease results in decreased mobility, swelling, and pain. The peak age of onset for JIA is between 1 and 3 years of age, with the illness occurring twice as often in females as in males (Petty & Cassidy, 2011). Approximately 1 of every 1000 children in the United States has JIA (Stanley & Ward-Smith, 2011).

Juvenile arthritis affects joints and surrounding tissues in addition to potential effects on other organs such as the heart, lungs, liver, and eyes. During the disease's course, the child may experience pain, impaired mobility, and interference with normal growth and development. Children may enter remission or manifest continued symptoms of a chronic disease. Remission may last for months, years, or a lifetime. Rarely, the disease is unresponsive to treatment or the child may suffer lasting impairment such as bone and joint changes. Children with early onset have a better prognosis for complete recovery.

ETIOLOGY AND PATHOPHYSIOLOGY

The cause of JIA is unknown, but it is thought to have an autoimmune basis. Inflammation begins in the joint and leads to pain and swelling (Figure 22–3). Scar tissue eventually develops, resulting in limited range of motion. Altered growth related to early closure of epiphyseal plates, small joint contractures, and synovitis may occur. Although terminology varies among the different classifications, the three major types of juvenile arthritis under the most current classification of JIA are oligoarthritis, polyarthritis, and systemic arthritis (Petty & Cassidy, 2011):

- *Oligoarthritis* involves one to four joints and is the most common type of JIA. Approximately 30% to 60% of children with JIA have oligoarthritis. **Uveitis** (inflammation of the middle layer of the eye) occurs in approximately 17% to 26% of children with oligoarthritis (Hsu, Lee, & Sandborg, 2013).
- *Polyarthritis* involves five or more joints. Rheumatoid factor–negative polyarthritis affects 10% to 30% of children with JIA, while rheumatoid factor–positive polyarthritis affects 5% to 10% of children with JIA. Uveitis occurs in approximately 4% to 25% of children with rheumatoid factor–negative JIA and 0% to 2% of those with rheumatoid factor–positive JIA (Hsu et al., 2013).
- *Systemic arthritis* is characterized by high fever; swollen, painful joints; and rash. Systemic arthritis affects internal organs and joints. Approximately 10% of children with JIA have systemic arthritis (Hsu et al., 2013; Nierengarten & Oski, 2014).

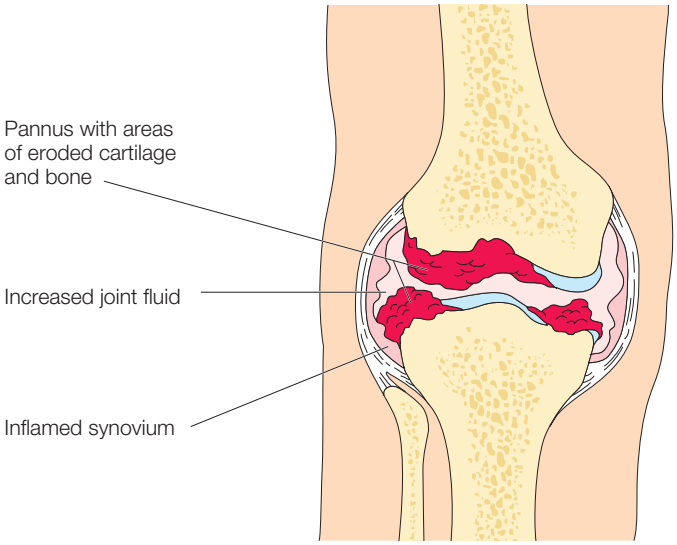

Figure 22–3 **Joint inflammation and destruction in juvenile arthritis.**

CLINICAL MANIFESTATIONS

Juvenile idiopathic arthritis may be restricted to a few joints or be systemic with involvement of multiple joints. Symptoms can include fever, rash, lymphadenopathy, splenomegaly, and hepatomegaly. The child with JIA may develop a limp or obviously favor one extremity over the other. A slow rate of growth or uneven growth of extremities may also be noted. Pain, stiffness, loss of motion, and swelling occur in the large joints such as the knees. Older children may develop symmetric involvement of the small joints of the hand. The disease is frequently chronic, extending over several years after an initial manifestation with pain and other symptoms. Remissions and exacerbations are characteristic.

CLINICAL THERAPY

No specific laboratory tests confirm the diagnosis; however, there are some tests to help support the diagnosis. The child may present with anemia and leukocytosis. Erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) tests may be helpful in determining the amount of inflammation. Rheumatoid factor and antinuclear antibody (ANA) tests may be positive (Petty & Cassidy, 2011). Radiographs are generally performed to exclude other causes, such as fractures, rather than as a definitive diagnosis, although radiographs are useful in monitoring for joint damage and bone development.

The goals of treatment are to relieve pain, control inflammation, preserve joint function, prevent deformities, achieve remission of the disease, minimize side effects of the disease and treatment, and promote normal growth and development (Petty & Cassidy, 2011). Nonsteroidal anti-inflammatory drugs (NSAIDs) such as ibuprofen, naproxen, indomethacin, diclofenac, and meloxicam are used to reduce inflammation and pain. Children who do not respond to NSAIDs may be treated with disease-modifying antirheumatic drugs such as methotrexate. Steroids such as prednisone and methylprednisolone may be used with children with more severe forms of juvenile arthritis. Biologic response modifiers such as etanercept, infliximab, and adalimumab have also been used to treat JIA (Petty & Cassidy, 2011; Stanley & Ward-Smith, 2011).

Complications such as chronic uveitis, which results from chronic inflammation, may occur in children with juvenile arthritis. Children with oligoarthritis and polyarthritis will need

eye examinations either every 3 to 4 months or 4 to 6 months depending on their age and the presence or absence of ANA. Because uveitis is rare in children with systemic arthritis, the recommended frequency for eye examinations is every 12 months (Petty & Rosenbaum, 2011).

Growth interference for the child with JIA is a potential complication. The specific disorder may result in bone growth disturbance such as contractures or effusions. The administration of corticosteroids can also inhibit growth.

Nursing Management

For the Child With JIA

Nursing Assessment and Diagnosis

A careful history is important, as it is sometimes the primary mode of diagnosis. Assess for joint swelling and deformities, pain, decreased mobility, morning stiffness, fever, nodules under the skin, growth delays, and enlarged lymph nodes. The following nursing diagnoses may apply to the child with juvenile arthritis (NANDA-I © 2014):

- ***Activity Intolerance*** related to chronic pain
- ***Mobility: Physical, Impaired,*** related to joint stiffness and inflammation
- ***Pain, Chronic,*** related to joint inflammation
- ***Body Image, Disturbed,*** related to condition and physical appearance

Planning and Implementation

Nursing care focuses on promoting mobility, encouraging adequate nutrition, and teaching the parents and child about the disease and its management. Most care will occur in the community, including physical therapy, with only occasional hospitalizations at the time of an exacerbation of the disease.

PROMOTE IMPROVED MOBILITY

The goals of physical therapy are to maintain joint function, strengthen muscles, increase tone, maintain body alignment, and prevent permanent deformities such as contractures. Range-of-motion exercises, stretching, hydrotherapy, and swimming exercises help to prevent deformities (Figure 22–4). Encourage the child to perform activities of daily living. Exercise may be painful or even difficult for the child, but it is important because it strengthens and stretches the muscles and prevents potential contractures. Emphasize the importance of establishing a regular exercise and activity routine. Encourage periods of rest during exacerbations, as the child fatigues more easily. Medications may be given to reduce joint swelling and inflammation. In addition, warm compresses to the involved joints are soothing.

Figure 22–4 **Passive range-of-motion exercises are an important aspect of physical therapy for a child or adolescent with juvenile idiopathic arthritis.**

PROMOTE ADEQUATE NUTRITION

Promote general health by encouraging a well-balanced diet. Children with decreased mobility may have reduced metabolic needs, and excess weight causes additional muscle strain. Periodically perform diet recalls and nutritional assessments. Plot growth carefully and watch for changes in growth percentiles. (See Chapter 14 for additional information regarding nutrition assessment.)

COMMUNITY-BASED NURSING CARE

The child with JIA may never, or rarely, be hospitalized. Most care takes place during visits to healthcare offices, clinics, and physical therapy. Educate parents on the child's condition and prognosis, and answer their questions about the child's treatment. The child may need support to adjust to the diagnosis of a chronic illness. Allow the child to express anger and frustration about the diagnosis of arthritis. Allow the opportunity for the child and parents to express feelings regarding the crippling effects of the disease. Social services, a child-life specialist, or a psychologist may be consulted as needed.

Encourage the child to maintain contact with peers and to attend school whenever possible. Explain to the child and parents that overexertion may exacerbate the disease. Inform parents about possible complications of JIA, such as altered growth related to early closure of epiphyseal plates, small joint contractures, and synovitis. Partner with the family and school officials to meet the child's needs.

Professionalism in Practice **Accommodations for Children With JIA**

Section 504 of the Rehabilitation Act of 1973 and the Individuals with Disabilities Education Act (IDEA) protect children with disabilities from discrimination. A formal plan such as an individualized education plan (IEP) should be developed for the child with arthritis that outlines accommodations and modifications that are needed at school (Solomon, 2014). The school nurse can work with the family and school administration to determine the plan. Accommodations at school may include providing a set of books for the home so that the child is not required to carry the books home daily. Additional time may be required for the child to move from class to class. The school nurse can refer parents and children to the Arthritis Foundation and the American Juvenile Arthritis Organization for further information and support. The adolescent should also be referred for vocational counseling and offered support for transition to adult services.

Growth and Development

Children with chronic illnesses such as JIA may develop increased dependence on their parents. It is essential that school-age children maintain as much independence as possible to promote their development of industry. These children should also have some responsibility for their treatment plan. Children with JIA may also need to miss school for periods of time. A plan should be developed so that the child is able to keep up with school assignments. In addition, ongoing contact with peers should be maintained to promote the child's social development.

TABLE 22–8 Characteristic Findings in Children With Allergies

SYSTEM/ORGAN	FINDINGS
Respiratory system	Wheezing, rhinitis (seasonal and perennial), cough, adventitious breath sounds, inspiratory stridor, edema of glottis, nasal congestion or discharge
Gastrointestinal system	Abdominal pain and colic, mouth sores, constipation, diarrhea, bloody stools, geographic tongue, vomiting
Skin	Angioedema, urticaria, eczema, atopic dermatitis, erythema multiforme, purpura, drug and food rashes, contact dermatitis
Nervous system	Headache, tension, fatigue, seizures, tremors, irritability, sleep disorders, decreased concentration
Eye	Conjunctivitis, ciliary spasm, iritis, itching of eyes, tearing
Blood	Thrombocytopenic purpura, hemolytic anemia, leukopenia, agranulocytosis
Musculoskeletal system	Arthralgia, myalgia, torticollis
Genitourinary system	Dysuria, vulvovaginitis, enuresis
Miscellaneous	Anaphylactic shock, serum sickness

Evaluation

Expected outcomes of nursing care for the child with juvenile arthritis include the following:

- The child maintains joint mobility and has absence of joint deformity.
- The child has absence of pain.
- The child has a positive body image.
- The child has absence of infection.
- The parents understand and support the therapeutic process.

Allergic Reactions

For unclear reasons, an increasing number of children are diagnosed with some types of allergy, such as allergic rhinitis and asthma. Why are some children allergic to cats, for instance, while no one else in the family has allergies? To answer this question, the nurse needs a basic understanding of the mechanisms of allergy.

An **allergy** is an abnormal or altered reaction to an antigen. Antigens responsible for clinical manifestations of allergy are called **allergens**. Allergens can be ingested in food or drugs, injected or absorbed through contact with unbroken skin, and inhaled. Food allergies are discussed in Chapter 14. Common allergens in children include:

- Medications (such as penicillin)
- Animal dander
- Dust, mites, and mold
- Plant pollens
- Foods (such as nuts, seafood, or egg white)

An allergic reaction is an antigen–antibody reaction and can manifest itself as anaphylaxis, atopic disease, serum sickness, or contact dermatitis. Therefore, the symptoms can be mild to severe or life threatening, and they can be localized or systemic. Characteristic findings in children with allergies are summarized in Table 22–8.

The **hypersensitivity response**, an overreaction of the immune system, is responsible for allergic reactions. Hypersensitivity reactions have been classified into four types (Table 22–9). Type I hypersensitivity reactions, the most common allergic reactions, occur within seconds or minutes of exposure to the antigen and may progress to anaphylaxis. The release of chemical substances such as histamine is responsible for the signs and symptoms exhibited. The first time a child is exposed to the allergen,

TABLE 22–9 Clinical Manifestations of Types of Hypersensitivity Reactions

TYPE	ETIOLOGY	CLINICAL MANIFESTATIONS	EXAMPLES
Type I: localized or systemic reactions (anaphylaxis)	Antibodies bind to certain cells, causing release of chemical substances such as histamine that produce an inflammatory reaction.	Hypotension, wheezing, spasm of smooth muscle; stridor, wheal, urticaria edema, vomiting, diarrhea	Anaphylaxis Extrinsic asthma
Type II: tissue-specific reactions	Antibodies cause activation of complement system, which leads to tissue damage.	Variable; may include dyspnea or fever	Transfusion reaction ABO incompatibility Hemolytic anemia
Type III: immune-complex reactions	Immune complexes are deposited in tissues, where they activate complement, which results in a generalized inflammatory reaction.	Urticaria, fever, joint pain	Acute glomerulonephritis Serum sickness
Type IV: delayed reactions	Antigens stimulate T cells that release lymphokines, which cause inflammation and tissue damage.	Variable; may include fever, erythema, pruritus, contact dermatitis, blistering	Contact dermatitis Tuberculin skin test Graft-versus-host disease Stevens–Johnson syndrome Allograft rejection

there is no reaction. With every exposure thereafter, however, the allergic child may have a reaction to the allergen.

SAFETY ALERT!

Anaphylaxis is a potentially life-threatening systemic reaction to an allergen that may manifest with itching; localized or generalized hives on the hands, feet, or mucosa; soft-tissue swelling; cough; dyspnea; pallor; sweating; and tachycardia. Symptoms can occur within minutes or up to 2 hours after exposure to an allergy-causing substance. The annual incidence of anaphylactic reactions in children ages 0 to 19 years in the United States is approximately 70 per 100,000 (Sampson, Wang, & Sicherer, 2016).

Type II sensitivity reactions occur within 15 to 30 minutes after exposure to the antigen. Type III hypersensitivity reactions may be difficult to distinguish from type II reactions. Hypersensitivity reactions generally peak within 6 hours.

Type IV reactions are delayed responses that do not appear until several hours after exposure and require 24 to 72 hours to fully develop. A type IV reaction, which is not confined to any specific tissue, is elicited by relatively complex antigens such as those of bacteria and viruses and by simple antigens such as drugs and metals.

Assessment of the child with an allergy includes a complete physical examination; laboratory, radiography, and pulmonary function studies; tests of nasal function; and serum and/or skin testing. Treatment generally involves avoidance of the allergen, such as substitution of a different drug when the child has a drug allergy. Desensitization may sometimes be used with increasing doses of the allergen administered subcutaneously in an office where resuscitation is readily available. This treatment is useful for allergy to bees or some pollens. For skin allergies, the allergen is avoided, skin is kept well lubricated, and topical steroids may be used. Oral antihistamines are sometimes used to treat allergy. Emergency medical care may be required to treat anaphylaxis.

Nursing Management

The child with allergies requires a thorough assessment, including a complete past medical history, family history, personal and social history, and review of symptoms. The history focuses on the following areas:

- What symptoms does the child experience? Children should be encouraged to describe the difficulty in their own words.
- Are the symptoms continuous or intermittent? What are the frequency and duration of episodes?
- When did the child first begin to experience symptoms? Did the child have eczema/atopic dermatitis or a feeding problem in infancy or childhood? Did the infant have frequent bouts of colic or skin problems when new foods were introduced? Was there a change in symptoms at puberty? Are the symptoms becoming worse or spontaneously improving?
- What known agents in the environment cause difficulties?
- Are there seasonal variations in symptoms? At what time of the day or night do symptoms usually occur?

The nurse may be responsible for performing intradermal skin tests for allergies (Figure 22–5). Nursing care focuses on treating the symptoms, alleviating the anxiety of the child and parents, and identifying the allergens. Educating the child and family on methods to minimize or avoid exposure to allergens is important.

Figure 22–5 Results of intradermal skin testing on the forearm. Injections are given on each side of the markings. Note the positive results marked by induration and erythema in response to certain antigens.

SOURCE: Southern Illinois University/Science Source.

Teach parents of children who have had severe reactions to bee or wasp stings how to take precautions and how to provide emergency treatment if the child is stung. An EpiPen may be prescribed, and the parents and child will require instructions on its proper use.

Families may need instructions on allergy-proofing the home. Pets, dust, carpets, fabrics, feather pillows and bedding, and cigarette smoke can all cause allergic reactions. If families are reluctant to give up pets, frequent baths can reduce dander, which is the usual allergen. Instruct the family on proper use of epinephrine.

SAFETY ALERT!

If the child has had a severe or systemic reaction in the past to a bee or wasp sting, ensure that the parents know how to handle an anaphylactic reaction if the child is stung again. Kits with syringes of premeasured epinephrine are available by prescription. Instruct family members on how to use the kit. Make sure that the kit is properly stored without exposure to sun or high temperature. Have the family check the expiration date of the epinephrine frequently. The child should wear a medical alert bracelet. A kit should be readily available at school, child care, or other settings, with someone instructed in its use. An allergy specialist should be consulted to determine whether desensitization injections would be helpful for the child.

When the child has type I reactions to an environmental substance, avoidance of the allergen is most critical. In addition, childcare providers, families, and school personnel must be able to treat anaphylaxis if exposure to the allergen occurs. When the child is hospitalized, be sure to label the child's chart and bed and apply a red armband to alert others to allergies. School nurses keep records about children's allergies and inform school personnel about the allergies and cautions that need to be followed. See Chapter 14 for more information about serious reactions to food, such as peanut allergy. Nurses must be aware of the resuscitation procedures and equipment in all facilities such as hospital units, offices, childcare centers, and schools. See Chapter 19 for airway maintenance.

Latex Allergy

Latex is a sap from the rubber tree. It is prevalent in the environment and is a component of many commercial products (Asthma and Allergy Foundation of America, 2014). Latex allergy is caused by an IgE-mediated response that develops after repeated exposure to latex. A reaction to latex products can be manifested as an irritant reaction of the skin; as a type IV delayed hypersensitivity reaction with contact dermatitis; or as a type I hypersensitivity, which is immediate and often has systemic manifestations (itchy eyes, asthma, or anaphylaxis) (Katrancha & Harshberger, 2012; Wade, 2012).

Latex allergy is present in approximately 1% of the general population (Katrancha & Harshberger, 2012). It is more common among certain occupations, including healthcare workers, and in specific types of clients. An estimated 8% to 17% of healthcare workers and up to 68% of children with spina bifida are allergic to latex (American Latex Allergy Association, 2014). In addition, children who have frequent medical procedures or multiple surgeries involving latex are at increased risk of developing allergy to latex (Asthma and Allergy Foundation of America, 2014).

Clinical Tip

In 1998, the U.S. Food and Drug Administration ordered that warning labels be placed on any medical products that contain latex, advising that use of the product might cause an allergic reaction (U.S. Food and Drug Administration, 2014). Check product labels in your healthcare facility for this warning. What products should have a label?

Children and adolescents at high risk should receive allergy testing for latex. When a positive skin test has occurred or when the person has had a reaction to latex, all latex products must be removed from the allergic individual's environment. Alternative products, such as nonlatex gloves and catheters, must be used when providing health care. People allergic to latex should also wear a medical identification bracelet at all times and should have an epinephrine kit readily available at home and school. Nurses should be alert for any signs of hypersensitivity when the child is receiving health care, and be prepared with drugs and equipment to treat anaphylaxis. This is especially important in operative settings when acute anaphylaxis is often life threatening. Nurses should emphasize to parents and children that many everyday products contain latex, including latex balloons and condoms (Table 22–10).

TABLE 22–10 Latex Sources in the Home and Community

• Art supplies	• Diapers
• Balloons	• Feeding nipples
• Koosh balls	• Handles on racquets, tools, and bikes
• Tennis balls	• Kitchen cleaning gloves
• Gym mats	• Pacifiers
• Chewing gum	• Paints and sealants
• Sneakers	• Condoms
• Sandals	• Rubber bands
• Toothbrushes	• Water toys and equipment

Clinical Tip

Healthcare personnel are at high risk of developing latex allergy because of intense exposure to products containing latex. Nurses can protect themselves by using the following measures:

- Decrease exposure by using alternative products whenever available (use synthetic rubbers, polyethylene, nitrile, neoprene, vinyl gloves).
- Use powder-free gloves if using latex gloves (the powder has high amounts of latex, which are inhaled).
- Avoid oil-based hand creams and lotions before putting on latex gloves, as these preparations break down the latex.
- When symptoms of sensitivity to latex occur on exposure (rash, hives, nasal congestion, conjunctivitis, cough, or wheeze), contact the employee health department of your facility.
- If diagnosed as latex allergic, avoid all contact and wear a medical identification bracelet.

Graft-Versus-Host Disease

Graft-versus-host disease can occur when organs are transplanted or when bone marrow or stem cells are transfused into a recipient, typically as treatment for leukemia or severe combined immunodeficiency disease. The donated cells attach to the recipient child's bone marrow and begin production. The child's

Families Want to Know

Removing Common Allergens From the Home

Preventing exposure to the known allergens in the home setting is important. Families can take several measures to minimize contact with allergens. These include:

- Keep pets out of the child's bedroom.
- Clean frequently with moist cloths and mops to remove dust.
- Use plastic covers on mattresses and pillows.
- Avoid using carpeting whenever possible; hard-surface floors are preferable.
- Avoid toys that collect dust (plastic and wood toys are better alternatives than stuffed fabric toys).
- Use high-efficiency air filters.
- Repair homes to prevent entry of water and subsequent molds.
- Consider dehumidification in moist climates, especially in the child's bedroom.

lymphocyte production increases and an immune response develops. However, despite blood and tissue typing, sometimes the donor cells are incompatible with the recipient cells and the new cells begin to mount an immunologic response in the child who has received the transplant. The incidence of the disease is lower in matched siblings than in matched nonsibling transplants (Velardi & Locatelli, 2016).

Graft-versus-host disease may be either acute or chronic. Acute disease has generally been thought of as occurring during the first 100 days after transplant, while chronic disease has been labeled as occurring 100 days posttransplant. In acute disease, the skin, liver, and upper and lower gastrointestinal tract are affected. Symptoms include a pruritic or painful rash, diarrhea, and abdominal pain. The diarrhea may be voluminous and lead to fluid and electrolyte imbalance. Liver enzymes and bilirubin are also elevated (Mandanas, 2014).

Chronic graft-versus-host disease is similar to an autoimmune reaction in the recipient's body and affects multiple systems, including skin, oral cavity, eyes, gastrointestinal tract, liver, lungs, and joints. Specific symptoms may include but are not limited to a rash, mouth sores, diarrhea, anorexia, nausea, vomiting, shortness of breath, chronic cough, itching, muscle weakness, and photophobia (Liu & Hockenberry, 2011).

Careful physical examination and laboratory tests assist in determining the presence of the disease and stage of reaction. Early identification is key to beginning therapy and stopping progression of this life-threatening condition. Several drugs have been used in treatment of graft-versus-host disease and include cyclosporine, tacrolimus, and prednisone or methylprednisolone. Topical corticosteroids such as triamcinolone 0.1% may be used for skin involvement (Mandanas, 2014).

Nursing care focuses on careful physical assessment of all children who have received transplants to assist in early identification of the disease process. All body systems can be involved, especially in chronic disease, so frequent and thorough assessments are needed. Place particular emphasis on skin examination and report rashes that occur. Monitor gastrointestinal functioning by asking about nausea, vomiting, diarrhea, abdominal pain, bloody stools, and dietary intake. Weigh and measure the child and compare to earlier findings. Auscultate the lungs and be alert for signs of infection. Inquire about pain in joints or other body parts. Perform regular eye examinations and ask about burning or itching of eyes. Perform prescribed blood tests to monitor for liver and bone marrow function.

Nursing care for the child who has had a bone marrow or stem cell transplant is complex. Emphasize the need for regular examinations to identify any signs of disease. Children and their families need information and support about this immune system complication of transplantation of bone marrow or stem cells.

Chapter Highlights

- The immune system recognizes any foreign substances within the body and eliminates them as efficiently as possible.
- The immune system is composed of antibodies, leukocytes (white blood cells), and lymphoid tissue.
- The infant is born with natural immunity from the mother and develops acquired immunity gradually in the first 6 years of life.
- Acquired immunity is humoral (antibody mediated) and cell mediated.
- B cells, T cells, natural killer (NK) cells, and complement proteins are the major components of a healthy immune system.
- Disorders of the immune system can have genetic causes (primary immunodeficiency) or they can be acquired (secondary immunodeficiency).
- Severe combined immunodeficiency disease (SCID) is life threatening and requires careful medical and nursing management.
- Human immunodeficiency virus (HIV) can lead to acquired immune deficiency syndrome (AIDS); care focuses on prevention of this viral infection.
- When the child is infected with HIV/AIDS, nursing care centers on preventing infection, promoting adherence to the medication regimen, managing pain, promoting respiratory and other organ function, promoting adequate nutritional intake, and providing emotional support to the parents and child while promoting the child's growth and development.
- Autoimmune disorders such as juvenile idiopathic arthritis and systemic lupus erythematosus occur when the body perceives its own tissue as being foreign and mounts a defense against it.
- Systemic lupus erythematosus (SLE), a generalized disorder mainly occurring in females, is a chronic inflammatory, autoimmune disease of unknown origin that involves many organ systems.
- Juvenile idiopathic arthritis (JIA) is a chronic autoimmune inflammatory disease characterized by joint inflammation resulting in decreased mobility, swelling, and pain. JIA occurs twice as often in females as in males.
- There continues to be a rise in the number of children diagnosed with some types of allergy. A thorough assessment and careful teaching can help the child with allergies to successfully manage reactions.
- Allergy to latex products is commonly seen in children, healthcare workers, and the general population. Children most at risk for latex allergy include those with spina bifida and those undergoing frequent medical procedures or multiple surgeries involving latex.
- Graft-versus-host disease can occur when organs are transplanted or when bone marrow or stem cells are transfused into a recipient.

Clinical Reasoning in Action

You are working at a pediatrician's office when 11-year-old Nirah and his parents come in. The husband, wife, and Nirah have all been infected with the human immunodeficiency virus (HIV). Nirah does not know he is HIV infected, but he has been very compliant with taking his antiretroviral medications. However, he has recently developed a cough and his parents decided to visit the pediatrician's office.

The pediatrician finds that Nirah has a fever of 102.0˚F (38.8˚C), respiratory rate of 60 breaths per minute, no visible retractions during respiration, and a pulse of 120 beats per minute. The healthcare provider decides to admit him to the hospital.

After the laboratory tests and radiographs are completed in the hospital, the healthcare provider tells the family that Nirah has pneumonia and strep throat. Nirah is started on IV antibiotics and shows improvement after 3 days of treatment. You monitor Nirah frequently and have him deep breathe. You also teach the parents how to encourage deep-breathing exercises.

1. How does HIV interfere with normal function of the child's immune system?
2. What are some of the measures of infection control for Nirah while he is hospitalized with HIV?
3. How can you promote Nirah's respiratory function?
4. When children, especially those with an immune system problem, are on antibiotics, they can develop thrush (*Candida* in the mouth). What is the treatment to prevent this side effect?

Chapter 23
Alterations in Hematologic Function

Blend Images/Alamy

Having a child with sickle cell disease is very difficult for us. We know this is a genetic disease, and we feel responsible for Michael's pain. We also never seem to expect the bad times when they come. He'll be doing well and we almost forget . . . then he gets sick or doesn't drink enough and we're in the hospital again. His older sister has started talking about how she worries that sometime she'll have a child with sickle cell disease and we don't know what to tell her.

—Father of Michael, 3 years old

Learning Outcomes

23.1 Describe the function of red blood cells, white blood cells, and platelets.

23.2 Discuss the pathophysiology and clinical manifestations of the major disorders of red blood cells affecting the pediatric population.

23.3 Discuss the pathophysiology and clinical manifestations of the selected disorders of white blood cells affecting the pediatric population.

23.4 Discuss the pathophysiology and clinical manifestations of the major bleeding disorders affecting the pediatric population.

23.5 Plan the nursing management and collaborative care of a child with a hematologic disorder.

23.6 Prioritize nursing interventions for a child receiving hematopoietic stem cell transplantation (HSCT).

The hematologic system is one of a few body systems that regulate, directly or indirectly, all other body functions. Because blood is involved in the function of all tissues and organs, changes in the blood may result in altered functioning of many body organs and structures. This chapter discusses the most common disorders of the blood and blood-forming organs in children. (See Chapter 24 for a discussion of leukemia.)

Anemias

Anemia is defined as a reduction in the number of red blood cells (RBCs), the quantity of hemoglobin, and the volume of packed red cells to below-normal levels. This condition can be caused by loss or destruction of existing RBCs or by an impaired or decreased rate of red cell production. Anemia also can be a clinical manifestation of an underlying disorder, such as lead poisoning or **hypersplenism** (a syndrome characterized by splenomegaly and blood cell deficiencies). Common childhood anemias are discussed in this section.

Iron Deficiency Anemia

Iron deficiency anemia is the most common type of anemia and the most common nutritional deficiency in children. Iron deficiency anemia can occur secondary to blood loss, malabsorption, or poor nutritional intake. See Chapter 14 for a discussion of iron deficiency anemia due to deficits in nutritional intake. Increased physiologic demands (such as rapid growth periods) for blood production can also lead to anemia.

Rapidly growing adolescents whose diets are high in fat and low in vitamins and minerals are particularly susceptible to iron deficiency anemia. Infants who do not consume adequate solid foods after 6 months of age and are fed only breast milk

Text continues on page 592

FOCUS ON:
The Hematologic System

Anatomy and Physiology

Blood has two components: a fluid portion called *plasma* and a cellular portion known as the *formed elements* of the blood. Plasma contains proteins, electrolytes, clotting factors, antibodies, and anticoagulants. The cellular elements are red blood cells or RBCs (erythrocytes), white blood cells or WBCs (leukocytes), and platelets (thrombocytes) (Figure 23–1). Table 23–1 gives normal values for these blood components in children.

Red Blood Cells

Red blood cells, or erythrocytes, are the most abundant of the cellular elements of blood. They are formed through a process called **erythropoiesis**. The primary function of red blood cells is to transport oxygen from the lungs to the tissues. These cells also help carry carbon dioxide from the tissues back to the lungs. Hemoglobin, a red pigment composed of protein and iron, is essential to this function.

Polycythemia is an above-average increase in the number of red cells in the blood. **Anemia** is a reduction in the number of red blood cells; the various types of anemia are discussed in the following main section.

White Blood Cells

White blood cells, or leukocytes, are the mobile units of the body's protective system. They are formed in bone marrow and lymphoid tissue. There are five types of white blood cells, each with a distinct function (Table 23–2).

A differential blood count indicates the percentages of the different types of white cells in the blood and is sometimes useful in identifying the cause of an illness. For example, infections cause an increase in neutrophils, and allergies are related to an increase in eosinophils. The role of lymphocytes is discussed with acquired immunodeficiency syndrome in Chapter 22. A decrease in the number of white blood cells is called **leukopenia**, and can be caused by immune or bone marrow disorders.

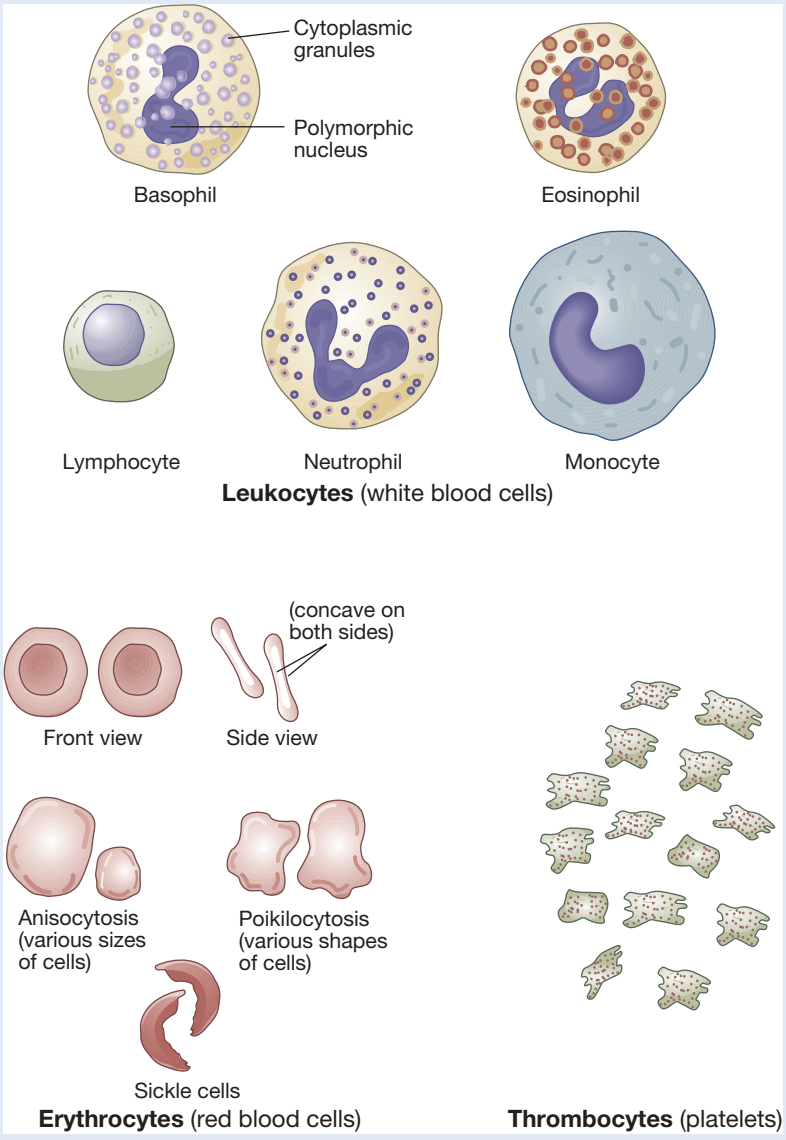

Figure 23–1 Types of blood cells.

Platelets

Platelets, or thrombocytes, are cell fragments that can form hemostatic plugs to stop bleeding. They are synthesized from components in the red bone marrow and are stored in the spleen. A deficiency of platelets can lead to bleeding disorders and is termed **thrombocytopenia**.

Pediatric Differences

Production of red blood cells begins in the embryo by the second week of gestation. White blood cell and platelet production begins at 8 weeks. Most of this early production occurs first in the embryonic yolk sac and then in the liver; however, by 20 to 24 weeks' gestation, liver production decreases as bone marrow production begins to dominate (Christensen & Ohls, 2016). At birth, **hematopoiesis**, or blood cell production, occurs in the marrow of almost every bone. The flat bones, such as the sternum, ribs, pelvic and shoulder girdles, vertebrae, and hips, retain most of their hematopoietic activity throughout life.

At birth, the newborn has a naturally occurring elevation in RBCs due to a high level of erythropoietin, which stimulates red cell production. Once the newborn begins breathing air and the oxygen level in the blood increases, this production slows. Levels of RBCs fall until about 2 to 3 months of age (to about 9 to 11 g/dL) and then begin increasing. Adult levels are reached during adolescence. Male adolescents have RBC levels slightly higher than those of female adolescents (see Appendix D).

The white blood cell count is highest at birth, although levels vary greatly among newborns. Values begin to decline after 12 hours of life and continue to do so during the first week. By 1 week of age, white blood cell values stabilize and remain stable until 1 year of age. After that, the white blood cell count slowly decreases until the adult value is reached in adolescence (Walovich & Newberger, 2016).

TABLE 23–1 Mean Values for Common Hematology Tests in Children

TEST*	MEAN VALUE
Red blood cell (RBC)	3.8–5.03 × 10^{12}/L
Hemoglobin (Hb)	10.2–13.4 g/dL
Hematocrit (Hct)	31.7%–39.8%
White blood cell (WBC)	4.86–11.4 × 10^{9}/L
Platelets	203–367 × 10^{9}/L

*See additional blood values in Appendix D.

TABLE 23–2 White Blood Cells and Their Functions

TYPE	FUNCTION
Neutrophils	Phagocytosis
Eosinophils	Allergic reactions
Basophils	Inflammatory reactions
Monocytes (macrophages)	Phagocytosis, antigen processing
Lymphocytes	Humoral immunity (B cell), cellular immunity (T cell)

TABLE 23–3 Laboratory Tests for the Hematologic System*

- Complete blood count
- Clotting indices (prothrombin time, thrombin time, platelets, reticulocyte count)
- Fetal hemoglobin level
- Hemoglobin electrophoresis
- Iron indices (ferritin, iron, iron-binding capacity)
- Red blood cell indices (mean corpuscular volume [MCV], mean corpuscular hemoglobin [MCH], mean corpuscular hemoglobin concentration [MCHC])
- White blood cell differential

*See Appendix D for information about these laboratory tests.

Platelet levels in newborns are lower than in older children and adults. Levels of many clotting factors are also lower in newborns (Scott & Raffini, 2016). Vitamin K is required for the synthesis of clotting factors II, VII, IX, and X. For this reason, all newborns receive a prophylactic injection of vitamin K at birth (Greenbaum, 2016).

Table 23–3 provides examples of diagnostic and laboratory tests used to evaluate the hematologic system; see Appendices D and E for more detailed descriptions. Use *Assessment Guide: The Child With a Hematologic Condition* to perform a nursing assessment of this system.

ASSESSMENT GUIDE | The Child With a Hematologic Condition

Assessment Focus	Assessment Guidelines
Family history	• Does a family member have sickle cell disease/trait or other blood disorder? • Does a family member have hemophilia or other inherited clotting alteration?
Growth and development	• Measure height and weight on a regular basis and plot on standardized growth charts. • Perform nutritional assessment to see if child is getting enough calories. • Assess child for attainment of developmental milestones.
Skin	• Assess for pallor, flushing, rashes, and ecchymosis. • Observe for prolonged bleeding/clotting time and easy bruising.
Joints	• Observe for edema, pain, inflammation, and range of motion.
Additional assessments	• Assess pain in various body parts. • Identify frequency of infections. • Assess for history of fatigue and lethargy.

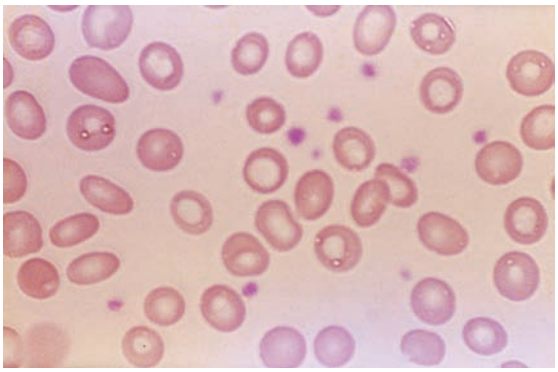

Figure 23–2 **In iron deficiency anemia, red blood cells appear hypochromic as a result of decreased hemoglobin synthesis.**

SOURCE: Biophoto Associates/Science Source.

or formula that is not fortified with iron are also at risk for iron deficiency because neonatal iron stores have been depleted by this time and their iron needs are not being met. In addition, if the mother's nutritional status during pregnancy was inadequate, or the infant was born prematurely or as part of a multiple birth, insufficient iron may have been stored in the latter part of pregnancy, placing the infant at higher risk for anemia in the first months of life.

Chronic blood loss is always a potential cause of iron deficiency anemia. Those at risk of anemia include the infant who has had bleeding in the neonatal period; the child who loses blood as a result of conditions such as Crohn disease, celiac disease, or parasitic gastrointestinal illness; and the female adolescent who has **menorrhagia** (heavy menstrual bleeding).

Clinical manifestations and severity of symptoms are directly related to the amount of iron deficiency or degree of iron deficiency anemia. Infants with mild to moderate anemia may be asymptomatic, while those with severe anemia may present with pallor, fatigue, irritability, poor feeding, tachypnea, and cardiomegaly (Mahoney, 2014). *Pica*, or consumption of nonfood items, is also a symptom of iron deficiency anemia (Harper & Conrad, 2014).

Diagnosis is made on the basis of clinical presentation and laboratory studies. The hemoglobin, hematocrit, mean corpuscular volume, mean corpuscular hemoglobin, red blood cell count, and reticulocyte count are evaluated to confirm the diagnosis (Harper & Conrad, 2014). A hemoglobin value less than 11 g/dL is indicative of anemia. For children with severe anemia, additional recommended testing includes serum iron, serum ferritin, total iron-binding capacity, transferrin saturation levels, and stool testing for occult blood. Microscopic analysis reveals RBCs to be microcytic (small) in size and hypochromic (pale) in appearance (Mahoney, 2014). (See Figure 23–2.) A diet history and analysis can provide information about food intake; see Chapter 14 for guidelines about diet history.

Treatment involves correction of the iron deficiency with oral elemental iron preparations. Ferrous sulfate at a dose of 3 to 6 mg/kg/day is a common treatment, followed by evaluation for its effectiveness (Mahoney, 2014; Powers & Buchanan, 2014). Oral iron preparations cause several side effects such as constipation and gastrointestinal discomfort; therefore, the child may receive iron medications (to restore blood levels of iron) while the iron content of the diet is increased above the recommended dietary allowances (RDAs). Oral iron medications can then be tapered off once the child's food intake can supply the needed iron; the child is evaluated in about 6 months for recurring anemia.

Nursing Management

Children with iron deficiency anemia are usually identified and treated in the community unless they have another serious illness. Nursing care focuses on screening for the disorder and educating the parents and child about the causes of iron deficiency anemia, dietary management, and the importance of complying with the medication regimen.

Screening for iron deficiency is recommended for all children at approximately 12 months of age (Mahoney, 2014; Powers & Buchanan, 2014). Rescreening is needed in children if risk factors are identified (Mahoney, 2014). Frequency of screening for anemia during adolescence should be determined on an individual basis. Male teens should be screened at least once during peak growth spurts. Female teens should be screened at least every 5 years beginning at 13 years of age. Risk assessment for anemia should be performed annually in adolescents. If risk factors are identified, the adolescent is screened more frequently (Abrams, 2014) (see Chapters 6 and 9). A hematocrit or hemoglobin level is obtained for screening. More detailed tests are performed if the blood test is abnormal. Children at high risk for nutritional deficiencies, such as those in low-income groups and WIC programs (Special Supplemental Nutrition Program for Women, Infants, and Children), may require tests earlier. Most children in Head Start are screened annually by nurses. In addition, children showing signs of anemia such as low energy and pallor should be screened. Height and weight measurements are obtained at each healthcare visit, plotted on growth charts, and compared with percentiles obtained at previous visits. Slow downward trends in percentiles are of concern and require further nutritional analysis (see Chapter 14). Perform developmental screening tests to assess for developmental delays (see Chapter 4).

Dietary management is the preferred long-term treatment for iron deficiency anemia. Teach the child and family to plan for foods that are rich in iron. Include teaching about foods with vitamin C since this vitamin may increase the absorption of iron (Powers & Buchanan, 2014). The infant over 6 months of age should have a diet that includes breast milk or iron-fortified formula and baby cereals with iron fortification. Avoid cow's milk in the first year of life because it can cause bleeding from the gastrointestinal tract, contributing to anemia. If the older infant or toddler consumes large quantities of milk and refuses to eat solid food, restrictions on milk intake may be required. Older infants and toddlers can eat finger foods such as thinly sliced meats. Adolescents can be encouraged to eat foods with high iron content and vitamin C such as hamburgers with a slice of tomato.

Oral iron preparations are given to correct anemia. Instruct the family about side effects such as black stools, constipation, and a foul aftertaste. Emphasize the importance of drinking fluids and eating foods high in dietary fiber to minimize constipation. The medicine should be stored safely to avoid accidental poisoning. Expected outcomes of care are intake of recommended levels of iron and return to normal hematocrit level.

Normocytic Anemia

In normocytic anemia, there is an increase in the destruction of red blood cells or decreased production of red blood cells. This type of anemia may be related to parvovirus B19, Epstein-Barr virus or other infections; bone marrow disorders such as leukemia; renal disease, G6PD (glucose-6-phosphate dehydrogenase) deficiency; inflammatory disorders or several other conditions (Lerner, 2016; Panepinto, Punzalan, & Scott, 2015). Clinical manifestations of normocytic anemia are similar to those seen in iron deficiency anemia, with the possible occurrence of hepatomegaly and splenomegaly as well.

Treatment of normocytic anemia depends on the underlying cause. When the anemia is associated with inflammation or infection, the underlying condition is treated. When hemorrhage is the underlying cause, the source of the bleeding is identified and treated. In acute emergencies, blood products are infused to make up for some of the losses.

Nursing Management

Nursing management of normocytic anemia depends on the cause of the decreased RBCs. Children with inflammatory or infectious diseases require careful assessment and management of medication and other treatment regimens. Administer blood products and other intravenous fluids as ordered to restore blood volume. Use follow-up or home visits to assess hematocrit, hemoglobin, and dietary intake. (Refer to the discussion later in this chapter for management of disseminated intravascular coagulation, to Chapter 25 for management of intestinal infections, and to Chapter 26 for management of hemolytic uremic syndrome.)

Sickle Cell Disease

Sickle cell disease (SCD) is a hereditary **hemoglobinopathy** characterized by the partial or complete replacement of normal hemoglobin with abnormal hemoglobin S (Hgb S) in red blood cells (Table 23–4). This causes occlusion of small blood vessels, ischemia, and damage to affected organs. Sickle cell trait (carrying one gene for the disease) affects approximately 2 million Americans. Approximately 1 in 12 African Americans are carriers of the disease (Maakaron & Taher, 2014). Individuals with sickle cell trait have one sickle cell hemoglobin gene and one normal hemoglobin gene. They are carriers of the disease and generally do not have symptoms, although symptoms have been known to occur when the body is under extreme conditions (Centers for Disease Control and Prevention, 2014).

TABLE 23–4 Types of Sickle Cell Disease

DISORDER	CHARACTERISTICS
Sickle cell anemia (HbSS)	Most common type of sickle cell disease
	RBCs are crescent shaped
	Homozygous condition (child has two sickle hemoglobin genes)
	Child is subject to sickle cell crises
	Average life span is 45 years of age
Sickle C disease (HbSC)	Child inherits one HbS gene and one HbC gene
	RBCs are C shaped
	Anemia is generally milder than in HbSS disease
	Painful crises occur about 50% as often as in HbSS disease
	Average life span is 64 years of age
Sickle beta + thalassemia disease (Hb + Sβ) and sickle beta 0 thalassemia disease (Hb0 Sβ)	Combination of sickle cell trait and thalassemia trait. In sickle cell beta+, there is a reduced amount of hemoglobin A, and the life span is near normal. In sickle cell beta 0, there is no hemoglobin A and the life span is mid-50s.

ETIOLOGY AND PATHOPHYSIOLOGY

Sickle cell disease is an autosomal recessive disorder. If both parents have the trait, with each pregnancy the risk of having a child with the disease is 25%. (See Chapter 3 for a discussion of recessive gene transmission.)

In the most common type of sickle cell disease (HbSS, also referred to as sickle cell anemia), the hemoglobin in the RBC acquires an elongated crescent or sickle shape (Figure 23–3). The sickled cells are rigid and obstruct capillary blood flow. Microscopic obstructions lead to engorgement and tissue ischemia. This local tissue hypoxia causes further sickling and ultimately large infarctions. Organ tissues become damaged by infarctions, leading to scarring and impaired function by 2 to 3 months of age. Levels of fetal hemoglobin decline, leading to splenic impairment (Yawn et al., 2014). Most children with HbSS disease will have functional asplenia by 5 years of age (DeBaun, Frei-Jones, & Vichinsky, 2016). Children with sickle cell disease may suffer from splenic sequestration when blood is trapped in the spleen, a life-threatening complication. Many children must undergo splenectomy in early childhood, leading to severely compromised immunity. Infection rate is high because of impaired immunity. Bacterial infections are the leading cause of death in young children with sickle cell disease.

A stroke occurs in some children with sickle cell disease. Eleven percent of children experience this complication by 20 years of age (Lovett, Sule, & Lopez, 2014). Other complications of sickle cell disease may include acute chest syndrome with pulmonary infiltrate and infection, priapism (sustained and painful penile erection), retinopathy, kidney damage, and gallstone formation (de Montalembert, Ferster, Colombatti, et al., 2011; Meier & Miller, 2012; Tanabe, Dias, & Gorman, 2013).

Sickling may be triggered by fever, hypoxia, emotional stress, or physical stress. Precipitating factors for sickle cell crisis include increased blood viscosity (such as from a low fluid intake or fever) and hypoxia or low oxygen tension. Potential causes of hypoxia or low oxygen tension include high altitudes, poorly pressurized airplanes, hypoventilation, vasoconstriction when cold, or an emotionally stressful event. Any condition that increases the body's need for oxygen or alters the transport of oxygen (such as infection, trauma, or dehydration) may result in sickle cell crisis.

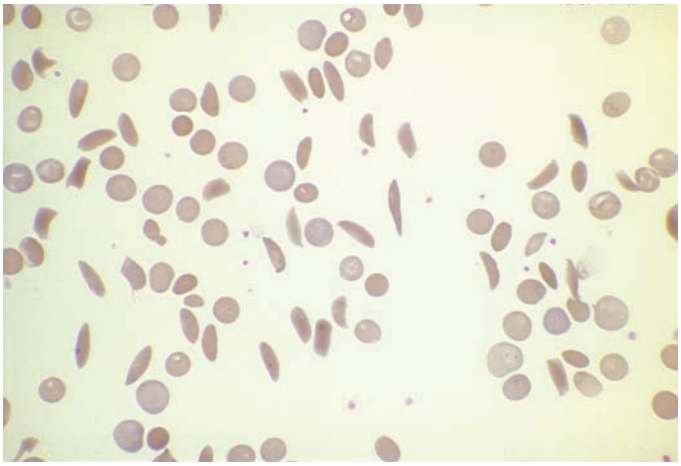

Figure 23–3 Many of these red blood cells show the elongated crescent shape characteristic of sickle cell disease.

SOURCE: Bruce Coleman Inc./Alamy.

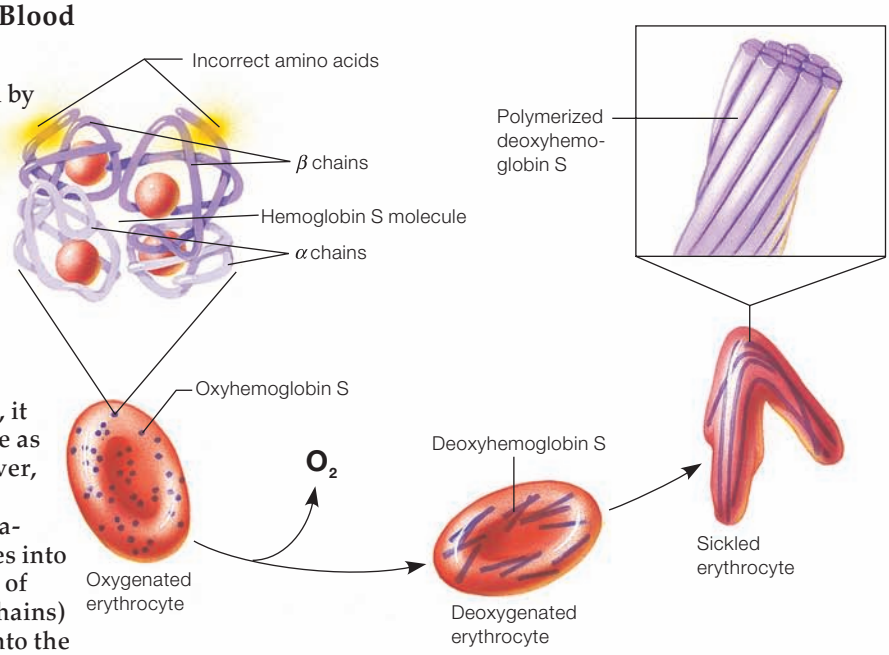
Pathophysiology Illustrated: **Sickle Cell Disease**

The clinical manifestations of sickle cell disease result from pathologic changes to structures and systems throughout the body.

Hemoglobin S and Red Blood Cell Sickling

Sickle cell anemia is caused by an inherited autosomal recessive defect in Hb synthesis. Sickle cell hemoglobin (HbS) differs from normal hemoglobin only in the substitution of the amino acid valine for glutamine in both beta chains of the hemoglobin molecule.

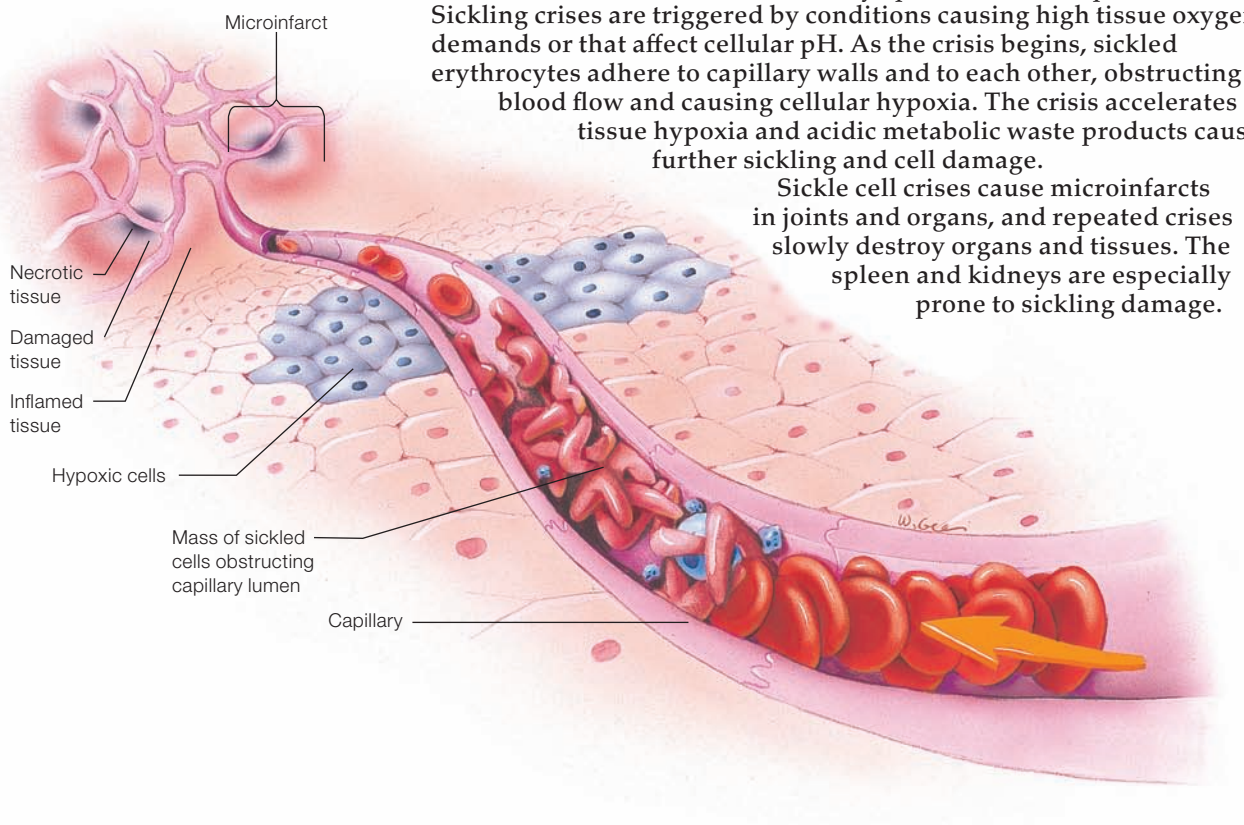
When HbS is oxygenated, it has the same globular shape as normal hemoglobin. However, when HbS loses its oxygen, it becomes insoluble in intracellular fluid and crystallizes into rodlike structures. Clusters of rods form polymers (long chains) that bend the erythrocyte into the characteristic crescent shape of the sickle cell.



The Sickle Cell Disease Process

Sickle cell disease is characterized by episodes of acute painful crises. Sickling crises are triggered by conditions causing high tissue oxygen demands or that affect cellular pH. As the crisis begins, sickled erythrocytes adhere to capillary walls and to each other, obstructing blood flow and causing cellular hypoxia. The crisis accelerates as tissue hypoxia and acidic metabolic waste products cause further sickling and cell damage.

Sickle cell crises cause microinfarcts in joints and organs, and repeated crises slowly destroy organs and tissues. The spleen and kidneys are especially prone to sickling damage.



Sickled cells can resume a normal shape when rehydrated and reoxygenated. However, the membranes of these cells become more fragile, and cell life is shortened to about 10 to 20 days rather than the usual 120 days. Chronic hemolytic anemia develops because of the continued destruction of RBCs (Maakaron & Taher, 2014; Myers & Eckes, 2012). (See *Pathophysiology Illustrated: Sickle Cell Disease*.)

CLINICAL MANIFESTATIONS

Affected children are usually asymptomatic until 4 to 6 months of age because sickling is inhibited by high levels of fetal hemoglobin. Clinical manifestations are directly related to the shortened life span of blood cells (hemolytic anemia) and tissue destruction resulting from **vaso-occlusion** (blockage of a blood vessel). Illness results from recurrent vaso-occlusive events that involve painful crises and chronic organ damage. Pathologic changes happen in most body systems, resulting in multiple signs and symptoms. Examples of common organs affected include the following:

- Brain—stroke, often manifested by headache, aphasia, convulsions, visual changes
- Eyes—retinopathy, retinal detachment, diminished vision
- Bones—chronic ischemia of bones with susceptibility to infection and bone degeneration, manifested by osteoporosis, osteomyelitis, spinal deformities, or aseptic necrosis of the femoral head
- Liver—impaired blood flow from capillary obstruction leads to enlargement and scarring of the liver, manifested by hepatomegaly or cirrhosis
- Spleen—splenic infarct leads to fibrosis and increased rates of infection
- Kidneys—ischemia of kidneys causes enuresis, hematuria, inability to concentrate urine
- Penis—microcirculatory obstruction and engorgement (priapism)
- Extremities—vaso-occlusion and chronic ischemia manifests as peripheral neuropathy, weakness, or arthralgia
- Skin—decreased peripheral circulation causes ulcerations

Sickle cell crises are acute exacerbations of the disease that vary markedly in severity and frequency. Table 23–5 outlines the most common types of crises affecting children with sickle cell disease. The most common reason for a visit to the emergency department for the child with sickle cell disease is acute pain crisis (Shihabuddin & Scarfi, 2014). Additionally, 60% to 80% of hospitalizations for children with SCD are related to pain (Meier & Miller, 2012). The sickled RBCs cannot move through the blood vessels and capillaries. Blood vessel occlusion occurs, leading to restricted blood flow and subsequent tissue ischemia. This is referred to as vaso-occlusive crisis (Myers & Eckes, 2012). Pain results from tissue ischemia. Pain is typically experienced in the back or extremities but can occur in other areas (Lovett et al., 2014). Children with sickle cell disease can also develop acute chest syndrome (ACS), a life-threatening complication of sickle cell disease in which a new pulmonary infiltrate is present on chest radiograph. Symptoms of ACS include fever, chest pain, tachypnea, coughing, and wheezing (Meier & Miller, 2012).

CLINICAL THERAPY

Newborns are screened for sickle cell disease. If the test is positive, hemoglobin electrophoresis should be repeated to confirm the diagnosis (Maakaron & Taher, 2014). (See *Developing Cultural Competence: Sickle Cell Disease*.)

Developing Cultural Competence Sickle Cell Disease

Historically, sickle cell disease has been thought of as occurring only in the African American population. In recent years, the disease has been diagnosed in those of Mediterranean, South American, Arabian, and East Indian descent. All newborns in the United States are screened for sickle cell disease as part of the newborn screening panel (March of Dimes, 2014). While African American families may be familiar with the need for screening, parents of children from other cultures may question this practice. Explain the importance of early diagnosis of sickle cell disease and reinforce the fact that heritage cannot be predicted from appearance or name alone.

TABLE 23–5 Types of Sickle Cell Crises

TYPE	CAUSE/PRECIPITATING EVENTS	CLINICAL MANIFESTATIONS	SEVERITY
Vaso-occlusive crisis (pain crisis); most common type of crisis.	Stasis of blood with clumping of cells in the microcirculation, ischemia, and infarction Precipitated by: • Dehydration • Temperature extremes • Infection • Localized hypoxemia • Physical or emotional stress	Extremely painful Symptoms include: • Fever • Tissue engorgement • Painful swelling of joints in hands and feet • Priapism • Severe abdominal pain	Thrombosis and infarction of local tissue may occur if the crisis is not reversed. Cerebral occlusion can result in stroke, manifested by paralysis and/or other central nervous system complications.
Splenic sequestration	Pooling of blood in the spleen	Profound anemia, hypovolemia, and shock	Life-threatening crisis—death can occur within hours.
Aplastic crisis	Triggered by infection with parvovirus B19 or depletion of folic acid	Diminished production and increased destruction of red blood cells Signs include profound anemia, pallor	Is life threatening.

Source: Data from Lovett, P. B., Sule, H. P., & Lopez, B. L. (2014). Sickle cell disease in the emergency department. *Emergency Medicine Clinics of North America*, *32*(3), 629–647; Maakaron. J. E., & Taher, A. T. (2014). *Sickle cell anemia*. Retrieved from http://emedicine.medscape.com/article/205926-overview; Meier, E. R., & Miller, J. L. (2012). Sickle cell disease in children. *Drugs*, *72*(7), 895–906; Myers, M., & Eckes, E. J. (2012). A novel approach to pain management in persons with sickle cell disease. *MEDSURG Nursing*, *21*(5), 293–298.

Management focuses on pain control, hydration, oxygenation, prevention of infection, and prevention of associated complications. Treatment of crises involves aggressive hydration, oxygen administration, pain management, and bed rest to reduce energy expenditure. Parenteral analgesics, such as morphine and hydromorphone (Dilaudid), are generally administered around the clock or via patient-controlled analgesia. In addition to parenteral narcotics, the child may also receive intravenous ketorolac (Toradol) or oral ibuprofen (Motrin) every 6 hours around the clock as adjunctive therapy. Oral and intravenous fluid replacement also promotes pain relief since dehydration is often a cause of crisis. Fluids also reduce the viscosity of the blood, so adequate hydration is essential. Oxygen is usually administered to provide comfort and decrease the incidence of pulmonary complications.

Infection in a child with sickle cell disease is a serious condition requiring immediate attention. When an infection is suspected, cultures (blood, urine, and throat) are obtained to identify the source of infection and the offending organism. Aggressive antibiotic therapy is implemented immediately.

Penicillin prophylaxis should be started in the newborn period or as soon as the child is diagnosed and continued until 5 years of age to prevent a potentially life-threatening bacterial infection with the *Streptococcus pneumoniae*. Newborn screening has led to earlier diagnosis and, therefore, earlier initiation of prophylaxis (Yawn et al., 2014). The medication may be continued past 5 years of age if the child has a history of severe pneumococcal sepsis, or if the healthcare provider feels the child is still at high risk for infection caused by *S. pneumoniae* (Sauntharajah & Vichinsky, 2013).

To prevent life-threatening infection in the child with sickle cell disease, it is essential for the child to receive recommended immunizations including the pneumococcal conjugate vaccine, HIB vaccine, hepatitis B vaccine, and influenza vaccine (see Chapter 16). In addition, children with SCD should receive the 23-valent pneumococcal vaccine (Pneumovax) at age 2 and age 5 and every 5 years as an adult (Sauntharajah & Vichinsky, 2013). Children with anatomic or functional asplenia should also receive the meningococcal vaccine beginning at 2 months of age. Specific guidelines are provided by the CDC (Centers for Disease Control and Prevention, 2015). Blood transfusions improve tissue oxygenation, reduce sickling, correct anemia, and temporarily reduce the percentage of HbS (Inati, Khoriaty, & Musallam, 2011).

Annual transcranial Doppler testing is recommended for children with SCD between the ages of 2 and 16 (Maakaron & Taher, 2014). Prophylactic transfusions are recommended for children with abnormal transcranial Doppler testing to prevent or decrease the risk of stroke (Lovett et al., 2014; Maakaron & Taher, 2014). However, frequent transfusions may result in an overload of iron in the body. The iron is stored in tissues and organs (**hemosiderosis**) because the body has no way of excreting it (Lovett et al., 2014). An iron-chelating drug such as deferoxamine (Desferal), which binds excess iron so it can be excreted by the kidneys, is administered. An oral chelator, deferasirox (Exjade), has been used in some patients since approval by the U.S. Food and Drug Administration (FDA) in 2005 and has demonstrated similar efficacy to deferoxamine infusion (Meier & Miller, 2012). Deferasirox could potentially simplify treatment and improve compliance by use of oral administration for patients requiring chelation therapy.

Treatment with hydroxyurea has been helpful in adults, and is being used frequently in children. This medication improves fetal hemoglobin levels and increases total hemoglobin concentration (Strouse & Heeney, 2012). The presence of fetal hemoglobin reduces sickling and subsequently the frequency of painful crisis secondary to vaso-occlusion. Although studies have demonstrated the effectiveness of hydroxyurea in children, the FDA labeling related to indications for the use of this drug refers only to adults, necessitating off-label usage in the pediatric population (Strouse & Heeney, 2012).

Hematopoietic stem cell transplantation (HSCT) is the only known cure for sickle cell disease and has been used in children with severe complications related to SCD. Only a few hundred people with sickle cell disease worldwide have received a stem cell transplant as a cure for sickle cell disease because its use is limited to those children who have a human leukocyte antigen (HLA)–compatible sibling. It is estimated that less than 20% of children with SCD have a sibling who is a match. The survival rate for children with sickle cell disease who have been able to receive a stem cell transplant is 93% to 97% (Meier & Miller, 2012). (See discussion regarding HSCT later in this chapter.)

SAFETY ALERT!

It is important for all health facilities to have current guidelines for transfusion protocols. Become familiar with the policies and procedures where you work. For example, the child's blood type and patient identification need to be checked by two registered nurses before starting the infusion. See the *Clinical Skills Manual* SKILLS for further information on blood transfusions.

Prognosis depends on the severity of the child's disease; children with more frequent exacerbations and hospitalizations have poorer prognosis. Newborn screening has led to early intervention in babies who have SCD (Maakaron & Taher, 2014). Early diagnosis, prophylactic antibiotics, and monthly transfusions for those at risk for stroke have extended life spans in individuals with sickle cell disease, with a median life span of 42 years of age for males and 48 for females (Tanabe et al., 2013). The life span of individuals with sickle cell trait is normal (Sickle Cell Information Center, 2012).

Nursing Management

For the Child With Sickle Cell Disease

Nursing Assessment and Diagnosis

The nurse may be involved in sickle cell gene testing to identify carriers and children who have the disease. Once a child is diagnosed with the disease, a comprehensive physical assessment is essential because sickle cell disease can affect any body system.

Professionalism in Practice **Newborn Screening for SCD**

Newborn screening for sickle cell disease is mandatory in all 50 states (National Newborn Screening and Genetics Resource Center, 2014). Nurses play an important role in educating parents about the importance of newborn screening and about the diagnosis and treatment plan once a diagnosis of sickle cell disease is made.

PHYSIOLOGIC ASSESSMENT

In children who are known to have sickle cell disease, obtain a detailed history from the parents or child about past crises, precipitating events, medical treatment, and home management. Measure the child's height and weight accurately and compare to past measurements since failure to thrive is common. Ask about chronic or acute pain that the child is experiencing. Pain may

occur in nearly any body part, but most commonly manifests as headache, extremity pain, or abdominal discomfort. The ill child with sickle cell disease should receive a careful multisystem assessment. Fever, neurologic changes such as decreased alertness or behavioral changes, and respiratory symptoms are emergency conditions that necessitate prompt treatment. When the child is in crisis, assess pain and note the presence of any signs of inflammation or infection. Carefully monitor the child for signs of shock (see Chapter 21).

Clinical Reasoning **Sickle Cell Disease**

Michael is a 3-year-old African American child with sickle cell disease who is admitted to the hospital with severe abdominal pain. What are the most important nursing assessments and interventions to integrate within Michael's care?

PSYCHOSOCIAL ASSESSMENT

The family of a child with sickle cell disease requires a thorough psychosocial assessment. Ask if other family members have the diagnosis. If the child is newly diagnosed with the disorder, the family needs assistance to deal with feelings related to the serious, life-threatening nature of the disease. Assess parents' understanding of the disease transmission and ask whether genetic counseling has been obtained. Determine whether the family has adequate healthcare coverage to pay for the child's medical expenses and whether the child qualifies for assistance because of the disability associated with the disease. Ask older children about their knowledge of the disease, and explore their feelings related to the management of a chronic condition. When siblings or other family members are carriers, periodic counseling is needed so they can understand implications for dating, marriage, and having children.

Several nursing diagnoses that might apply to the child with sickle cell disease are presented in the accompanying *Nursing Care Plan*. Other nursing diagnoses might include the following (NANDA-I © 2014):

- ***Caregiver Role Strain*** related to illness chronicity
- ***Parenting, Risk for Impaired,*** related to having a child with a physical illness
- ***Development: Delayed, Risk for,*** related to effects of physical disability
- ***Mobility: Physical, Impaired,*** related to pain
- ***Knowledge, Deficient (Child or Parents),*** related to lack of exposure about cause and treatment of sickle cell disease

Planning and Implementation

The accompanying *Nursing Care Plan* summarizes nursing care for the child with sickle cell disease. Nursing management for the child in crisis focuses on increasing tissue perfusion, promoting hydration, controlling pain, preventing infection, ensuring adequate nutrition, preventing complications, and providing emotional support to the child and family.

INCREASE TISSUE PERFUSION

Administer blood transfusions and oxygen as ordered. To prevent hemolysis, the intravenous fluid used before and after a blood transfusion must be saline rather than D_5W. Monitor for transfusion reactions (Table 23–6). Encourage the child to rest. Work with the child and family to avoid emotional stress. Any activities that increase cellular metabolism also result in tissue hypoxia. Schedule caregiving activities and play to allow for optimal rest.

PROMOTE HYDRATION

The child with sickle cell disease is adversely affected by dehydration. Calculate the child's fluid maintenance requirements (minimum daily fluid intake) (see Chapter 18) and monitor the child's oral fluid intake. Administer intravenous fluids as ordered. Adjust oral intake as necessary to keep the child well hydrated.

CONTROL PAIN

Administer prescribed analgesics around the clock during crises. If patient-controlled analgesia is used, be sure that the constant infusions run as ordered and that the parent or child understands the use of the button for dosing when needed (see Chapter 15). Help the child assume a comfortable position. Avoid putting stress on painful joints. See *Evidence-Based Practice: Sickle Cell Disease and Pain Management*.

SAFETY ALERT!

Blood reactions can occur as soon as a blood transfusion begins. Administer the first 20 mL of blood slowly and observe the child carefully for a reaction. Assess the child according to agency policy and promptly report changes in condition. If a reaction occurs, stop the transfusion immediately, call the healthcare provider, monitor vital signs, keep the intravenous line open with normal saline, check for hematuria, and administer medications as ordered.

PREVENT INFECTION

Infection makes the child more susceptible to a crisis, and the crisis, in turn, increases susceptibility to infection. Teach the parents how to administer antibiotics for prophylaxis or treatment of infection. Because infections are particularly virulent in these children, tell parents to get immediate care when the child is ill. Emphasize the importance of immunizations. See the discussion earlier in this chapter and Chapter 16 for further information about recommended and supplemental immunizations.

TABLE 23–6 Clinical Manifestations of Blood Transfusion Reactions

TYPE OF REACTION AND ETIOLOGY	CLINICAL MANIFESTATIONS
Allergic reaction related to immune response to protein in the blood	Urticaria, itching, respiratory distress
Hemolytic reaction related to mismatched blood, history of multiple transfusions, or infusion with a solution containing dextrose or other additives	Fever, chills, hematuria, headache, chest pain; can progress to shock
Febrile or septic related to contamination of blood; may also be caused by idiopathic conditions	Chills, fever, headache, decreased blood pressure, nausea or vomiting, and leg and back pain
Circulatory overload related to infusions of excessive amounts of fluid or too rapid administration	Labored breathing, chest or low back pain, productive cough, rales upon auscultation, distended neck veins, increased central venous pressure

Nursing Care Plan: The Child With Sickle Cell Disease

1. Nursing Diagnosis: *Tissue Perfusion: Peripheral, Ineffective,* related to affinity of hemoglobin for oxygen (NANDA-I © 2014)

GOAL: The child will show few signs and symptoms of tissue hypoxia.

INTERVENTION	RATIONALE
• Instruct child to avoid physical exertion, emotional stress, low-oxygen environments (e.g., airplanes, high altitudes), and known sources of infection.	• Decreased activity and exposure reduce the body's need for oxygen.

EXPECTED OUTCOME: Child will have no shortness of breath and shows no signs of hypoxia.

GOAL: Repeated stroke will be avoided.

INTERVENTION	RATIONALE
• Administer blood transfusions as ordered.	• Packed cells increase number of red blood cells available to carry oxygen to tissue cells. Transfusions promote circulation.
• Perform several caregiving activities together whenever possible.	• Grouping activities allows for optimum rest.
• Give oxygen as ordered.	• A high concentration of oxygen in alveoli increases diffusion of gas across membranes.
• Administer and teach the family about prophylactic transfusions for the child who has had a stroke.	• Lowers potential for a future stroke.

EXPECTED OUTCOME: Child does not suffer a stroke.

2. Nursing Diagnosis: *Fluid Volume: Deficient, Risk for,* related to inadequate fluid intake and dehydration (NANDA-I © 2014)

GOAL: The child will maintain or be restored to adequate hydration.

INTERVENTION	RATIONALE
• Calculate the child's daily fluid requirements. Monitor the child's usual fluid consumption and make necessary adjustments. Encourage the child to take fluids. Observe for signs of dehydration.	• Optimizing fluid intake ensures that the child gets needed fluid. Dehydration exacerbates crises.
• Record intake and output.	• Early intervention can be effective in minimizing complications from dehydration. Child may need oral or intravenous rehydration therapy.

EXPECTED OUTCOME: Child will show signs of adequate hydration.

3. Nursing Diagnosis: *Pain, Chronic,* related to physical disability and clustering of sickled cells (NANDA-I © 2014)

GOAL: The child will verbalize that pain is controlled.

INTERVENTION	RATIONALE
• Administer analgesics, such as morphine or hydromorphone (Dilaudid), as ordered. Continuous intravenous infusion is used for the duration of a painful crisis.	• Pain of sickle cell crises is excruciating.
• Position carefully.	• Joints and extremities can be extremely painful.

EXPECTED OUTCOME: Child will be pain free or pain control will be significantly improved.

4. Nursing Diagnosis: *Infection, Risk for,* related to chronic disease and splenic malfunction (NANDA-I © 2014)

GOAL: The child will not develop infection.

INTERVENTION	RATIONALE
• Ensure adequate nutrition by providing high-calorie, high-protein diet. Ensure that the child's immunizations are up-to-date and that children less than age 5 years are receiving prophylactic antibiotics. Make sure that parents have a thermometer in the home and know how to use it. Report any signs of infection to a healthcare provider immediately.	• Children with a chronic illness are at greater risk of infection.
• Isolate the child from possible sources of infection. Instruct parents about signs of infection and encourage them to seek prompt health care.	• Restriction of persons with infection decreases the child's contact with infectious agents. Prompt care for infection reduces the chance of sickle cell crisis.

EXPECTED OUTCOME: Child will be free of infection.

EVIDENCE-BASED PRACTICE | Sickle Cell Disease and Pain Management

Clinical Question

What are effective pain management strategies for children with sickle cell disease? How well is pain assessed and managed in children with sickle cell disease?

The Evidence

Severe episodes of sickle cell crisis require visits to the emergency department (ED) and/or hospitalization for pain management. Relief of pain is the primary goal for healthcare providers and is most significant to the child experiencing pain.

Zempsky, Corsi, and McKay (2011) performed a retrospective chart review of 77 patients with sickle cell disease (SCD), ages 3 to 21 years, to evaluate the relationship between pain scores and time to administration of pain medication. Triage pain scores using the visual analog scale (VAS) in the ED for patients with sickle cell disease averaged 7.7, whereas those for patients with long bone fractures averaged 6.7. For every point increase on the VAS for patients with fractures, the time to administration of pain medication decreased by 5.6 minutes. There was no relationship between the pain score for patients with SCD and time to administration of pain medication. This suggests that pain scores are not used initially when making decisions in the ED regarding pain management for individuals with sickle cell disease but are used for patients with other painful conditions.

Ender et al. (2014) evaluated the use of a clinical pathway in the acute management of pain in children with sickle cell disease. Data were collected from 35 patients before the pathway was introduced and from 33 patients after the pathway was introduced. All patients with sickle cell disease older than 6 months of age who presented to the pediatric ED with sickle cell pain were eligible to be included in the study. Patients with SCD with pain from another cause or those in whom a stroke was suspected were excluded from the study. Data collected at triage included time of patient registration and first set of vital signs, patient weight, time of first pain medication administration, type of medication and dosage administered, pain score, and whether or not the child was admitted to the hospital. The pathway included a checklist that provided instructions for triage, monitoring, timing of assessments and interventions, and medication administration. Results of the study showed that after the clinical pathway was introduced, the mean time interval for administration of the first analgesic was reduced from 74 minutes to 42 minutes. The mean time interval for administration of the first opioid was reduced from 94 minutes to 46 minutes. This represented significant improvement in administration of the first analgesic and first opiod and was statistically significant. The mean time interval for pain reassessment showed improvement, with the time reduced from 110 minutes to 72 minutes, but was not statistically significant. The study concluded that use of a clinical pathway can lead to improvement in pain management of patients with SCD.

Dobson and Byrne (2014) evaluated the effects of guided imagery training on school-age children ages 6 to 11 years with a diagnosis of sickle cell disease. Changes in pain perception, use of analgesia, self-efficacy, and imaging ability were described. Twenty children who had been treated in the clinic for at least a year served as the sample for the study. The children completed pain diaries every day for 2 months. Baseline and end-of-treatment imaging ability and self-efficacy were measured. The results of the study showed that training in the use of guided imagery led to reductions in pain intensity, decreased use of analgesics, and a significant increase in self-efficacy. The study concluded that guided imagery is effective in the management of pain related to sickle cell disease.

Best Practice

Children and adolescents with sickle cell disease who present to the ED with a painful episode have high levels of pain. These patients may have been in pain for several days prior to coming to the hospital. They may wait for a period of time before receiving opioid pain medication.

Protocols or clinical pathways should be established to ensure that children and adolescents who present to the ED with a painful episode receive pain medication in a timely

(*continued*)

manner. While in the ED and if hospitalized, pain intensity should be evaluated on a regular basis using an appropriate pain scale and the pain regimen adjusted as needed.

Clinical Reasoning

How will you determine which pain assessment tool is most appropriate to assess pain in children of different ages? How will you determine if the child in sickle cell crisis is obtaining adequate pain relief? (Consult Chapter 15 for ideas.) In addition to analgesics, what are appropriate nonpharmacologic methods that you can use to decrease pain in children with SCD?

ENSURE ADEQUATE NUTRITION

Emphasize the importance of adequate nutrition to promote growth. Encourage the child to eat a high-protein, high-calorie diet. Stress the importance of folic acid and vitamin C as supplements as prescribed. Perform regular growth measurements, and if slow growth is apparent, perform 24-hour recalls and other nutritional assessments.

Growth and Development

To encourage fluid intake in a small child:

- Use a favorite cup or glass.
- Use straws.
- Take advantage of times the child is thirsty, such as on awakening or after play.
- Leave a cup within easy reach of the child.
- Offer frozen juice pops and crushed ice drinks.

PREVENT COMPLICATIONS OF CRISES

Observe the child for signs of increasing anemia, infection, shock, and acute chest syndrome. Assess vital signs frequently and note changes that might be indicative of complications. Maintain ongoing monitoring of the child's neurologic status for evidence of altered cerebral function. Monitor the child's respiratory status for signs of acute chest syndrome. Assess for an enlarged spleen by gentle palpation. Administer blood transfusions and observe the child for any adverse reaction. Assess growth and developmental milestones.

PROVIDE EMOTIONAL SUPPORT

Sickle cell disease is a chronic disease accompanied by life-threatening episodic crises. Family members often need help to deal with their feelings about the diagnosis and its implications. Explore resources in the home and community to see if parents will be able to administer medications and fluids and to provide adequate nutrition. Assess parents' knowledge of signs of infection and of sickle cell crisis and when to seek medical care for the child. Refer the parents for genetic counseling, particularly if they plan to have more children. Encourage adolescents and young adults in the family to receive genetic counseling and testing as well. Referrals to support groups and contact with others with the disease can be helpful.

DISCHARGE PLANNING AND HOME CARE TEACHING

Identify and address home care needs well in advance of discharge. Give parents information about sickle cell disease and the child's treatment. Even parents of a child previously diagnosed with the disorder may benefit from information about the disease process and its management. Explain the basic effect of tissue hypoxia and the effects of sickling on circulation. Assist the family to explore resources in the home and community and determine if parents will be able to administer medications and fluids and to provide adequate nutrition.

Teach parents to look for signs of dehydration, such as dry mucous membranes, weight loss, and a sunken fontanelle in infants. Give specific instructions about how many ounces of liquid the child needs to drink each day. Emphasize that increased fluid intake is needed to replace the fluids lost from overheating or exposure to hot weather. Make sure both the child and family understand the triggers and precipitating factors for sickle cell crises. Encourage them to avoid situations that cause crises. Instruct the child and parents about signs and symptoms of crises that should be reported to their healthcare provider.

When regular blood infusions are used, the resulting iron overload is damaging to body organs. Provide the family with instructions about the treatment for iron overload.

Tell parents that it is important to inform all treating healthcare providers and dentists of the child's medical condition. The child should also wear medical identification (e.g., a medical identification bracelet). Special precautions are necessary when the child undergoes surgery of any kind because hypoxia resulting from anesthesia is a major surgical risk.

Family members need ongoing support to deal with the stress of having a child with a chronic condition. Provide resources, respite care for parents, and information as needed for siblings.

Encourage older children with sickle cell disease to participate in activities with other children between crises but to avoid strenuous physical exertion and contact sports. Play and social interactions that promote learning and development are important.

Evaluation

Expected outcomes of nursing care for the child with sickle cell disease include the following:

- Pain is managed to facilitate comfort level.
- The child maintains an adequate hydration state to prevent cell sickling.
- Side effects of the disease are absent in the respiratory system, central nervous system, and body organs.
- The child maintains a normal immune status and prevents infection.
- The family or child promptly recognizes and treats the complications of the disease.
- The child maintains normal growth and development.
- The nurse provides necessary services and resources for the parents and other family members.
- The family has knowledge of disease and its treatment.

Families Want to Know

Home Care Considerations for the Child With Sickle Cell Disease

- Follow recommended schedules for health promotion visits.
- Keep scheduled appointments with the child's hematologist.
- Be sure the child's immunizations are up-to-date.
- Special testing, such as heart and eye examinations, may be needed periodically to check for sequelae of the disease.
- Follow instructions for antibiotic administration.
- Assess the child's pain and give pain medication as prescribed for acute and chronic pain.
- Ensure that the child gets extra fluids in hot weather, when ill, during physical activity, and during travel. Dehydration can lead to crisis.
- As the child develops, provide information about the disease and encourage self-care.
- Be sure the school personnel understand the child's diagnosis and any care required during school hours.
- Contact your healthcare provider if the child has a high fever, a common illness that lasts more than 1 day, seizures, change in behavior, severe pain, abnormal skin color or breathing pattern, or any other symptoms that concern you.
- Inform all care providers of the child's condition and need for special planning prior to surgery.

Thalassemias

The thalassemias are a group of inherited blood disorders of hemoglobin synthesis characterized by anemia that can be mild or severe. There are three types of beta-thalassemias (β-thalassemias): thalassemia minor, or thalassemia trait (produces mild anemia); thalassemia intermedia (produces moderate anemia and may require transfusions); and thalassemia major, also known as Cooley's anemia (produces anemia requiring transfusion). Clinical manifestations of β-thalassemia are caused by the defective synthesis of hemoglobin, structurally impaired RBCs, and the shortened life span of the RBCs. Symptoms of thalassemia major generally develop during the second 6 months of age and include pallor, jaundice, growth retardation, irritability, hepatomegaly, and splenomegaly (Giardina & Rivella, 2013). In alpha-thalassemia (α-thalassemia), the child may have a one-gene defect (α-thalassemia silent carrier) and generally be symptom free; have a two-gene defect (α-thalassemia trait) and have mild anemia; or have α-thalassemia major, which results in hydrops fetalis. Intrauterine transfusion can increase the survival rate in the fetus with α-thalassemia major. Those who survive will be transfusion dependent. Hematopoietic stem cell transplant is the only cure (DeBaun et al., 2016).

Diagnosis is made by hemoglobin electrophoresis, which reveals a decreased production of one of the globin chains in hemoglobin and an elevated F and A hemoglobin. A complete blood count shows a decreased hemoglobin, hematocrit, and reticulocyte count (DeBaun et al., 2016). Prenatal testing using chorionic villi sampling or amniocentesis can detect the disease in the fetus. Treatment is supportive. The goal of medical management is to maintain normal hemoglobin levels. A chronic transfusion program, in which blood transfusions are administered every 2 to 4 weeks, is the conventional therapy used to treat children with severe disease. Since iron overload is a side effect of this treatment, children may need to receive an iron-chelating drug such as deferoxamine or deferasirox (Exjade). (See previous discussion.) A splenectomy may be required for the child with splenomegaly. Hematopoietic stem cell transplantation (HSCT) may be offered as an alternative therapy for children newly diagnosed with the disorder.

Nursing Management

Nursing care focuses on observing for complications of transfusion therapy, supporting the child and family in dealing with a chronic life-threatening illness, and referring the family for genetic counseling. Encourage parents to take an active role in the child's treatment regimen. Teach parents the technique for subcutaneous infusion of deferoxamine if that route is to be used for therapy at home.

Compliance with transfusion therapy often becomes an issue as children reach adolescence. Offering the adolescent treatment options, such as when to undergo transfusion, can help improve compliance. Adolescents with β-thalassemia and parents of newly diagnosed children can be referred to the Thalassemia Action Group, a national organization for those with this disease, or to the Cooley's Anemia Foundation. Expected outcomes of nursing care include maintenance of normal hemoglobin and hematocrit, safe transfusion of blood products, maintenance of recommended body iron levels, and family understanding about the genetic transmission of the disease.

Hereditary Spherocytosis

Hereditary spherocytosis (HS) is a hemolytic disorder occurring in 1 in 5000 people of Northern European descent. The inheritance pattern of hereditary spherocytosis is most commonly autosomal dominant, but in some cases is autosomal recessive. Additionally, up to 25% of cases have no family history (Segel & Casey, 2016). Erthrocytes assume a spherical shape due to an intrinsic membrane defect. Spectrin deficiency is most common (Gonzalez & Eichner, 2014). The erythrocytes are retained and removed by the spleen, leading to splenomegaly in the child (Hsiao et al., 2013).

Clinical manifestations appear in the neonatal period or during early infancy. Severity of the anemia varies, but mild jaundice is usually evident. Aplastic crisis (discussed in Table 23–5) is the most serious complication the child experiences. Gallstones are a complication associated with hereditary spherocytosis. Complete blood count reveals anemia, and microscopic examination reveals the abnormally shaped cells (Gonzalez & Eichner, 2014).

Treatment of children with hereditary spherocytosis includes daily folic acid and red blood cell transfusions when indicated. Children with mild, uncomplicated disease may be managed without surgery (Gonzalez & Eichner, 2014). Splenectomy is indicated in children with severe disease and in those with moderate disease who show signs of growth failure or significant signs and symptoms of anemia. Removal of the spleen increases the risk of infection and sepsis (Das et al., 2014; Gonzalez & Eichner, 2014). Infants and young children are especially at risk. Delaying the surgery until after age 6 reduces the risk of bacterial infection and sepsis (Gonzalez & Eichner, 2014). Nursing care for the child with hereditary spherocytosis is the same as care for the child with anemia.

Aplastic Anemia

Aplastic anemia is a deficiency in the number of blood cells that results from failure of the bone marrow to produce adequate numbers of all types of circulating blood cells. The condition may be congenital or acquired. Eighty percent of cases of aplastic anemia are acquired, and it is thought to be an autoimmune disease (Bakhshi, 2014).

Acquired aplastic anemia in children can develop after treatment with radiation or after ingestion of drugs such as chloramphenicol, NSAIDS, or anticonvulsants. This type of anemia can also be a result of an infectious process such as viral hepatitis, mononucleosis, or cytomegalovirus; related to nutritional deficiencies in vitamin B_{12} or folic acid; or related to exposure to chemicals such as insecticides and pesticides (Hartung, Olson, & Bessler, 2013).

Symptoms are related to the degree of bone marrow failure and include **petechiae** (small pinpoint red or purple spots on the mucous membranes or skin), **purpura** (irregular bluish purple areas of bleeding into the tissues), menorrhagia in postmenarchal girls, and epistaxis. Symptoms associated with anemia include pallor, fatigue, and exercise intolerance. Symptoms related to neutropenia include fever and bacterial infections (Hartung et al., 2013). Death can result from complications associated with hemorrhage and sepsis.

Diagnosis is made by complete blood count studies, which reveal leukopenia with marked neutropenia, thrombocytopenia, and **pancytopenia** (decreased number of blood cell components), and by bone marrow aspiration, which reveals yellow, fatty bone marrow instead of red bone marrow.

Supportive treatment includes transfusions of packed cells, platelets, or both. Immunosuppressive drug therapy is effective for many children because it is believed the child's immune system is attacking the bone marrow. Immunosuppressive agents generally include antithymocyte globulin (ATG) and cyclosporine. The treatment of choice for children with severe aplastic anemia is hematopoietic stem cell transplantation (HSCT) from an HLA-matched sibling donor (Bakhshi, 2014).

Nursing Management

Nursing interventions focus on preventing bleeding, administering and monitoring blood transfusions, preventing infection, encouraging mobility as tolerated, educating the parents and child about the disorder, and providing emotional support. Families need support in dealing with a child who has a life-threatening disease. Refer them to support groups for counseling, if indicated, and to social services. Expected outcomes of nursing care include absence of infection, no bleeding, and parental education related to the disease and treatment.

Bleeding Disorders

Hemophilia

Hemophilia refers to a group of hereditary bleeding disorders that result from a deficiency in specific clotting factors. Hemophilia A, or classic hemophilia, is caused by a deficiency of factor VIII in the blood and occurs in 1 in 5000 male births (Ozgonenel et al., 2013). Hemophilia B, also known as Christmas disease, is caused by a deficiency of factor IX and occurs in 1 in 25,000–30,000 male births (Zaiden, 2014). Hemophilia A accounts for 85% of persons with hemophilia, and 10% to 15% have hemophilia B (Scott, 2016).

ETIOLOGY AND PATHOPHYSIOLOGY

Hemophilias A and B are X-linked recessive disorders, which manifest almost exclusively as affected males and carrier females. Genes for clotting factors VIII and IX are located near the terminal long arm of the X chromosome (Scott, 2016). A daughter will inherit the gene from her father with hemophilia and may transmit it to her sons. (See Chapter 3 for a description of genetic transmission.) Some children affected by hemophilia do not have a family member with a history of a clotting disorder. In these cases, the disorder is caused by a new mutation. (Scott, 2016). The degree of bleeding is related to the amount of clotting factor and the severity of the injury.

CLINICAL MANIFESTATIONS

Hemophilia is manifested in different children by bleeding tendencies that range from mild to moderate or severe. Children with hemophilia often do not demonstrate symptoms until after 6 months of age as they become more mobile and incur injuries and bleeding from falls.

Spontaneous bleeding, **hemarthrosis** (bleeding into a joint space), and deep tissue hemorrhage occur. Affected children frequently experience bleeding into the joint spaces of the knees, ankles, and elbows. Bleeding into joint spaces causes the child to have limited motion because of pain and swelling. Bone changes and flexion deformities can result from the effects of blood in the joint structures (Rodriguez-Merchan, 2012).

Males may have bleeding after circumcision. Other symptoms include easy bruising (**ecchymosis**), hematuria, and bleeding after tooth extraction, minor trauma, or minor surgical procedures. Subcutaneous, intramuscular hemorrhages and gastrointestinal bleeding can occur. Intracranial bleeding occurs in 10% of patients with severe hemophilia and has a mortality rate of 30%. Females who carry the trait for hemophilia do not usually manifest symptoms of the disease (Zaiden, Furlong, Crouch, et al., 2014).

CLINICAL THERAPY

Diagnosis of affected children and carriers can be done before birth through chorionic villus sampling or amniocentesis. Genetic testing of family members is increasingly being used to identify carriers. Diagnosis can also be made on the basis of the history, physical examination, and laboratory data. Laboratory tests show low levels of factor VIII or IX, and prolonged activated partial thromboplastin time (aPPT). Prothrombin time (PT), thrombin time (TT), fibrinogen, and platelet count are normal.

The goal of medical management is to control bleeding by replacing the missing clotting factor. Desmopressin (DDAVP), an analog of vasopressin, stimulates the release of factor VIII stored in the blood vessels, thereby increasing the percentage of available factor by approximately threefold. DDAVP is effective in

some patients with mild and moderate hemophilia A (Roman, Larson, & Manno, 2013).

Many recombinant factor VIII concentrates are available as replacement therapy for hemophilia A (Zaiden et al., 2014). Factor IX concentrates are also available to treat hemophilia B (Zaiden, 2014). The child with severe hemophilia may be on a prophylactic regimen of replacement therapy, whereas the child with mild to moderate hemophilia may only receive episodic therapy. Prophylaxis decreases bleeding episodes and joint damage that may result from repeated episodes of hemarthrosis (Koerper, 2012). Prompt and adequate treatment is needed to prevent serious bleeding episodes and their sequelae. Gene therapy is being explored for treatment of hemophilia in hopes that an eventual cure will be found (Chuah, Evens, & Vandendriessche, 2013).

Nursing Management

For the Child With Hemophilia

Nursing Assessment and Diagnosis

PHYSIOLOGIC ASSESSMENT

Obtain a complete medical history from the parents or child. In particular, ask about previous episodes of bleeding and the occurrence of hemophilia or any other bleeding disorders in family members. The history of bleeding will vary, depending on the severity of the disease.

Assess the child for any joint pain, swelling, or permanent deformity, particularly around the knees, elbows, ankles, and shoulders. Observe for prolonged bleeding or oozing of blood. Note the presence of hematuria and mild flank pain. Conduct a neurologic assessment because the risk for intracranial hemorrhage and bleeding can lead to peripheral neuropathies.

PSYCHOSOCIAL ASSESSMENT

It is difficult for families to manage care of the child with hemophilia, especially if the disease is severe. Assess the family's coping mechanisms and support systems. Determine the family's ability to manage procedures and treatments; the factor concentrates and infusion equipment are costly. Assess older children's understanding of the disease, limitations, and their adaptation to the disease.

DEVELOPMENTAL ASSESSMENT

Because the child with hemophilia may have physical activity restrictions, physical skills may be delayed. Perform frequent developmental assessments, being particularly attentive to fine and gross motor skills.

The most important nursing diagnosis for the child with hemophilia is ***Injury, Risk for,*** related to bleeding disorder. Some of the other nursing diagnoses that might apply include the following (NANDA-I © 2014):

- ***Pain*** related to bleeding episodes
- ***Mobility: Physical, Impaired,*** related to joint stiffness or contractures
- ***Home Maintenance, Impaired,*** related to challenges of hemophilia
- ***Family Processes, Interrupted,*** related to family role shift required to care for a child with a chronic illness
- ***Development: Delayed, Risk for,*** related to effects of physical disability

Planning and Implementation

Nursing care focuses on preventing and controlling bleeding episodes, limiting joint involvement and managing pain, and providing emotional support. Both short-term interventions and long-term management are necessary.

PREVENT AND CONTROL BLEEDING EPISODES

Bleeding problems are rare in infants with hemophilia. However, as children learn to walk and develop other motor skills they often fall and suffer cuts and bruises. The risk of injury can be reduced by emphasizing to parents the need for close supervision and a safe environment. Parents should encourage children to play with safe, age-appropriate toys.

When the child is hospitalized, use nursing approaches to minimize the possibility of bleeding. Ensure that the hospital environment is safe by orienting the child to the room and keeping the floor and room clear of hazards as much as possible. If significant bleeding does occur, offer supportive measures and assist with factor replacement therapy. Carefully monitor the child's condition for any side effects when factor replacement therapy is administered. Control any superficial bleeding by applying pressure to the area for at least 15 minutes. Immobilize and elevate the affected area, and apply ice packs to promote vasoconstriction.

LIMIT JOINT INVOLVEMENT AND MANAGE PAIN

During bleeding episodes, hemarthrosis is managed by the administration of factor replacement as quickly as possible, elevating and immobilizing the joint and applying ice packs, and administering analgesics for pain. Once bleeding has been controlled, range-of-motion exercises strengthen muscles and joints and prevent flexion contractures. Physical therapy may be needed. Because excessive weight can place added stress on joints, encourage the child to maintain an appropriate weight.

PROVIDE EMOTIONAL SUPPORT

The needs of families with children who have hemophilia are best met through a comprehensive team approach. Refer the parents for genetic counseling as soon as possible after diagnosis. It is important to identify family members who carry the trait because they may suffer excessive bleeding during surgery.

Encourage the parents to verbalize their feelings. Be understanding and sensitive to their needs. Teach the parents about hemophilia and explain how the disorder affects both the child and other family members. Refer the parents and child to organizations such as the National Hemophilia Foundation for further information.

DISCHARGE PLANNING AND HOME CARE TEACHING

The child may be hospitalized briefly during the first manifestation of bleeding for diagnosis and management. Most care will subsequently take place in the home. Home care needs should be identified and addressed well in advance of discharge. Advise parents to have the child wear a medical identification bracelet. Dentists and all other healthcare providers should be aware of the diagnosis.

Explain the cause of bleeding so both the child and parents understand the disease process. Teach the child and family how to identify internal bleeding. Signs and symptoms such as joint pain, abdominal pain, and obvious bleeding are indicators for immediate factor infusion. Make sure the child and parents know what situations could cause bleeding to occur. Teach parents to give acetaminophen instead of aspirin and aspirin-containing products.

Instruct the parents and the child, when appropriate, to prepare and administer factor concentrate. If infusion of the missing factor is scheduled regularly, bleeding episodes can be controlled or avoided. Have the parents demonstrate the procedure and make sure they can administer the product correctly. Ensure that parents know where they can get the factor concentrate.

The child will need an individualized school health plan (see Chapter 12). Members of the school staff should be instructed in management of emergencies. The nurse can identify key staff members in the school and teach them the actions that need to be taken.

Help the family and school in planning an appropriate schedule of activities for the child. Explain how the parents can coordinate their child's care with a number of healthcare professionals. Provide ongoing case management, assisting the family to take on this task if able.

Hemophilia is a debilitating disorder for the child, and it also can be financially draining for the family. Frequent outpatient visits, emergency department visits, hospital admissions, and the cost of factor replacement can exhaust a family's resources. If indicated, refer families to appropriate social services (e.g., the state's maternal and child health program for children with special healthcare needs) and organizations such as the National Hemophilia Foundation. Sharing experiences with other families of children with hemophilia can provide support.

Evaluation

Expected outcomes of nursing care include the following:

- Injury to the child is prevented.
- Pain is managed to promote comfort level.
- The nurse and family promote normal growth and development for the child.
- The child and family have adequate knowledge of disease management, including recognition of bleeding and prompt initiation of infusions.

Clinical Tip

Use the acronym RICE (**r**est, **i**ce, **c**ompression, **e**levation) to help you remember important measures to control a bleeding episode.

Clinical Tip

Take the following precautions when caring for children with bleeding disorders:

- Avoid taking temperatures rectally or giving suppositories.
- Avoid intramuscular injections unless absolutely necessary and only after factor replacement has been given. Children should receive recommended immunizations subcutaneously with firm pressure to the injection site for 5 minutes following the injection.
- Apply firm, continuous pressure to venipuncture sites 5 minutes after any venipuncture procedure.
- Do not give aspirin or aspirin-containing products.

Von Willebrand Disease

Von Willebrand disease is the most common hereditary bleeding disorder. The various subtypes of this disorder are classified based on the amount and functionality of the von Willebrand factor (vWF), a plasma protein and the carrier for clotting factor VIII. The most common form of the disorder is transmitted as an autosomal dominant trait, and can occur in both males and females (Acharya, 2014).

The characteristic manifestations are prolonged and excessive mucocutaneous bleeding. In children, this is generally exhibited through easy bruising and recurrent epistaxis. Increased bleeding also occurs during surgery and dental extractions. Affected female teenagers may have menorrhagia (increased menstrual bleeding) (Acharya, 2014; Weickert, Miesbach, Alesci, et al., 2014).

Growth and Development

Encourage children with hemophilia to participate in leisure activities such as computer games, reading clubs, and crafts as well as social clubs such as Boy Scouts. Swimming, bicycle riding, hiking, and other noncontact sports are excellent options for the child. Protective equipment appropriate to the sport or recreational activity the child is participating in should be worn. Activities important to development can be encouraged when coaches, teachers, and others know how to treat bleeding episodes.

Diagnosis of von Willebrand disease is made after laboratory studies reveal decreased von Willebrand factor levels, von Willebrand factor antigen levels, and factor VIII activity; reduced platelet agglutination; and prolonged or normal activated partial thromboplastin time (aPPT).

Treatment is similar to that for the child with hemophilia and involves infusion of von Willebrand protein concentrate. Desmopressin (DDAVP) is administered to promote release of stored vWF and to prevent bleeding associated with dental or surgical procedures (Thiagarajan, 2014).

Nursing Management

Teach parents about the disorder and instruct them not to give the child any aspirin or other drugs that can cause bleeding or inhibit platelet function. Teach management of bleeding episodes and intravenous infusion techniques, as for hemophilia. The prognosis is good, and children with von Willebrand disease usually have a normal life expectancy. Expected outcomes of nursing care include prompt management of bleeding and prevention of disease complications.

Disseminated Intravascular Coagulation

Disseminated intravascular coagulation (DIC) is a life-threatening, acquired pathologic process in which the clotting system is abnormally activated, resulting in widespread clot formation in the small vessels throughout the body. Excess thrombin is generated, followed by deposition of fibrin strands in body tissues. The circulating fibrin fragments later begin to interfere with platelet aggregation and other aspects of the clotting mechanism, resulting in bleeding or hemorrhage (LeMone, Burke, Bauldoff, et al., 2015).

The most common cause of DIC is sepsis. Infections caused by gram-negative and gram-positive bacteria, fungi, viruses, and protozoa may lead to DIC (LeMone et al., 2015). Symptoms can include gingival bleeding, mucosal bleeding, hemoptysis, petechiae, purpura, bruising, oozing of blood after an injection, hematuria, frank bleeding from incisions, tachycardia, and hypotension (LeMone et al., 2015; Levi & Schmaier, 2014).

Medical management includes platelet and factor replacement so that platelets and clotting factors are restored. Although controversial, heparin may be administered to treat uncontrolled thrombosis (LeMone et al., 2015; Levi & Schmaier, 2014).

Nursing Management

Disseminated intravascular coagulation is a complex disorder managed by a critical care team. Nursing care focuses on assessing the bleeding, preventing further injury, and administering prescribed therapies. Observe for petechiae, ecchymoses, and all body orifices and skin breaks for oozing every 1 to 2 hours. Careful monitoring of dependent areas is essential because blood will pool in these locations. Intravenous sites are particularly prone to oozing and should be assessed every 15 minutes. Examine stool for the presence of blood, and measure blood loss as accurately as possible. Measure intake and output.

Because all body systems can be involved, careful, continuous assessment of all systems is needed. Institute bleeding control precautions, monitor prescribed therapy (transfusion, anticoagulant therapy), and report any signs of complications. Desired outcomes of nursing care are management of bleeding and adequate function of all body systems. Adequate family support in this life-threatening situation is a focus of nursing care.

Immune Thrombocytopenic Purpura

Immune thrombocytopenic purpura (ITP), also known as *idiopathic thrombocytopenic purpura,* is a bleeding disorder characterized by increased destruction of platelets in the spleen. Platelets are destroyed as a result of the binding of autoantibodies to platelet antigens (Kessler & Sandler, 2014). When the rate of platelet destruction exceeds the rate of platelet production, the number of circulating platelets decreases and blood clotting slows. The cause of ITP is unknown, but it usually follows an infectious illness.

Symptoms include multiple ecchymoses and petechiae and mucosal bleeding in the mouth or nose. Diagnosis is made by history and through physical and laboratory findings, which show a decreased platelet count (generally less than 20,000 mm^3/dL) (Kessler & Sandler, 2014; Warrier & Chauhan, 2012). The child has normal hemoglobin and white blood cell counts. A bone marrow aspiration may be performed to rule out other diagnoses (Warrier & Chauhan, 2012).

Patients with a platelet count greater than 10,000 and little bleeding may be carefully observed without the need for additional treatment. Modalities of treatment vary among healthcare providers and may include corticosteroids, intravenous immune globulin (IVIG), and intravenous anti-D immunoglobulin. Platelet administration is not generally an aspect of treatment, except in cases of severe hemorrhage (Heiner & Morgan, 2014). With ITP, platelet administration will control bleeding temporarily since the administered platelets will be destroyed.

It is estimated that 20% of children with ITP will develop chronic disease (Warrier & Chauhan, 2012). Children who fail to respond to treatment for acute ITP and persist with thrombocytopenia for longer than 12 months are considered to have chronic ITP (Generali & Cada, 2013). Splenectomy may be an option for children with persistent or chronic disease, significant bleeding, lack of response to drug therapy, or altered quality of life (Neunert, 2011).

Nursing Management

Nursing care focuses on controlling and reducing the number of bleeding episodes. Preventive measures are similar to those for the child with hemophilia. Teach parents to use acetaminophen, rather than aspirin, to control pain. Provide emotional support to the family. Have the child avoid contact sports. Perform careful assessments of bleeding and take vital signs. Expected outcomes of care are prevention of bleeding and restoration of normal coagulation patterns.

Hematopoietic Stem Cell Transplantation

Hematopoietic stem cell transplantation (HSCT) is a treatment used for diseases such as severe combined immunodeficiency disease, severe and unresponsive aplastic anemia, and leukemia (refer to Chapters 22 and 24). Hematopoietic stem cells exist primarily in the bone marrow but also circulate in the peripheral blood. These cells can grow into new body cells, and have become useful in treatment of immune and hematologic diseases when restoration of normal cells is needed. Stem cells can be obtained from bone marrow, cord blood, or peripheral blood (Kolins, Zbylut, McCollom, et al., 2011; Moore & Ikeda, 2014).

Hematopoietic stem cell transplants are either autologous or allogeneic. In **autologous transplantation**, the child's own marrow is taken, treated, stored, and reinfused after the child has received chemotherapy. **Allogeneic transplantation** may be syngeneic (from an identical twin), related, or unrelated. In allogeneic transplantation, the donor, often a sibling (related), has a compatible human leukocyte antigen (HLA). HLAs are proteins found on the surface of nearly all nucleated cells within the body, and they are responsible for regulating the immune response. When no relative is found to match the child, a histocompatible donor (unrelated) may be sought from the National Marrow Donor Program or a cord blood bank (Kolins et al., 2011; Moore & Ikeda, 2014). With the development of this registry, bone marrow transplantation from HLA-matched unrelated donors has become possible for some children.

The transplantation procedure begins with chemotherapy and, sometimes, total body irradiation directed at destroying circulating blood cells and the diseased bone marrow in the ill child. The chemotherapy program for destruction of bone marrow ranges from 7 to 10 days (Moore & Ikeda, 2014). During this time, the child is cared for in strict isolation in a special unit that provides a germ-free environment (Figure 23–4). Following

Figure 23–4 **The child undergoing bone marrow transplantation is hospitalized in a special sterile unit while receiving chemotherapy before the transfusion. The child remains in the unit for several weeks afterward until the new marrow produces enough cells to maintain health.**

the immunosuppression procedure, the child receives an intravenous transfusion with the donor stem cells. This procedure is similar to administration of a blood product. The healthy stem cells migrate to the bone marrow. Healthy bone marrow, capable of making blood cells, is the anticipated result. If the transplantation is successful, the cells implant in the child's marrow and begin to produce blood cells within approximately 2 to 4 weeks.

Pancytopenia (marked decrease in RBCs, WBCs, and platelets) lasts for several weeks following the transplant. Major risks during this period are anemia, infections, and bleeding. Once the bone marrow begins to produce new cells, graft-versus-host disease (rejection) is the major threat. Refer to Chapter 22 for a discussion of graft-versus-host disease.

Monitor the child undergoing HSCT by assessing the skin, mucous membranes, gastrointestinal function, respiratory function, cardiac function, and hydration status. Because graft-versus-host disease may occur at any time, even after the child returns home, frequent thorough assessments are necessary after discharge.

Supportive care after the transplantation procedure focuses on preventing infection, controlling bleeding, maintaining a nutritious diet and hydration, monitoring for signs of rejection, and providing psychosocial support. The treatment is lengthy, the child is often critically ill, and parents may have traveled to a medical center many miles from home for the procedure. Ask parents about other family members and how they are managing. Provide information about inexpensive housing available near the medical center. Encourage parents to discuss their feelings with other parents of children receiving bone marrow transplantation. Organizations such as the Bone Marrow Transplant Family Support Network can serve as resources for families.

When the child is ready for discharge, be sure the family is prepared to administer medications, recognize signs of graft-versus-host disease, provide adequate nutrition for the child, and perform other necessary care. Arrange for follow-up visits and provide the names of local healthcare contact people who can offer support and provide information. The child may need tutors or other educational assistance to promote integration back into the school setting. The major expected outcome of nursing care is the proper activity of bone marrow in the child with resulting normal levels and function of blood cells. Other outcomes are provision of family support, ongoing care and education for the child, adequate nutrition, and prevention of infection. See *Health Promotion: The Child With Hematopoietic Stem Cell Transplantation (HSCT)*.

Health Promotion The Child With Hematopoietic Stem Cell Transplantation (HSCT)

Growth and Development

- Measure and plot height and weight at each visit using standard growth curve charts.
- Measure onset and progression of puberty using Tanner staging.
- An individualized education plan (IEP) should be performed yearly to identify learning problems.
- Routine hearing screening is advised since hearing loss may occur as a result of ototoxic drug therapy.
- Vision should be screened at each primary care visit since corticosteroid use can cause cataracts, graft-versus-host disease (GVHD) can result in keratoconjunctivitis, and cytomegalovirus (CMV) can cause retinitis.
- Blood pressure should be monitored at each visit because children are commonly placed on medication for hypertension after HSCT because of nephrotoxic medications.
- Instruct parents to measure and record blood pressure at home if necessary.

Nutrition

- Teach family to avoid foods with potential vectors for infection, such as unpasteurized products and undercooked meats.
- A low-sodium diet may be required if the child has hypertension.
- Calcium supplements may be administered to reduce the risk of osteopenia.

Physical Activity

- If the child has thrombocytopenia, physical activity may be restricted.
- The child may experience fatigue. Ask about activity tolerance.

Oral Health

- Dental screening and any required restorative care should be done before transplant to reduce potential sources of infection.
- Routine dental care is resumed once the child's immune system is restored. Ask the family about the child's routine dental care.

Mental and Spiritual Health

- Apply developmental approaches to assess the child's feelings after a HSCT.
- Ask the child about coping with being in the hospital and at home rather than attending school.
- Many physical changes occur with treatment that may interfere with body image. Assess the child's or adolescent's body image in a manner appropriate to age.

Relationships

- In-hospital or in-home schooling is required after HSCT for 6 to 12 months until immune function has been obtained to reduce the risk of infection.
- Encourage peer contact, telephone calls, e-mail, and letters to reduce the child's feelings of isolation.
- On returning to school, the child is encouraged to participate fully in school activities.
- For the adolescent, sex education is important, especially to avoid sexually transmitted infections.

Disease Prevention Strategies

- Teach the family that hand hygiene is essential to prevent the spread of infection.
- Dishes should be washed in a dishwasher. Teach safe food preparation techniques.

- In-home child care is recommended because of the risk of infection in other childcare settings.
- Teach the family that the child should have minimal direct contact with animals to avoid infections.

- Determine the child's need for an altered immunization schedule after HSTC.
- Instruct parents to monitor the child for infection and report any temperature elevation to the healthcare provider.
- Encourage the family to obtain an influenza vaccine annually for the child and all household or close contacts.
- Teach signs and symptoms of infection and stress the importance of prompt reporting.

Injury Prevention Strategies

- Review safe medication storage with the family.
- Help the family develop a plan for the safe disposal of used needles and syringes.

Chapter Highlights

- Erythrocytes (red blood cells) are a major component of the blood and transport oxygen from the lungs to body tissues.
- Polycythemia is an increase in the number of red blood cells. Anemia is characterized by a decrease in red blood cell number.
- Leukocytes (white blood cells) are important in the cell's defenses against disease.
- Thrombocytes (platelets) are necessary for normal clotting of blood.
- The major anemias of childhood include iron deficiency anemia, normocytic anemia, sickle cell disease, thalassemia, hereditary spherocytosis, and aplastic anemia.
- Sickle cell disease is a genetic disease in which an abnormal shape, or sickling, of red blood cells prevents the normal flow of blood.
- Children with sickle cell disease are at risk for vaso-occlusive (pain) crisis, splenic sequestration, and aplastic crisis.
- Complications of sickle cell disease include stroke, acute chest syndrome with pulmonary infiltrate and infection, priapism, retinopathy, kidney damage, and gallstone formation.
- Nurses assist families in dealing with chronic diseases such as sickle cell disease by providing information about the disorder and resources that can provide assistance, monitoring child growth and development, instituting preventive care, and managing exacerbations of the disease.
- The thalassemias are a group of genetic diseases of red blood cells, which cause defective synthesis of hemoglobin.
- Children who receive chronic blood transfusions for sickle cell disease or thalassemia are at risk to develop iron overload and may need to receive an iron-chelating drug such as deferoxamine or deferasirox (Exjade).
- Hereditary spherocytosis (HS) is a hemolytic disorder in which the erythrocytes assume a spherical shape due to an intrinsic membrane defect. The erythrocytes are retained and removed by the spleen, leading to splenomegaly in the child.
- Aplastic anemia is a deficiency of all blood cells related to poor bone marrow function; it can be congenital or acquired after exposure to certain drugs or harmful environmental toxins.
- Hemophilia is a bleeding disorder transmitted by genes; hemophilia A is most common and results in a decrease in clotting factor VIII.
- The goal of treatment for hemophilia is to control bleeding by preventive care and replacement of the missing factor.
- Major nursing concerns for the child with hemophilia include managing bleeding episodes, controlling pain during bleeds, minimizing physical immobility, supporting the family in learning management of this chronic disease, and explaining genetic implications of the disease.
- Von Willebrand disease is a hereditary bleeding disorder characterized by a deficiency of von Willebrand factor, a plasma protein that is a carrier for clotting factor VIII.
- Disseminated intravascular coagulation is a serious condition in which clotting mechanisms are disturbed, leading to extensive clotting and tissue damage.

- Immune thrombocytopenic purpura causes destruction of platelets and most frequently follows a childhood viral disease.
- Management of immune thrombocytopenic purpura includes corticosteroids, intravenous immune globulin (IVIG), and intravenous anti-D immunoglobulin. The disease is considered to be autoimmune in nature.
- Hematopoietic stem cell transplant (HSCT) is a useful treatment in some diseases of the hematologic system and some cancers; it involves infusion of bone marrow, peripheral stem cells, or neonatal stem cells from a donor into the blood of the recipient where it circulates, implants into the bone marrow, and begins making new blood cells.
- Nursing care before and after HSCT includes infection prevention, careful physical assessment, administration of medications, and support for the family.

Clinical Reasoning in Action

Frederick is admitted to the hospital with severe abdominal pain. He has been hospitalized for his sickle cell disease several times in the past and now, as an 8-year-old, he and his mother are very familiar with the routine. The disease is stable most of the time, but about twice annually he is admitted to the hospital for complications of the disorder. His mother expresses how upsetting it is to watch her son suffer pain from this disease.

In the hospital, a priority nursing intervention is to control Frederick's pain. The doctor diagnoses that the abdominal pain is caused by sickled cells in his spleen. Frederick's hemoglobin is 6 g/dL, and a blood transfusion is ordered. Fluids and oxygen are also administered. Frequent vital signs and other monitoring are performed to identify any infections.

1. Besides correcting the anemia, what is another reason Frederick would be given a transfusion?
2. What is happening to Frederick's spleen such that it is causing his abdominal pain?
3. In what way does sickle cell disease affect the various systems of the body?
4. When giving a blood transfusion to Frederick, should warm or cold blood be given? What is the reason for your answer?

Chapter 24
The Child With Cancer

Ollyy/Shutterstock

Rasheed was just diagnosed with leukemia seven months ago, but already he has been in the hospital five times. This time he had enterocolitis, an infection of the intestines. But he has now improved and is determined to fight the disease. It's his will and strength that help us all to be strong and to know that he will do well after his treatment is finished.

—Mother of Rasheed, 12 years old

Learning Outcomes

24.1 Describe the incidence, known etiologies, and common clinical manifestations of cancer.

24.2 Synthesize information about diagnostic tests and clinical therapy for cancer to plan comprehensive care for children undergoing these procedures.

24.3 Integrate information about oncologic emergencies into plans for monitoring all children with cancer.

24.4 Recognize the most common solid tumors in children, describe their treatment, and plan comprehensive nursing care.

24.5 Plan care for children and adolescents of all ages who have a diagnosis of leukemia.

24.6 Prioritize elements of comprehensive care planning for children with soft-tissue tumors.

24.7 Analyze the impact of cancer survival on children and use this information to plan for ongoing physiologic and psychosocial care in the children's futures.

Cancer is a daunting diagnosis at any age, but in children, it seems even more profound. The diagnosis and treatment are met with shock and disbelief, they require a change in the roles of everyone in the family, and challenge all children and families involved in many ways. Nurses who work in pediatric oncology have unique opportunities to assist children and families in mobilizing resources and learning about maximizing physical, emotional, and developmental health while dealing with the challenges of the illness and treatment.

Why do children develop different types of cancers than adults? Cancer in adults is often the result of dietary practices or habits such as smoking. Some adult-onset cancers are the result of oncogenic responses to stimuli—that is, responses that stimulate cancerous changes in cells. Other cancers that occur in adults result from prolonged exposure to toxins such as coal dust and asbestos. Some cancers are known to be related to genetic causes. In adults, prevention through general lifestyle changes is a major focus of interventions. However, in children, cancer is usually embryonic (occurring during development of the fetus) or oncogenic in origin. Thus, lifestyle changes that begin in childhood have little effect on the incidence of childhood cancer, although they may help reduce the incidence of later cancer or other diseases. Occasionally, an environmental exposure is linked to the incidence of cancer in children.

Text continues on page 613

FOCUS ON:
Cellular Growth

Anatomy and Physiology

Abnormal cellular growth can occur in any area of the body. Why are some growths called cancer and others are not? Changes in cellular growth within the body are called neoplasms (meaning new growth). A neoplasm is further classified as benign or malignant. **Benign** means that a growth does not endanger life or health; it tends not to recur after treatment. **Malignant** means that progressive growth of the tumor will, if not checked by treatment, spread to other sites in the body (**metastasis**), resulting in death. The common term for this type of cellular growth is *cancer*.

Pediatric Differences

Cancers in children often have different etiology than those in adults. Most adult cancers are epithelial in origin, whereas in children the nonepithelial or embryonal cell types predominate. While many adult cancers are slow-growing and result from exposure to carcinogens over time, most childhood cancers are fast-growing, so that a child who appears healthy becomes ill over a period of days or weeks. Different types of cancers predominate at various ages in childhood, demonstrating the multiple causes and their relationship to age and development (Figure 24–1).

Although not common, some neonates have cancer that is diagnosed soon after birth. The types of cancers most common in this age group include brain tumors, neuroblastoma, leukemia, retinoblastoma, and teratomas (arising from primary germ layers). While treatments are usually as effective in neonates as in older children, rapid growth at this age makes side effects of therapy more serious.

A major physiologic difference between adults and children that affects cellular growth involves the immune system, which plays a part in preventing some cancers but functions immaturely in the young child (see the following text for further description of immune immaturity). The rate of cell growth in children can also play a role in the rapidity with which some childhood cancers progress. The continuing presence of fetal cells in small children is related to some cancers. These immature cells decrease and finally disappear as children grow but can be related to cancers such as neuroblastoma in very young children.

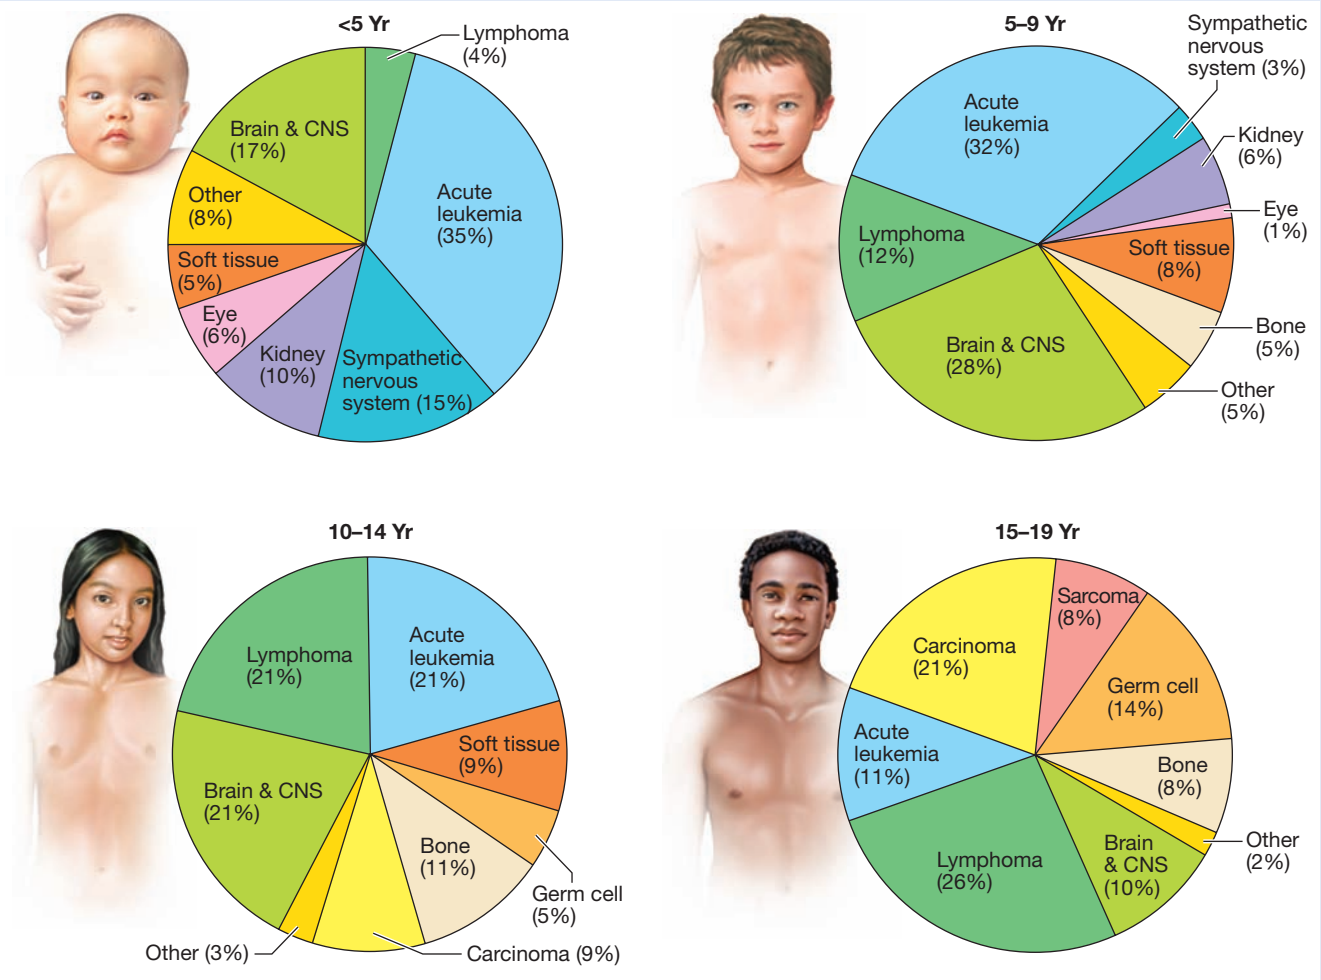

Figure 24–1 **Percentage of primary tumors by site of origin for different age groups.**

TABLE 24–1 Diagnostic Procedures and Laboratory Tests for Cancer

DIAGNOSTIC PROCEDURES	LABORATORY TESTS
Biopsy	Complete blood count (CBC) with differential
Bone marrow aspiration and biopsy	Red and white blood cell indices
Computed tomography (CT) and computerized axial tomography (CAT)	Serum chemistry panel
Lumbar puncture	Tumor markers
Magnetic resonance imaging (MRI)	Urinalysis
Positron emission tomography (PET) scan and single-photon emission computed tomography (SPECT)	
Radiograph (x-ray)	
Nuclear medicine scans	
Ultrasound	

The immune system defends the body against foreign organisms and substances through two responses: nonspecific and specific. In a *nonspecific response,* the components of the immune system attack a variety of targets. Nonspecific components include phagocytic (cell destroying) cells such as mononuclear leukocytes, polymorphonuclear (PMN) leukocytes, natural killer (NK) cells, and complements (noncellular proteins) that work together to destroy invading cells and substances. During the first month of a child's life, the nonspecific response is immature, so phagocytic cells have little ability to move toward cancer cells and fulfill their function. The nonspecific response is also impaired in premature and small-for-gestational-age (SGA) infants.

In a *specific response,* T lymphocytes and immunoglobulin (Ig) attack only one type of invader. The specific response capability also is immature in infants. B-cell production of various proteins called immunoglobulins (IgM, IgG, and IgA) is below adult levels, so that the infant is vulnerable to bacterial and viral infections. (For a discussion of immune function, see Chapter 22.)

In children, many cells are growing quickly; this fast growth can lead to the proliferation of both cancerous and normal cells. Cell division that is out of control may normally trigger a mechanism called **apoptosis**, whereby the cell "realizes" something is wrong and destroys itself. The process of apoptosis or physiologic cell death limits the growth of cancerous cells but may not be well developed in young children.

Examples of diagnostic and laboratory tests used to evaluate cancer are provided in Table 24–1; see Appendices D and E for further information about these diagnostic procedures and tests common in cancer care.

Use *Assessment Guide: The Child With an Alteration in Cellular Growth* to identify and monitor alterations in cellular growth.

ASSESSMENT GUIDE | The Child With an Alteration in Cellular Growth

Assessment Focus	Assessment Guidelines
Growth and development parameters	• Assess the child's weight and height and plot on growth grids; be alert for weight loss. • Inquire about nutritional intake and any recent changes in appetite. • Perform developmental assessment and be alert for slow progress or regression. • Ask about school performance for children enrolled in school; include this information in every assessment of children who were treated for cancer in the past.
Pain	• Pain is abnormal if there is no known acute injury or chronic condition; assess any pain for length, duration, and type. • Does the child exhibit limping, headache, decreased activity level, or other symptoms indicative of pain?
Skin	• Is there bruising and other signs of bleeding on the skin? • Is there pallor and other signs of anemia? • Describe skin lesions.
Eyes, ears, nose, and throat (EENT) and sensory	• Inspect the symmetry and general condition of the eyes, ears, mouth, throat, head, and neck. • Inspect eye movements, corneal light reflex, and red reflex. • Evaluate hearing and vision and note any recent changes.
Chest, heart, and respiratory system	• Inspect the shape of the chest, respiratory rate, and ease of respirations. • Auscultate heart and lungs. • Ask about endurance and activity levels.

Assessment Focus	Assessment Guidelines
Abdomen	• Be alert for abdominal masses. Stop palpation immediately if any are noted and inform the physician. • Is there repeated vomiting, anorexia, or weight loss?
Urinary and gastrointestinal systems	• Evaluate frequency of urination and feces. • Assess for intake and evidence of vomiting or food intolerance. • Ask about blood or other discoloration in urine or stool. • Be alert for urinary tract infections.
Musculoskeletal system	• Observe for expected developmental tasks. • Is there asymmetry of bone or muscle? • Does the child limp or have other abnormalities of gait?

Childhood Cancer

The care of children who have cancer is a challenging specialty in pediatric nursing. In some cases, the child undergoes treatments that may continue for years and result in a variety of side effects. Today, treatments for cancer have improved prognoses in many cases, but in some, the prognosis still requires that the family deal with a life-threatening illness (see Chapter 13). The child is often cared for at home with outpatient visits for treatment and occasional hospitalization when needed. The periods of hospitalization are times of intense physical vulnerability for the child and intense emotional vulnerability for both the child and the family. To monitor the child closely, nurses need a sound knowledge of physiologic and psychologic responses, medical interventions, and nursing care. Integration of developmental knowledge into assessment and intervention is essential. Effective communication skills are necessary to support the child and family and promote realistic hope. See the *Nursing Management* sections and the *Nursing Care Plans* later in this chapter for specific interventions required.

Incidence

In the United States, cancer is diagnosed annually in approximately 11,000 children under 15 years of age, and about 1500 die from cancer annually (American Cancer Society [ACS], 2011). In children under 15 years of age, cancer is the leading cause of disease-related death, and it is the second leading cause of overall death after unintentional injury (ACS, 2011). However, mortality rates have declined by about 47% since 1975. The overall survival rate is 80% for childhood cancer. Survival rates vary related to the stage of disease at time of diagnosis and differ for specific types of cancer, ranging from 66% for neuroblastoma to 95% for Hodgkin disease (ACS, 2011; Arndt, 2011a). Figure 24–1 shows the most common forms of childhood cancers among children in different age groups.

Etiology and Pathophysiology

Alterations in cellular growth occur in response to external and internal stimuli. **Neoplasms** are caused by one or any combination of three factors: (1) external stimuli that cause genetic mutations, (2) immune system and gene abnormalities, and (3) chromosomal abnormalities.

EXTERNAL STIMULI

External stimuli may affect the child's general health and cause mutations in body cells. **Carcinogens** are chemicals or industrial processes that, when combined with genetic traits and in interaction with one another, result in cancer. Several carcinogens cause cancers that are diagnosed during childhood. Others cause cancers that begin in childhood but are not identified until adulthood. Some chemicals suspected of causing childhood cancer include diethylstilbestrol (maternal use of therapeutic estrogen hormones), anabolic androgenic steroids, alkylating chemotherapeutic agents, and immunosuppressants used for organ transplantation. Radiation exposure has been known to cause cancers such as leukemia and thyroid tumors in children exposed to nuclear fallout from atomic bombs, other nuclear accidents, and other excessive radiation sources.

External stimuli may also lead to secondary cancers in children, or those occurring after treatment for a primary cancer and of a different cellular type than the primary cancer. Secondary cancers can result when the child is treated for a primary cancer with high doses of radiation. Excessive exposure to ultraviolet radiation from the sun predisposes children to development of skin cancer in adolescence and adulthood (see Chapter 31).

IMMUNE SYSTEM AND GENE ABNORMALITIES

One critical function of a normal immune system is immune surveillance, in which phagocytic cells circulate throughout the body, detecting and destroying abnormal and cancerous cells. Children with congenital immune deficiencies, such as Wiskott-Aldrich syndrome, in which immune surveillance may fail, are at high risk for cancer. A form of non-Hodgkin lymphoma develops in some children treated with immune system–suppressing drugs. Children with acquired immunodeficiency syndrome (AIDS) may also be at higher risk of certain types of cancer, such as Hodgkin disease, non-Hodgkin lymphoma, Kaposi sarcoma, and leiomyosarcoma (Sigel et al., 2011).

Viruses and other substances may alter the immune system, thereby allowing cancer to occur (see *Pathophysiology Illustrated: Proto-Oncogene Alteration*). Their action is based on changing certain genes that normally regulate cellular growth and development (called **proto-oncogenes**) into related genes that allow unregulated cell division and cancerous growth (called **oncogenes**). Among the cancers thought to be linked to viral action and the change of proto-oncogenes to oncogenes are certain leukemias, rhabdomyosarcoma, Burkitt lymphoma, and some forms of Hodgkin disease.

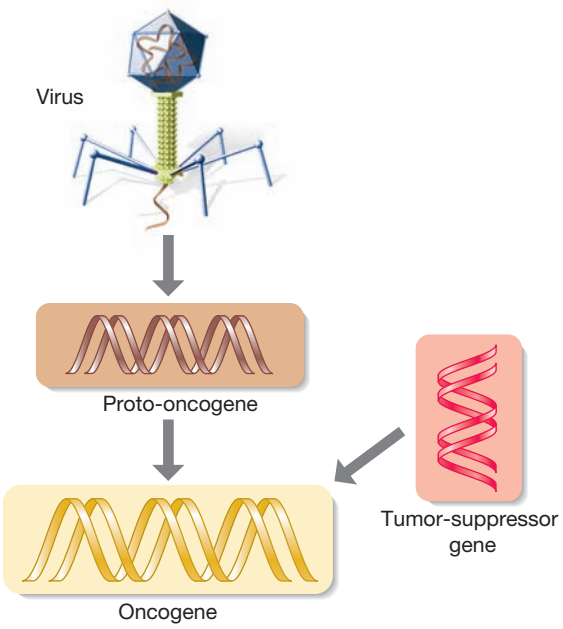
Genetic changes can include autosomal dominant, autosomal recessive, and X-linked transfer. In these cases, the resulting cancers often occur relatively early in life. Cancers of these types are typically aggressive since the child has inherited the abnormal gene and it is within each cell, rather than a single mutation of one gene in a specific cell. Because of the progress made in the Human Genome Project, there is increasing ability to perform genetic testing for certain familial cancers. Examples of cancers that are sometimes caused by genetic abnormalities within families include retinoblastoma and Wilms tumor (described later in this chapter), multiple endocrine neoplasia, type 2 (thyroid cancer), and familial adenomatous polyposis (invasive colon cancer). Not all cases of these cancers are familial, but their incidence suggests the need for careful history taking to identify any other cases in the family.

Providing recommendations for referral to genetic counseling services and following up with further education and psychologic support are important nursing roles.

Professionalism in Practice Nursing Genomics Competencies

Cancer's relationship with genetic characteristics is increasingly recognized, and treatments may target certain genes. For these reasons, it is important that nurses who work in oncology nursing achieve genomic competency. The Genomic Nursing Concept Inventory (GCNI) has been developed and evaluated to measure genomic literacy and advance evidence-based nursing education (Ward, Haberman, & Barbosa-Leiker, 2014). Nurses believe that genomic competency is important, but it has been found that a deficit in this knowledge affects nurses regardless of academic preparation (Calzone, Jenkins, Culp, et al., 2014). Genetic and genomic competencies have been developed to encompass risk assessment and interpretation; genetic education, counseling, testing, and results interpretation; clinical management; ethical, legal, and social implications; professional role; leadership; and research (Greco, Tinley, & Seibert, 2011). See Chapter 3 for further information about genetics and genomics.

Pathophysiology Illustrated: **Proto-Oncogene Alteration**



A proto-oncogene normally regulates cellular growth and development. When altered by a virus or other external cause, it can change to an oncogene, which allows unregulated genetic activity and tumor growth. Tumor suppressor genes regulate the effects of oncogenes to decrease wildly proliferating cellular growth.

Tumor suppressor genes counteract the effect of oncogenes, keeping cellular growth within normal limits. When tumor suppressor genes are missing, unstemmed cellular growth can occur. These genes are commonly missing in children with retinoblastoma and Wilms tumor.

CHROMOSOMAL ABNORMALITIES

Normal chromosomes undergo change as a part of the genetic process. Most changes are not harmful. However, some result in chromosomal abnormalities such as hyperploidy (more than the normal number of chromosomes), deletion, translocation, and breakage.

Some chromosomal abnormalities have been linked to an increased incidence of cancer. Children with Down syndrome have a much higher incidence of leukemia than nonaffected children; the risk varies greatly according to the type of leukemia (Roberts & Izraieli, 2014). Children missing a band of genetic material on chromosome 13 often have retinoblastoma. Similarly, a Wilms tumor often develops in children missing part of the genetic material from chromosome 11.

Regardless of the location and cause of abnormal cellular growth, the pathophysiologic process of cancer is similar. The altered cell begins to multiply as directed by the altered genetic structure of its DNA and the absence or inactivation of tumor suppressor genes. Each new cell transmits the new or altered pattern to the next generation. As the abnormal cells replicate, they form a growing neoplastic mass. Normal cells usually die as the increased metabolic rate of the neoplastic cells depletes available nutrition. The altered DNA in the tumor cells may also cause the abnormal cells to invade adjoining tissue. Through continued growth the mass expands until it enters and disrupts a major vessel or a vital organ.

Families Want to Know

Ways to Decrease the Incidence of Cancer in Children

Many parents ask what they can do to decrease the incidence of cancer in children as they grow into adulthood. Three major teaching areas should be addressed:

1. Have children increase intake of fruits and vegetables. Most children do not eat enough of these foods, and increased intake is associated with lower rates of many cancers. Aim for a minimum of five servings daily.
2. Protect skin with sunscreen. Early excessive exposure to sun, and having had one or repeated severe sunburns during childhood, increases chances of skin cancers developing in adulthood. Tanning bed exposure is a prime risk factor for skin cancer; all children and adolescents, and particularly those with cancer, should strictly avoid tanning beds (Greinert & Boniol, 2011).
3. Discourage smoking among children and be sure children are not exposed to environmental tobacco smoke. This will decrease the future chance of developing lung cancer.

When there is a history of cancer in the family, particularly of a type associated with familial incidence such as some breast or ovarian cancers, encourage the family to learn more about the cancer and teach their children to receive regular surveillance as they enter young adulthood.

Inform youth in all families about screening, such as the Papanicolaou test, breast self-examination, and testicular examination that can lead to early detection. Encourage youth to receive the human papillomavirus quadrivalent vaccine recombinant (Gardasil) to prevent cervical cancers and other health problems caused by human papillomavirus (HPV). (See Chapter 16 for further information.)

Clinical Manifestations

Each type of childhood cancer signals its presence differently. Because many of the presenting signs and symptoms of cancer are typical of common childhood illnesses, diagnosis may be delayed. In some cases, no symptoms are noted until the cancer is advanced. Some of the common presenting symptoms of cancer follow:

- *Pain* may be the result of a neoplasm either directly or indirectly affecting nerve receptors through obstruction, inflammation, tissue damage, stretching of visceral tissue, or invasion of susceptible tissue.
- *Cachexia* is a syndrome characterized by anorexia, weight loss, anemia, asthenia (weakness), and early satiety (feeling of being full).
- *Anemia* may be experienced during times of chronic bleeding or iron deficiency. In chronic illness, the body uses iron poorly. Anemia is also present in cancers of the bone marrow when the number of red blood cells (RBCs) is reduced, in part because of the presence of large numbers of other bone marrow products. Treatment of cancer often promotes further anemia.
- *Infection* is usually a result of an altered or immature immune system. In addition, infection occurs when bone marrow cancers inhibit maturation of normal immune system cells. Infection may also occur in children treated with corticosteroids. Because their immune response is altered, the normal signs of infection may not appear.
- *Bruising* and *petechiae* can occur if the bone marrow cannot produce enough platelets; bleeding after even minor trauma can lead to ecchymosis.
- *Neurologic symptoms* may result from impingement on the brain or nervous system. Signs of increased intracranial pressure, decreased or altered consciousness, eye abnormalities, or other neurologic or behavioral changes may be evident.
- *Palpable mass* may be present for certain cancers. This is most commonly abdominal but may be mediastinal, in the neck, or at other sites.

A variety of other symptoms can occur depending on the location of the cancer. Subcutaneous nodules may appear if leukocytosis is present. Superior vena cava syndrome or respiratory difficulty can occur with mediastinal tumors (such as neuroblastoma), and enlarged lymph nodes are common with lymphomas.

Diagnostic Tests

The most common diagnostic tests performed on children with cancer are a complete blood count (CBC) with differential, bone marrow aspiration (BMA), bone marrow biopsy (BMBX), lumbar puncture (LP), peripheral blood studies, radiographic examination, magnetic resonance imaging (MRI), computed tomography (CT; Figure 24–2), ultrasound, and biopsy of tumor. See Table 24–2.

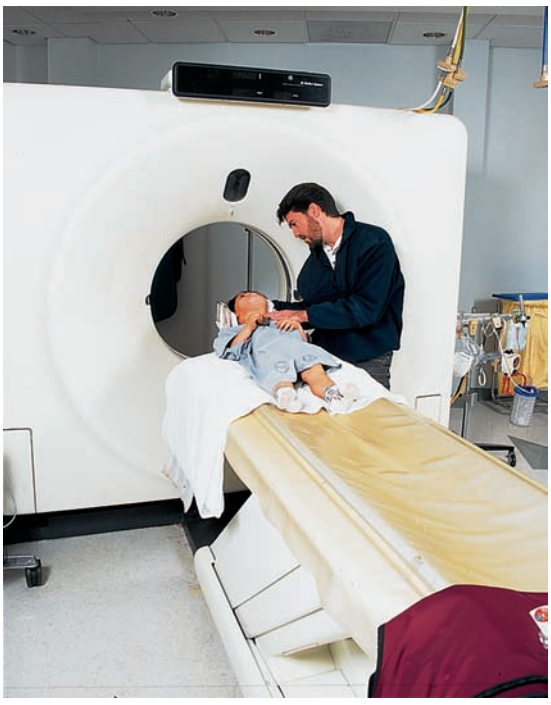


Figure 24–2 **Computed tomography can be a frightening procedure for children. This 2-year-old boy is comforted by his father before the procedure.**

TABLE 24–2 Selected Diagnostic Tests for Childhood Cancer

TEST	PURPOSE	NORMAL LABORATORY VALUES	DIAGNOSTIC VALUES
Bone marrow aspiration	Examines bone marrow.	Less than 5% blast cells (immature)	Greater than 25% blast cells in acute lymphoblastic leukemia, most with hypercellular marrow
Lumbar puncture	Examines cerebrospinal fluid.	Cell count (microliters) Polymorphonuclear leukocytes 0 Monocytes 0–5 RBCs 0–5	Presence of malignant cells indicates central nervous system involvement
Complete blood count and differential	Examines cellular components of blood.	WBC less than 10,000/mcL Platelets 150,000–400,000/mcL Hemoglobin 12–16 g/dL	WBC greater than 10,000/mcL OR depressed levels of WBCs Platelets 20,000–100,000/mL Hemoglobin 7–10 g/dL
Absolute neutrophil count (ANC)	Examines blood component ratio: (% of segmental neutrophils plus % of bands [immature neutrophils]) times WBC count; this number is then divided by 100.	ANC greater than 1000	ANC less than 1000 = risk of infection

SAFETY ALERT!
Remove all jewelry and clothes with metal snaps from the child before an MRI scan. Ask about and remove body piercings; they may not always be visible. Some metallic objects implanted in the body are compatible with MRI but others contraindicate the use of MRI. Metallic objects include orthodontic braces, metal dental bridgework, cochlear implants, surgical clips or plates, and orthopedic rods. When there are metal objects in the body or tattoos, be certain to report them to the managing healthcare provider and radiology technician so they can determine if it is safe to perform MRI.

Additional studies helpful for certain cancers are nuclear medicine scans with radioactive isotopes such as gallium or iodine, bone scan with technetium 99m, or positron emission tomography (PET) and single-photon emission computed tomography (SPECT), which combine nuclear medicine with CT. Specific tests such as pulmonary function tests and echocardiograms may be used in certain situations. Urine analysis is also performed.

The blood work is very detailed and includes RBC, WBC, platelets, hematocrit and hemoglobin, serum electrolytes, liver studies, and markers that are elevated in specific types of tumors. Absolute neutrophil count (ANC) is important; it uses both the segmented (mature) and bands (immature neutrophils) as a measure of the body's infection-fighting capability. ANC is calculated by adding the percentage of segmented neutrophils to the percentage of bands, and then multiplying this percentage by the WBC count.

The tests are aimed at identifying the source of the cancer and any metastases to additional sites. This enables the oncology specialist to stage the cancer. *Staging* refers to the process of labeling the type of cancer cells, severity, and spread, which will determine the recommended treatment and assist in teaching the family about treatment and prognosis. Stage 1 indicates less severe cancer without spread to other parts of the body; higher numbers indicate both greater severity and spread to other sites.

Clinical Therapy

Clinical therapy for cancer is extremely complex and is managed by a specialist in pediatric oncology. The cancer itself is treated, its effects on the body are addressed, and the side effects of treatment are managed. Examples of the effects of cancer on the body include altered nutritional status from anorexia due to the cancer diverting nutrients to itself, decreased immune response from impaired manufacture of white blood cells and other immune components, and a variety of symptoms as a tumor presses on vital organs. In addition, cancer treatment itself has many potential side effects that require constant monitoring and adjustments in treatment.

Cancer is treated with one or a combination of therapies: surgery, chemotherapy, radiation, **biotherapy** (treatment that uses and/or enhances the body's abilities to fight disease, particularly by using biologic agents to promote immune response), and bone marrow transplantation. The choice of treatment is determined by the type of cancer, its location, and staging. Treatments all have side effects and these will also require clinical management. Many families also choose to use some type of complementary therapy in addition to traditional medical approaches.

The goal of treatment may be curative, supportive, or provision of end-of-life care. Curative treatment rids the child's body of the cancer. Supportive treatment includes transfusions, pain management, antibiotics, and other interventions to assist the body's defenses and increase the child's comfort. End-of-life treatment is designed to make the child as comfortable as possible when no curative treatment is possible. (See Chapter 13 for a detailed discussion of end-of-life care for children.) Whatever combination of treatment is used, families have many questions and need resources for information.

SURGERY

Surgery is used to remove or debulk (reduce the size of) a solid tumor. An example of a cancer that is commonly treated with surgery is a Wilms tumor. Surgery may also determine the stage and type of cancer.

CHEMOTHERAPY

Chemotherapy is the administration of specific drugs that kill both normal and cancerous cells. The administration of various chemotherapeutic drugs is timed to achieve the greatest cellular destruction. The cell's cycle of replication determines

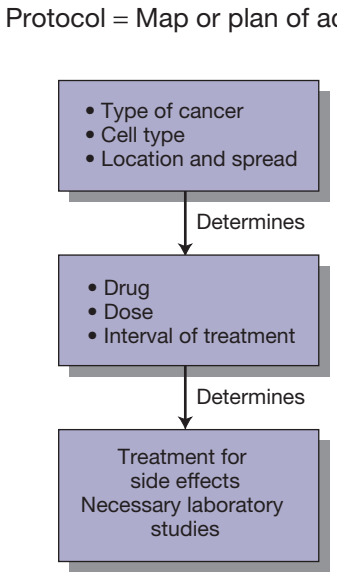

Figure 24–3 **Chemotherapy protocol. A protocol is a map or plan of action that directs therapy by identifying the drug and its accompanying treatment.**

the schedule (see *Pathophysiology Illustrated: Chemotherapeutic Drug Action*). Several chemotherapeutic drugs are administered simultaneously to maximize their lethal impact on cells at all stages of activity (see *Medications Used for: Cancer Chemotherapy*). Medications are most commonly oral, intravenous, or **intrathecal** (into spinal canal). Whereas DNA in a normal cell can repair itself after chemotherapy, the DNA in a neoplastic cell cannot. The particular chemotherapeutic treatment protocol used is based on research into different types of cancer cells. A **protocol** is a plan of action for chemotherapy based on the type of cancer, its stage, and the particular cell type (Figure 24–3).

Other drugs used in the treatment of children with cancer include colony-stimulating factors, antiemetics, and nutritional supplements. Colony-stimulating factors are hormone-like glycoproteins that enhance blood cell production and counteract the myelosuppressive effects of chemotherapeutic drugs. For example, erythropoietin is produced in the kidney, and a recombinant form (epoetin) is available that can be used to treat anemia of cancer, thereby decreasing the number of transfusions needed. Filgrastim (Neupogen) increases production of neutrophils by the bone marrow (see *Medications Used During Cancer Treatment: Colony-Stimulating Factors*). Antiemetics, such as ondansetron (Zofran), can be used to treat the nausea and vomiting that are common side effects of therapy. Nutritional supplements help maintain nutritional status.

RADIATION

Radiation therapy involves unstable isotopes that release varying levels of energy to cause breaks in the DNA molecule and thereby destroy cells. Radiation has been used as a treatment method since the early 1900s, shortly after its discovery. It is often used for the local and regional control of cancer, and in combination with surgery and chemotherapy; it may be curative or palliative.

The area to be irradiated (treatment field) includes the tumor site and sometimes other involved areas, such as lymph glands. The goal is to irradiate the tumor but not healthy adjacent tissue. The total dose of radiation is divided (or fractionated) and given over several weeks. A common course of

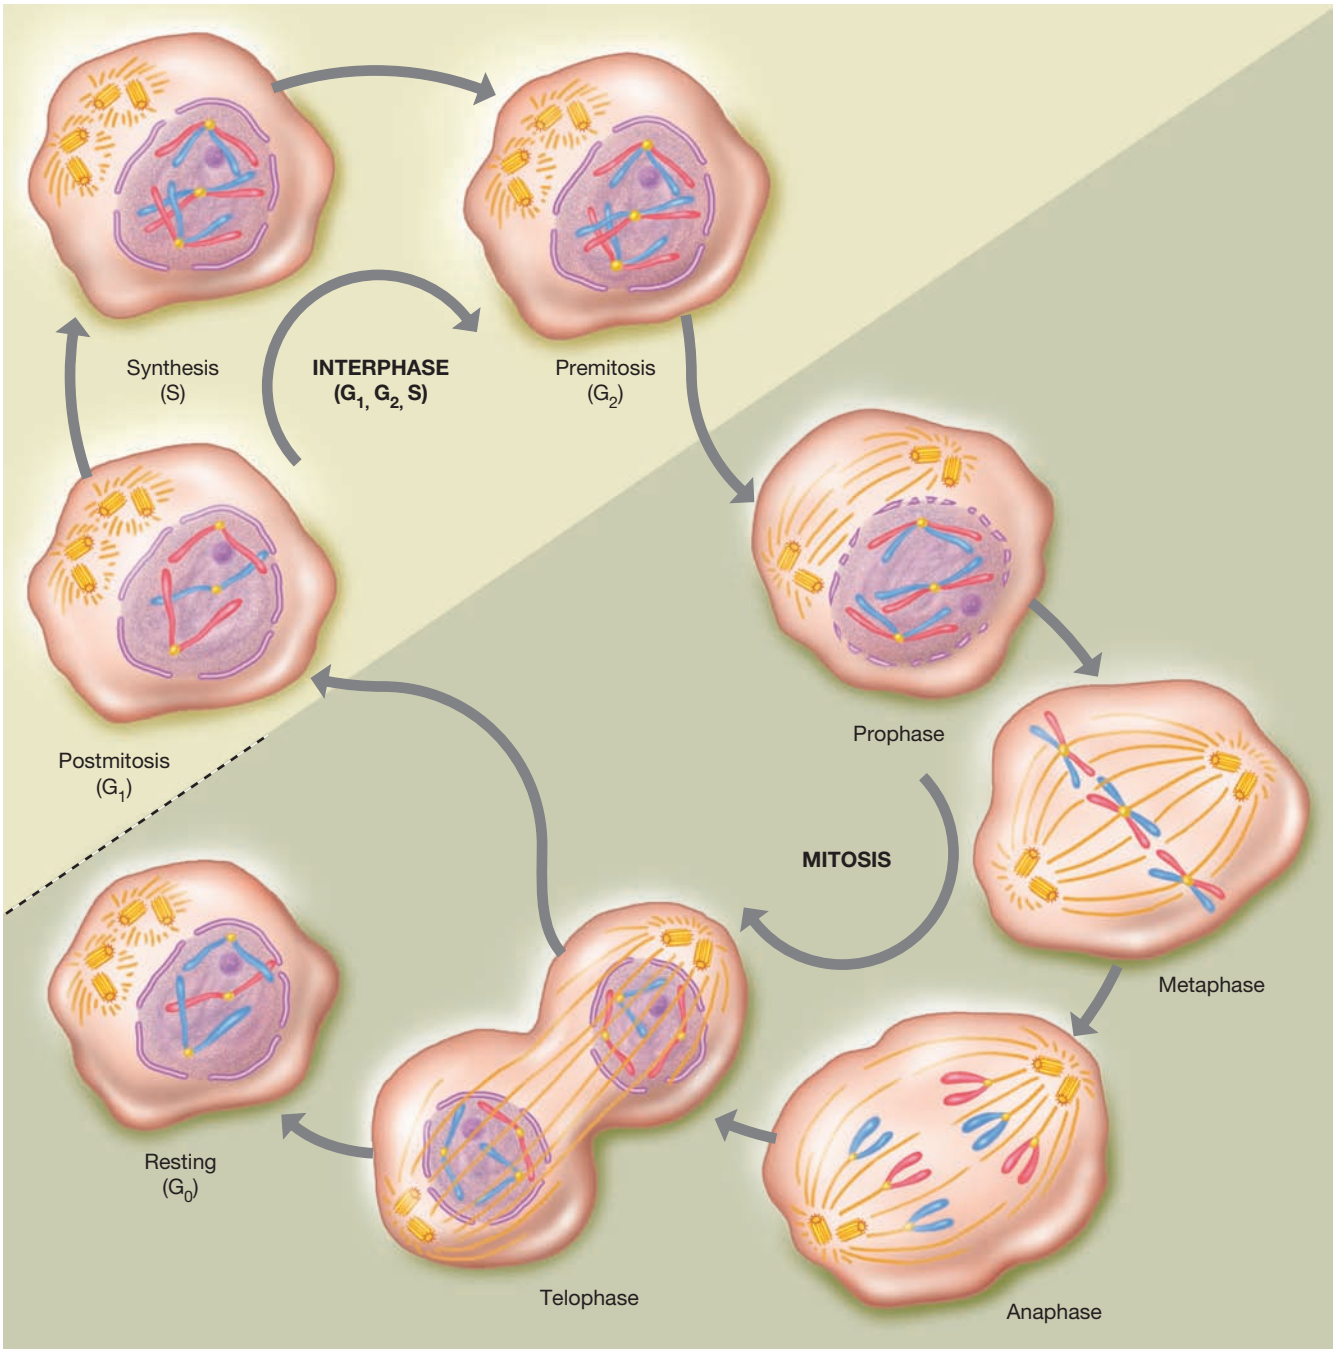
Families Want to Know

Cancer Therapy

Most parents are not aware of the effects of cancer treatment and how they can help children through this experience. Depending on the stage and type of treatment, there are several ways to help:

- Children in radiation therapy and chemotherapy become fatigued because of cancer and treatment effects. Provide extra rest periods with shorter activity periods between them.
- Have a suitcase ready in case the child develops a complication and needs to be taken to stay in the hospital for a few days. Several hospital stays of a few days are normal during treatment.
- Parents are often key in identifying problems early. They should be encouraged to share their observations and concerns about symptoms the child is experiencing.
- Parents are usually concerned about providing central line care but feel more comfortable after a few days of caring for the line.
- Children may not feel hungry because of anorexia from the disease and as a side effect of treatment. When they are ready to eat, intake should be nutritious.
- Remember that children with cancer are still at their normal developmental age. Treat them appropriately for their age, not as if they are older or younger. Utilize the child-life specialist in the hospital to assist with planning activities appropriate to the child's developmental age.
- Try to maintain contact with the child's peer group and family members. When school attendance or direct contact is not possible because of immune suppression, arrange for phone calls, videocam exchanges, and other methods of communication.
- Seek information from other parents, the Internet, and other resources on cancer care.
- Many families use complementary approaches to deal with the child's cancer. Most of these approaches are not contraindicated. However, be sure to tell the oncologist about what treatments you are choosing to use to be sure none of them will injure your child.
- Take time to get away and relax so that you have enough energy and are better able to deal with your child's therapy.

Pathophysiology Illustrated: **Chemotherapeutic Drug Action**



Chemotherapeutic drugs either act at specific parts of the cell cycle or are nonspecific for action (act throughout all cell phases). See *Medications Used for: Cancer Chemotherapy* for further information about specific drugs and their site of action in the cell cycle.

SAFETY ALERT!
Nurses who care for a child receiving implant radiation or who work in a radiation department need to wear a dosimeter film badge at all times to measure their radiation exposure.

radiation treatment might be once daily 4 or 5 days per week for a period of 2 to 7 weeks.

Examples of cancers treated with radiation include Hodgkin disease, Wilms tumor, retinoblastoma, rhabdomyosarcoma, and central nervous system disease in leukemia. Tumors that have a low sensitivity to radiation, such as osteosarcoma and soft-tissue sarcomas, require higher doses of radiation, or other treatments may be preferred.

Medications Used for: Cancer Chemotherapy

MEDICATION AND ACTION/INDICATION	NURSING IMPLICATIONS
Cell Cycle–Specific Agents	
Antimetabolites • 5-Azacytidine • 5-Fluorouracil • 6-Mercaptopurine • 6-Thioguanine • Cytosine arabinoside (cytarabine) • Hydroxyurea • Methotrexate The antimetabolites work at the synthesis phase of cell division; interfere with function of nucleic acid; inhibit DNA or RNA synthesis.	Various routes are used for individual agents, such as oral, intravenous, and intrathecal. Most common side effects are nausea and vomiting, myelosuppression, stomatitis. Specific agents such as methotrexate and cytarabine can cause neurologic toxicity with high doses. Consult drug books and package inserts for a detailed list of side effects. Obtain baseline CBC, liver function, renal function. Monitor intake and output and body weight. Ensure hydration and output levels ordered by oncologist. Monitor vital signs and cardiovascular and respiratory function. Watch for bleeding and signs of infection. Monitor carefully during administration for signs of anaphylaxis.
Vinca alkaloids • Etoposide • Teniposide • Irinotecan • Paclitaxel • Vinblastine • Vincristine Act during mitosis; bind with cell proteins to inhibit nucleic acid and protein synthesis.	Most are given intravenously with some drugs also available for oral route. Common side effects include nausea and vomiting, abdominal cramping and diarrhea, constipation, paralytic ileus, hair loss, hypotension or hypertension, peripheral neuropathy and neurologic toxicity (latter especially with vinblastine and vincristine). Obtain baseline blood work. Consult specific drug information for period of maximum myelosuppressive effect. Be alert for bruising, infection, and other signs of myelosuppression. Monitor carefully during administration for signs of anaphylaxis, particularly with etoposide and paclitaxel.
Miscellaneous—G_1 phase activity • L-asparaginase Causes depletion of asparagine, needed by cancer cells; makes cell in G_1 phase vulnerable to other agents; interferes with synthesis. Used in combination with other agents in leukemia and other cancers.	Administered intravenously or intramuscularly. Major side effects are severe nausea and vomiting, hypersensitivity, renal failure, myelosuppression, acid–base imbalance. Because of the risk of life-threatening hypersensitivity reactions, emergency medications and care must be immediately available. Perform CBC, serum amylase, glucose, coagulation factors, bone marrow function, liver function tests before therapy and twice weekly. Monitor intake and output, neurologic status, gastrointestinal symptoms, abdominal pain.
Miscellaneous—G_2 phase activity • Etoposide Works at G_2 phase; binds cellular proteins to cause metaphase arrest; also acts on S phase of DNA synthesis. Used with other agents, particularly in recurrent disease.	Administered orally and intravenously. Common side effects are nausea and vomiting, myelosuppression, hair loss, diarrhea. Can cause anaphylaxis; hypotension and IV site pain with rapid infusion. Perform baseline CBC, liver, and renal function tests. Check IV site frequently since extravasation can cause necrosis. Monitor vital signs during infusion and stop drug if hypotension occurs. Keep emergency drugs and equipment readily available.

(*continued*)

Medications Used for: Cancer Chemotherapy (*continued*)

Cell Cycle–Nonspecific Agents

Alkylating agents • Cyclophosphamide • Carboplatin • Cisplatin • Busulfan • Chlorambucil • Ifosfamide • Thiotepa • Mechlorethamine • Melphalan • Procarbazine • Dacarbazine Substitute an alkyl group for a hydrogen atom, leading to blockage of DNA replication. Used for treatment of many cancers, either alone or in conjunction with other agents.	Most are administered orally and/or intravenously. Array of side effects depending on specific drug. Some common side effects are nausea and vomiting, diarrhea, myelosuppression, hair loss, neuropathies, pulmonary toxicity, renal damage; secondary tumors later in life associated with some agents. Obtain CBC and full blood work before and during treatment. Mesna may be administered with some alkylating agents to lower the risk of hemorrhagic cystitis. Monitor for side effects of the specific agents administered. Ensure generous hydration and monitor intake and output. Teach family the importance of long-term monitoring for secondary tumors.
Antibiotics • Doxorubicin • Mitomycin-C • Dactinomycin • Bleomycin • Daunorubicin • Idarubicin • Mitoxantrone Interfere with nucleic acid, inhibiting DNA or RNA synthesis. Used in combination with other agents to treat leukemia and other childhood cancers.	Most are administered intravenously. Common side effects include nausea and vomiting, myelosuppression, oral ulcers, skin and pulmonary toxicity. Several have cumulative dose toxicity, such as cardiac abnormalities (doxorubicin) and skin/pulmonary (bleomycin); total dose the child has received must be monitored. Obtain baseline CBC and other blood studies and monitor throughout therapy. Monitor vital signs, lung function, cardiac function, and neurologic status throughout and following therapy. Be alert for signs of myelosuppression and mucosal ulcers.
Nitrosoureas • Carmustine • Lomustine Cross-breakage in DNA strands so that DNA and RNA replication cannot occur. Used in lymphomas and other childhood cancers. Can cross blood–brain barrier.	Administered orally (lomustine) or intravenously (carmustine). Major side effect is myelosuppression. Others include pulmonary fibrosis, eye infarction, skin changes, hair loss, nausea, and vomiting. Obtain baseline and periodic CBC and other studies. Monitor pulmonary function, skin, and signs of infection or bleeding such as ecchymosis or petechiae.
Hormones • Prednisone • Prednisolone • Dexamethasone Analog of hydrocortisone; anti-inflammatory; delayed and depressed immune response. Used in conjunction with other agents for many types of childhood cancer.	Often administered orally. Numerous side effects including edema, moon face, mood lability, increased appetite, disturbed sleep, immunosuppression, disturbed glucose control, osteoporosis. Teach child and family the effects of the drug. Minimize exposure to persons with infection. Monitor for infections in all systems. Monitor weight regularly. Take vital signs. Teach to take as directed. Drug must be tapered slowly at end of therapy.

Topoisomerase I inhibitor • Irinotecan • Mitoxantrone • Topotecan Inhibit the enzyme topoisomerase I in the cell nucleus, relaxing DNA and preventing its duplication. Used in conjunction with other agents to treat acute lymphocytic leukemia and other childhood cancers.	Administered intravenously: topotecan can be given intrathecally. Common side effects include nausea and vomiting, diarrhea, fever, dehydration, myelosuppression. Can alter liver function and cause skin changes. Obtain baseline and periodic CBC and other studies, including liver function. Monitor for signs of myelosuppression, gastrointestinal distress, change in liver function.

BIOTHERAPY

Biotherapy is the use of biologic retooling and molecular intervention to produce targeted cancer therapy. Biologic retooling uses parts of the human body that are programmed to destroy cells, and applies them to the cancer cells. An example of this technique includes development of antibodies that are tumor specific to certain cancers, and produced by the body in response to antigens of cancer cells (Smith & Reaman, 2015). These antibodies promote apoptosis or death of the cancerous cells. Another example is the group of drugs that stimulate the body's own immune response. Cancer vaccines are under development that may work to help the body fight cancers; already developed is human papillomavirus vaccine (see Chapter 16). The actions of many of these agents are not completely understood and may have different effects in children versus adults, and some agents have more than one effect. For example, interferon has both antiviral and antiproliferative effects on some malignant cells. Interferon and tumor necrosis factor (TNF) are undergoing clinical trials to study their effectiveness and to develop protocols for their safe use against selected cancers.

Molecular targeting involves interference with metabolic pathways (e.g., through enzyme disruption) in the tumor cells. It may therefore disturb the cell's growth and development and thereby depress proliferation.

Medications Used During Cancer Treatment: Colony-Stimulating Factors

MEDICATION AND ACTION/INDICATION	NURSING IMPLICATIONS
Epoetin alfa (human recombinant erythropoietin) This glycoprotein stimulates the bone marrow in RBC formation; useful when numbers of RBCs are low because of chemotherapeutic effects.	Give subcutaneously or intravenously. Do not shake and do not use if discolored or particles are present. Single-dose vials only, so discard any solution that is not used. Obtain red blood cell tests before therapy and periodically after; improvement in hematocrit should be seen in 7–14 days. Monitor blood pressure before and during therapy because hypertension can result. Monitor for change in neurologic response and headache; both seizures and strokes are possible side effects.
Filgrastim (Neupogen) and pegfilgrastim (Neulasta) These human granulocyte colony-stimulating factor preparations (G-CSF) increase the bone marrow's production of neutrophils.	Administered subcutaneously and intravenously; prepare as directed for IV infusion to prevent its absorption by IV tubing. Single-dose vials only so discard any solution that is not used. Incompatible with many medications; check package insert; do not give within 24 hr before or after chemotherapeutic drugs or their effect may be decreased. Obtain baseline and twice weekly CBC. Monitor for side effects such as bone pain and heart arrhythmias; report fevers and be alert for other signs of infection when neutrophil count is low.
Oprelvekin (Neumega) A hematopoietic growth factor, interleukin-11, that increases platelet count; useful in low platelet count due to chemotherapeutic effects on bone marrow.	Administered subcutaneously. Single-dose vials only, so discard any solution that is not used. Obtain baseline CBC and platelet count; monitor platelets throughout treatment. Monitor for side effects such as edema, fever, CNS changes, tachycardia, respiratory problems, and skin rash. Take daily weights and monitor for fluid retention.

An additional type of biologic therapy is gene therapy, or attempting to replace a faulty gene with one that is normal. Genetic technology is growing rapidly and shows promise for future treatment of cancer and other childhood diseases. This complex field includes research to identify genes that lead to disease, recombinant techniques to enable genetic engineering, and studies of enzymes active in DNA and RNA formation. Nurses need to have enhanced knowledge of this important work as technologies are increasingly applied in cancer treatment (Calzone et al., 2014; Greco et al., 2011).

BONE MARROW AND HEMATOPOIETIC STEM CELL TRANSPLANTATION

Bone marrow and hematopoietic stem cell transplantation (HSCT) are used to treat leukemia, neuroblastoma, and some noncancerous conditions such as aplastic anemia. The goal of therapy is to administer a lethal dose of chemotherapy and radiation that will kill the cancer, and then to resupply the body with stem cells either from the child's own bone marrow that was previously removed (autologous transplant) and stored or from a compatible donor (allogeneic transplant). Umbilical cord blood is a potential source of stem cells used for transplant, as are peripheral blood stem cells (obtained from the donor's circulating blood rather than from bone marrow). The donor, whether autologous or allogeneic, can be given growth factors prior to donation to stimulate production of stem cells. An advantage of peripheral stem cells is that they can be easily collected somewhat less painfully and invasively than by the procedure of a bone marrow aspiration.

Transplantation has become the treatment of choice for some cancers when a relapse occurs while the child is receiving another form of cancer therapy and for primary treatment of certain cancers. First, a histocompatible donor must be located. The child then receives intensive chemotherapy, often followed by total body irradiation. Beginning 7 to 10 days before the transplant, this treatment kills all circulating blood cells and bone marrow contents. Following this treatment, the child is intravenously transfused with the donor bone marrow or other source of stem cells. New blood cells usually form within 2 to 8 weeks. (See Chapter 23 for a description of care for the child undergoing transplantation.)

Stem cells that become established in the host child's bone marrow can also be obtained from newborn umbilical cord blood. For some children this has become a better option than waiting for a matching bone marrow donor. Cord blood can be easily collected at birth from a sibling of the ill child because histocompatible matches often occur in siblings, or cord blood banks may offer a match. The umbilical cord blood is then infused into the child undergoing treatment, and the same mechanism occurs as in transplantation of bone marrow—implantation of the stem cells into the child's bone marrow and production of normal blood cells over about 2 to 6 weeks. Advantages of umbilical cord blood are that, unlike bone marrow collection, it is not painful for the donor and does not require anesthesia, there is an opportunity to easily collect samples from many ethnic groups that are underrepresented in bone marrow donor registries, graft-versus-host disease after treatment is less prevalent, and storage of umbilical cord blood for use later in life is possible. A variety of federally funded and private blood banks are available to store and provide umbilical blood.

COMPLEMENTARY THERAPIES

Many families use **complementary therapies** in treatment of a child's cancer. These approaches to care are also referred to as alternative or unconventional, and may involve nutritional supplements, oral herbal supplements, touch therapy, and mind/body interventions. Little research has been done on complementary therapies, although up to 80% of children with cancer have used at least one such therapeutic approach (Paisley, Kang, Insogna, et al., 2011). Healthcare providers should be aware of these practices, inquire in a nonjudgmental manner about the therapies, and attempt to learn about specific therapies and practices. Although some herbs and nutritional products such as St. John's wort may decrease serum concentration of chemotherapeutic agents, or some may act as hormones in the body, most are not known to negatively affect contemporary medical treatment. The families should be assisted in seeking information and supported in use of their chosen therapies. Eating fruits and vegetables is associated with lower cancer incidence in adults, and some foods such as garlic and oranges may slow cancer growth or enhance medical chemotherapy. Some individuals use herbal supplements to treat cancer; these include cat's claw (bark of a tree root), mistletoe, and shark cartilage. The U.S. Food and Drug Administration has allowed testing of the efficacy of some herbal treatments for cancer. Some herbs can decrease nausea and vomiting, and others can boost the immune system's function. Several cancer drugs such as vincristine and paclitaxel are obtained from plant products.

END-OF-LIFE CARE

In spite of modern medical practices and complementary therapies, some children do not survive childhood cancer. In these cases, the focus of health care is to provide comfort and emotional support for the child and family. Too often, healthcare providers feel uncomfortable when a child is expected to die and may withdraw from close contact with the child or family, fail to provide adequate comfort measures, and leave the family without access to needed resources. When recognition of prognosis is delayed, children suffer more and end-of-life care is less integrated. Some symptoms for which children are commonly undertreated include pain, dyspnea, nutrition, elimination, and fatigue. Additionally, care may be required from a wide array of specialists, which can lead to fragmentation of care and lack of integrated palliative approaches.

Care for the dying child can be enhanced by an end-of-life or palliative care team; an integrated plan of care; collaboration among families and healthcare providers; and a focus on the child's developmental level and family needs. Parents state that an advanced care directive that outlines the medical care plans for the child is helpful in preserving the child's quality of life and increases the child's comfort. See Chapter 13 for a detailed description of terminal care for children with terminal disease.

Special Issues in Childhood Cancer

ONCOLOGIC EMERGENCIES

Oncologic emergencies can be organized into three groups: metabolic, hematologic, and those involving space-occupying lesions. The most common metabolic emergencies include tumor lysis syndrome and septic shock, while common hematologic emergencies include bone marrow suppression, gastrointestinal and central nervous system bleeding, and disseminated intravascular coagulation. The most common emergencies involving space-occupying lesions include brain herniation, spinal cord compression, and superior vena cava compression from a superior mediastinal mass. The next sections describe these and other oncologic emergencies in more detail.

Metabolic Emergencies. Metabolic emergencies result from the lysis (dissolving or decomposing) of tumor cells, a process called *tumor lysis syndrome*. This cell destruction results in hypocalcemia, hyperkalemia, hyperphosphatemia, and hyperuricemia. It is seen most commonly in children with non-Hodgkin

TABLE 24–3 Clinical Manifestations and Management of Tumor Lysis Syndrome

ETIOLOGY	CLINICAL MANIFESTATIONS	CLINICAL THERAPY	NURSING IMPLICATIONS
Breakdown of malignant cells releases intracellular components into blood.	Hyperuricemia Hyperkalemia Hyperphosphatemia Hypocalcemia	• Vigorous hydration with 2–4 times maintenance fluid • Correction of electrolyte imbalances • Administration of allopurinol or urate oxidase (Rasburicase) to reduce conversion of metabolic by-products to uric acid	• Administer fluids, beginning before therapy. • Carefully measure intake and output. • Record daily weight. • Monitor urine specific gravity; it should remain less than 1.010. • Monitor for desired and side effects of drug therapy.
Electrolyte imbalance causes metabolic acidosis and serious abnormalities.	Cardiac arrhythmias Impaired renal function Tetany, neurologic and mental status changes	• ECG monitoring • Medications such as furosemide to facilitate potassium excretion • Dialysis may be needed	• Administer electrolytes and medications. • Urine pH should remain 7.0–7.5. • Perform Trousseau and Chvostek signs for tetany monitoring and assess neurologic function. • Perform mental status examination. • Obtain laboratory specimens as needed.

lymphoma (especially the subtype Burkitt lymphoma), acute lymphocytic leukemia, and acute myeloid leukemia (Burns, Topoz, & Reynolds, 2014; Kishimoto et al., 2014). (See Table 24–3.) The nurse collects laboratory studies, including CBC, absolute neutrophil count (ANF), serum electrolytes, bicarbonate, uric acid, blood urea nitrogen (BUN) and creatinine, and urinalysis. The emergency can be life threatening, and the family will need ongoing support and explanations about care.

A second type of metabolic emergency is septic shock. During periods of immune suppression, the child is vulnerable to overwhelming infection, resulting in circulatory failure, inadequate tissue perfusion, and hypotension. Septic shock can be fatal (see Chapter 21 for a description of septic shock), so early and aggressive treatment improves outcome. Factors contributing to massive infection include inadequate neutrophil production, abnormal granulocytes (not able to be actively phagocytic), erosions through normal barriers such as blood vessels and mucous membranes, and altered bone marrow production caused by chemotherapy and some forms of radiation. Such infections may manifest with hyperthermia or hypothermia, tachycardia, tachypnea, hypotension, mental changes, and peripheral cyanosis and coolness, and must be vigorously treated with antimicrobial therapy and hydration management.

A third type of metabolic emergency occurs when treatment destroys large amounts of bone, resulting in hypercalcemia (elevated calcium in the serum). Hypercalcemia is most common in children with acute lymphocytic leukemia and rhabdomyosarcoma. Treatment includes hydration and adequate oral phosphate supplement (Demirkaya, Sevinir, Yalcinkaya, et al., 2012; Kolyva, Efthymiadou, Gkentizi, et al., 2014).

Some children develop syndrome of inappropriate antidiuretic hormone (SIADH) and have excessive release of ADH. The resulting decreased urinary output leads to water intoxication. See Chapter 30 for a detailed description of SIADH.

Hematologic Emergencies. Hematologic emergencies result from bone marrow suppression or infiltration of brain and respiratory tissue with high numbers of leukemic blast cells (hyperleukocytosis). Bone marrow suppression results in anemia and thrombocytopenia with resultant hemorrhage. Gastrointestinal and central nervous system bleeding (strokes) are common. Disseminated intravascular coagulation (DIC) occurs in some children and is a life-threatening complication. See Chapter 23 for a thorough description of this condition. Disruption of normal WBC production and resulting hyperleukocytosis can lead to obstruction of small blood vessels throughout the body.

Treatment involves infusion of packed red blood cells for anemia; and platelet transfusion, vitamin K, and fresh frozen plasma for thrombocytopenia and hemorrhage. Hyperviscosity is treated by plasmapheresis, hydroxyurea, and close management of chemotherapy. Respiratory and other vital support is needed (Henry & Sung, 2015; Lewis, Hendrickson, & Moynihan, 2011).

Space-Occupying Lesion. Extensive tumor growth may result in spinal cord compression, increased intracranial pressure, brain herniation, seizures, massive hepatomegaly, and superior vena cava syndrome (obstruction of the superior vena cava by tumor). These emergencies are often caused by neuroblastoma, medulloblastoma, astrocytoma, Hodgkin disease, or lymphoma. After biopsy of the mass, treatment involves radiation therapy, chemotherapy, and corticosteroids.

PSYCHOSOCIAL NEEDS

The diagnosis of cancer is devastating for families. They cannot believe that their vibrant, young child or adolescent has a potentially life-threatening disease. Families are in a state of crisis when the diagnosis is made, with the first response being one of shock. At the same time that they are in a state of shock about the diagnosis, parents must gather resources to support the child, make treatment decisions, and adjust family life to integrate the needs of the child with cancer. Some families need to travel a great distance for the child's treatments, and others may have financial constraints that make healthcare costs a major concern. For nearly everyone, parental work schedules as well as arrangements for other children must be adjusted. Most cancer treatment will last for a minimum of several months up to several years, necessitating nearly constant adaptation. Parents, siblings, and extended families should all be included in plans of care.

The child reacts to the diagnosis based on age. Infants and toddlers are unaware of the severity of the disease, but react to a change in routine and to the anxiety of the care providers. Preschoolers are beginning to understand illness; however, they may think they caused their illness and are confused about why the parent cannot make the illness go away. School-age children can understand a diagnosis of cancer and benefit from opportunities to talk about the experience. Adolescents find contact with others who have gone through their experience reassuring and supportive. Nearly all children are hospitalized after diagnosis, and care should include proximity to parents, involvement in self-care appropriate for age, positive relationships with staff, and emotional care. Programs such as group therapy sessions, computer programs about cancer and treatment, and school reintegration all show potential for assisting youth who are adjusting to cancer. Children with cancer are commonly anxious about the treatments and disturbed schedules and routines (National Cancer Institute, 2011d).

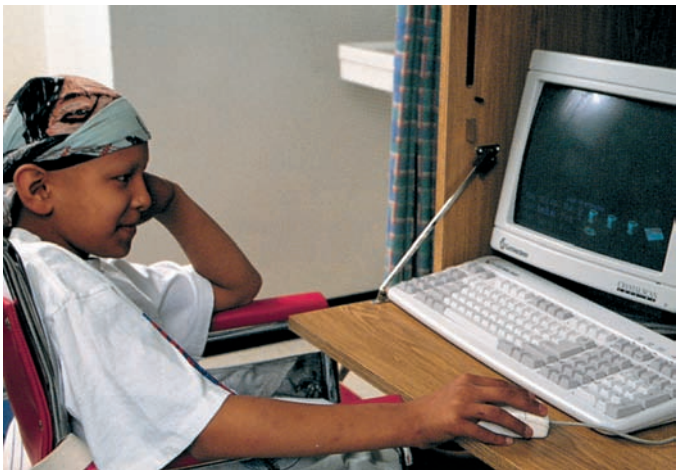


Figure 24–4 One of the most common threats to a child's body image at any age is hair loss induced by chemotherapy. Use of hats can improve self-concept.

Nursing Management

For the Child With Cancer

Nursing Assessment and Diagnosis

HISTORY

During health promotion visits of all children, nurses take into account the importance of a history of cancer in the family. Particularly when more than one person has had cancer, and when young children in the extended family have been affected, complete a family history, or genogram, to isolate cases in the family (see Chapter 3 for examples of genograms). A history of exposure to known carcinogens is also important. Does a parent work in an industry with substances like chemicals or asbestos that might remain on clothing worn home? Was the child treated with radiation or chemotherapy for a previous cancer? Does the child have an identified condition with a high incidence of some type of cancer, such as Down syndrome? Does the child have any recognized congenital anomalies? A number of conditions are more commonly associated with certain types of cancer.

PHYSIOLOGIC ASSESSMENT

When performing any physiologic assessment on children, consider the possible signs and symptoms of cancer. These include anemia, frequent infections, bleeding disorders, loss of weight, fatigue, pain, and changes in mental health and neurologic status. Assessment of children with the most significant types of childhood cancers is presented later in the chapter.

Once cancer has been diagnosed, a thorough physical assessment of all systems is needed to help identify the presence and extent of cancer (see Chapter 5). Systems needing particularly thorough assessments are neurologic, respiratory, cardiac, and gastrointestinal. Assess hydration status and the tumor site if it is visible. Carefully measure height and weight, and compare with prior findings for the child. Observe gait and coordination, as well as any changes in mental status. Evaluate immunization status, pain, nutritional intake, fatigue, infections, bruising, shortness of breath, and elimination problems. Periodic laboratory studies will be performed. Tailor assessments to the side effects of particular treatments. For example, the child on chemotherapy is likely to experience a **nadir** (lowest point) of WBC count about 10 days after drug administration so blood counts are needed then.

PSYCHOSOCIAL ASSESSMENT

Assessment of body image, stress and coping abilities, knowledge of the condition and cognitive level, support systems, and developmental level provides data that help determine the appropriate nursing interventions for the child with cancer and the family.

Body Image

Hair loss, surgical scars, and cushingoid changes are three common treatment-induced threats to body image. Most children being treated for cancer experience hair loss (Figure 24–4). Children who have cranial surgery lose hair as part of the surgical preparation. Chemotherapy frequently results in some degree of hair loss. The speed of hair loss is unique to the child and can be as rapid as overnight or slower, with hair left on the pillow and in the hairbrush.

A second challenge to the child's body image is surgery. The scars of cranial and neck surgery are obvious, as are amputation and limb salvaging. Abdominal surgery for lymphoma is more easily concealed but is still a threat to the child's body image.

A third source of altered body image is the cushingoid features, such as round and flushed face, prominent cheeks, double chin, and generalized obesity (Figure 24–5), that result from the

Figure 24–5 The child with cushingoid changes frequently has a rounded face and prominent cheeks.

As Children Grow: **Children Need Help in Coping With the Physical Effects of Cancer Treatment**

Children of different ages experience differing threats to body image as a result of cancer treatment. A preschool girl may be most upset at hair loss because she now looks like a boy. For many parents, especially of daughters, the loss of the child's hair can be devastating. Ask the parents and the child what the loss is like for them. Prepare them for the fact that hair loss can be rapid or slow. Find out how they will plan to cope. Some children want the hair cut very short so its loss will not be as traumatic. Offer resources for wigs, hats, or other ideas. Put them in touch with children who have lost hair and with those who have now regrown it.

A school-age child has the most difficult time with changes that interfere with the developmental task of industry. Amputation, which decreases the child's ability to participate in activities such as sports, dancing, and schoolwork, can be a major challenge during the school-age years. Assist children to adapt to new sports when they are able to do so. Partner with schools, coaches, and families to facilitate children's participation in activities they choose.

Teenagers are often most worried about changes like hair loss and cushingoid features, which cause them to look different from peers. Introducing adolescents to others of their own age who are coping with similar conditions can assist them in their developmental tasks.

use of corticosteroids. As the child's weight increases, stretch marks similar to those of pregnancy may occur. These stretch marks often remain after the corticosteroids are decreased.

Body image disturbances occur when a child cannot integrate changes and continues to cling to old images despite their inconsistency with reality. Common means for assessing body image are drawings, colored pictures cut out by the child to form a collage, discussion, and observation. See Chapter 11 for further discussion of these and other assessment techniques that can be used with children.

Stress and Coping

The diagnosis of cancer is a major stressor for both the child and the family. Although each child's prognosis and each family's coping mechanisms are unique, most families deal with the diagnosis in a manner similar to that of other families who have a child with a life-threatening illness (see Chapter 13). Assess the family (and child if old enough) for their understanding and acceptance of the diagnosis. Find out if the family has told the child and siblings about the diagnosis and if they need assistance in deciding how to do this. Assess the level of anxiety during healthcare visits and scheduled treatments (Figure 24–6). Evaluate the family's methods of coping, such as the ability to integrate relaxing and meaningful activities into family life, the use of support systems in the extended family and community, and the ability to alter expectations to take into account the child's health status. Some families demonstrate resilience and the ability to assist the child and all of their members. Other families, however, may be experiencing multiple stresses, making adaptation to the new diagnosis particularly difficult. Concurrent stressors increase the difficulty of coping with childhood cancer. Evaluate the family for stressors such as illness or death of another family member, occupational changes, financial problems, relocation, and change in vacation plans. Evaluate the family's knowledge of the U.S. Family and Medical Leave Act benefits, which enable parents to use sick time, vacation, and leave without pay to care for an ill family member while safeguarding employment.

Figure 24–6 The child with cancer depends on parents and family members to provide support. Nurses can assist families and draw on their strengths to help the child.

Knowledge

Anxious people tend to narrow their scope of attention and may read unintended messages into the behaviors of healthcare personnel. Anxiety also limits a person's ability to retain information.

Assess the child's knowledge of cancer and its treatment throughout the treatment period. As the child matures cognitively, reevaluate knowledge. Cancer and its treatment are complex topics. Parents are exposed to information in various forms, including written material, news reports, and Internet websites and resources. Evaluate their knowledge and information sources and provide them with opportunities to ask questions. Evaluate the learning style of the child and family in order to adapt approaches to meet their needs.

Support Systems

Cancer treatment generally occurs over a long time. The extended family is crucial in providing necessary support to the child, parents, and siblings. Identify key people in the family. They may be the parents, grandparents, or aunts and uncles. Support groups for children or other family members often help individuals and the family meet the challenges of the disease. Thoroughly assess the coping strategies the family uses to meet the various challenges posed by the child's illness. This information helps predict the success of interventions, such as home care with intravenous medications, and assists in deciding when referrals for other supportive therapies are needed.

The return to school may pose difficulties for the child with cancer or it may be a source of support to be connected again to peers. The child is encouraged to go to school, even if only for half a day per week, to stay connected to peers. Evaluate the school's ability to accept a child who is medically vulnerable into

the classroom. Assess whether the other children and teachers have been prepared for the appearance and needs of the child with cancer. Nurses who work in the oncology department of the hospital or clinic can ask if the family would give consent to visit the school, meet with the school nurse, and plan together to meet the child's educational needs. Help the teacher devise a plan to prepare the children, and offer to visit the classroom to explain what the child with cancer is experiencing. Arrangements can be made for tutors to help children keep up with schoolwork if they cannot attend school. An individualized education plan is needed. Parents need information about the legal right to home schooling and a specialized plan since the child is newly ill and they will likely not have been exposed to this in the past.

Assess family resources to identify support systems available to help the family during crises and if a child is expected to die. Extended supports include friends, jobs, insurance coverage, religious affiliations, cultural support systems, and the school system. Parents commonly lose contact with close friends after the diagnosis of cancer in a child. This is an additional stressor for the family. Jobs are often a source of support because coworkers may have gone through the same experience. It may also be comforting for parents to return to their jobs where they can feel a sense of security in tangible accomplishments. However, jobs can also be a source of stress if employers are unsympathetic to the demands of the child's hospitalization and clinic or office visits.

The nurse caring for a child and family in the end-of-life care phase can best support family members by helping them view the child's unique characteristics, conveying care and concern for the family, and continuing to have close contact with the dying child. Faith-based affiliations can be an important source of support. Evaluate whether such affiliations are meaningful for the family and, if so, plan for visits from the appropriate clergy. In some cultures, spiritual leaders are an important part of the family's support system. Enable a healer to visit the child and conduct a healing ceremony if that will be supportive to the family and child.

DEVELOPMENTAL ASSESSMENT

Developmental assessment of children should be performed regularly during treatment for cancer at times when the child is feeling well so that results are accurate. Assessment of the child's physical and neurologic development helps determine the progress made during treatment and provides a baseline for evaluating the long-term effects of treatment. Children under 6 years of age who have cancer should receive regular developmental assessment with a standardized screening tool (see Chapter 6). A home healthcare nurse can perform such testing, or it can be done by a nurse in the pediatric healthcare home (medical home) who sees the child for a general health supervision visit. Recommend referral to a neuropsychologist for testing early in treatment and if changes in developmental performance are noted. Children who have received cranial radiation and intrathecal chemotherapy need regular scholastic evaluations. Impaired neurocognitive performance may be a long-term effect of treatment. Observe developmental milestones at each contact with the child and refer for further assessment if regression has occurred. Performance in school and engagement in social activities with friends provide important information about expected developmental milestones in older children. If the parents have signed up for a clinical trial (research) treatment for the child, children should also give verbal or written assent when they have the cognitive maturity to do so.

ASSESSMENT FOR IMPACT OF CANCER SURVIVAL

Children with cancer have a variety of common psychologic and physiologic problems regardless of their specific type of

A

B

C

Figure 24–7 **Survivors of childhood cancer. *A*, Nicole, 11 years old, is undergoing chemotherapy for Ewing sarcoma. Her mother emphasizes, "It's our faith that has gotten us through this. The hardest part is how busy you are coming to treatments all the time. Nicole's younger brother sometimes feels neglected." *B*, According to Jesse, who is 10 years old and waiting for a bone marrow transplant, "The thing that has helped me the most [in dealing with acute lymphoblastic leukemia] is all the mail I got from my friends." His mother adds, "We're just really positive and think that everything will turn out all right." *C*, Cassie, 19 months old, has been diagnosed with neuroblastoma. At this age, it is hard for her to understand what is happening to her. Her mother has stayed with her each time she has come to the hospital, which has helped Cassie adjust to therapy. Her caregivers are confident that she will respond well to her treatment.**

Healthy People 2020

(C-14) Increase the mental and physical health-related quality of life of cancer survivors

cancer. They and their families are dealing with a complex illness that will influence their lives for years. The impact of this experience extends into all areas of function. During the past 20 to 30 years, treatment for childhood cancers has been increasingly successful, and 80% of children with cancer are now expected to have long-term survival. However, the success of new modalities and treatment combinations has created special healthcare needs for many survivors (Landier,Armenian, & Bhatia, 2015; Rueegg et al., 2013) (Figure 24–7).

Surgery can have many results. Body organs may be removed and manipulated, leading to adhesions, intestinal obstruction, visual impairment, neurologic disruption, and sterility. Removal of the spleen can lead to serious infections. Amputation necessitates the need for prosthetic devices and physical rehabilitation.

Radiation has several long-term effects. It can impair the growth of bones and teeth, leading to conditions such as scoliosis, leg length discrepancy, or poor dental health. Chronic pain can result from skeletal toxicity. Hypothyroidism can be observed in those who have had head and neck radiation. Cardiotoxicity and pulmonary toxicity can result from mediastinal radiation. Delayed puberty and sterility can result from radiation effects to the cranium and spinal regions. Impaired neurocognitive performance may occur as long-term effects of treatment, especially with higher doses of radiation.

Secondary cancers, most commonly solid tumors, occur in some survivors. **Secondary cancers** are also called *second malignant neoplasms (SMNs)*. They occur subsequent to the primary cancer and treatment but are of a different histologic type. Cancers of the central nervous system, skin, breast, bone, and thyroid are examples of secondary neoplasms (Reulen et al., 2011). Most of these cancers can be effectively treated, emphasizing the need for thorough and frequent monitoring of the treated patient with cancer. Other chronic conditions, such as heart failure, congestive heart failure, cognitive dysfunction, and reproductive problems are more common in cancer survivors who are adults than in the general population, whereas cardiovascular risk and insulin resistance may even be more prevalent in child cancer survivors (Steinberger et al., 2012).

TABLE 24–4 Common Side Effects of Chemotherapy

SIDE EFFECT	CLINICAL MANIFESTATIONS	CLINICAL THERAPY
Bone marrow suppression	Evidence of suppression usually appears 7–10 days after administration of chemotherapy; recovery is usually complete within 3–4 weeks.	Blood transfusions are administered when anemia is severe (Hgb less than 7–8 g/dL) or platelets are very low and clinical examination reveals signs and symptoms of anemia or bleeding. Some institutions use a low-microbial diet to decrease the possibility that infectious organisms will colonize the intestine. Septra is used for *Pneumocystis jiroveci* pneumonia (formerly known as *P. carinii*) prophylaxis; additional drugs for antifungal and antibacterial prophylaxis are under investigation. Instruct the family and child about the importance of protecting the body from bruising during periods of mild to moderate thrombocytopenia (platelet count: 5000–20,000/mm^3). Careful hand hygiene is essential. Encourage use of masks if family or staff has nasopharyngeal infections.
Nausea and vomiting	Symptoms may occur immediately or 5–6 hr after administration of chemotherapy and may last 48 hr.	Antiemetics, such as ondansetron (Zofran), granisetron (Kytril), metoclopramide (Reglan), and diphenhydramine (Benadryl), are used to treat this side effect. Teach relaxation techniques, hypnosis, and systematic desensitization (a hypnotic process that progressively reduces reactions to objects that cause strong emotional or physical responses) to help decrease the child's symptoms. Encourage mild exercise and change of diet (eating only easily digestible foods) 12 hr before chemotherapy.
Anorexia and weight loss	May occur at any time.	Hyperalimentation is necessary if dietary changes are unsuccessful in halting the child's weight loss. Pay careful attention to changes in taste that affect food preferences. Referral to a dietitian may be helpful to achieve successful modification of the child's diet.
Oral ulcers	The oral mucositis resulting from chemotherapy usually occurs within 3–4 days and is often a contributing factor in anorexia.	Antifungal agents, such as nystatin or clotrimazole, lessen the possibility of candidal infection. Promote good oral hygiene, use soft foam wand or water irrigation to clean teeth; commercial mouthwashes are not recommended because they contain alcohol and increase drying of the oral cavity; specially formulated pharmacologic mouthwash may promote comfort.

(*continued*)

TABLE 24–4 Common Side Effects of Chemotherapy (*continued*)

SIDE EFFECT	CLINICAL MANIFESTATIONS	CLINICAL THERAPY
Constipation	Can occur at any time in treatment but becomes more common as therapy progresses and dietary intake and physical activity decrease.	Stool softeners and laxatives are used to treat this side effect (e.g., MiraLAX). Advise parents to increase fluids and fibrous foods in the child's diet.
Pain	Pain can occur at any time and is best understood by subjective explanations of the child.	Acetaminophen, morphine, steroids, and antidepressants may be used to manage pain; nonsteroidal anti-inflammatory drugs are often avoided because of their promotion of bleeding. Careful pain assessment is important; the location of the pain may provide a clue to its cause, for example, metastasis to the skull, infiltration of joints, or damage to soft tissue; pain associated with chemotherapy may also be related to oral mucositis, myalgia, or tumor embolization; painful polyneuropathy can follow treatment with vincristine or cisplatin. Acetaminophen for pain can mask the presence of fever, which signals infection; careful and complete physical assessment is needed to identify infection. Pharmacologic, nonhypnotic (deep breathing, self-control), and hypnotic methods of pain control may be used; the nonpharmacologic methods often prove helpful to children with pain from multiple etiologies.

Chemotherapy can cause a wide variety of effects, both during its administration and for years afterward (Table 24–4). Cardiomyopathy can occur with some drugs, especially the anthracyclines. Temporary or permanent pulmonary toxicity and renal complications can develop. Neurologic effects of some drugs can lead to hearing loss (e.g., cisplatin and ifosfamide), cataracts, and paraplegia (e.g., intrathecal methotrexate for leukemia). Learning disabilities or change in intelligence quotient (IQ) occurs in some children; infertility may result (Kirchhoff et al., 2011).

The diagnosis and stress of treatment, along with the risk of recurrence, are significant stressors for the child with cancer. Families may find it difficult to obtain full insurance coverage for the child who has had a prior cancer. Employment can be a potential problem for cancer survivors if employers have concerns about the earlier cancer diagnosis. Most people with cancer report fear of recurrence of the disease, which is a stressor. Some children report decreased quality of life (QOL) and emotional distress (Rueegg et al., 2013; Winick, 2011). Conversely, hopefulness and the sense of having an added purpose in life can be positive outcomes for many cancer survivors. Some meet with others who have a recent diagnosis, or work on fund-raising events that financially support cancer research. Survivorship services and care plans promote positive health outcomes (Eshelman-Kent et al., 2011).

Nurses are involved with families when a diagnosis of cancer is made, during the therapy process, and in the years that follow. For a child who survives cancer, ongoing care is essential. Evaluate the child regularly with thorough physical, psychosocial, developmental, and cognitive assessments. Carefully monitor all body systems (e.g., cardiovascular; respiratory; musculoskeletal; eye, ear, nose, and throat; genitourinary). Record height and weight, growth patterns, and nutritional patterns. Ask about the child's interactions with peers and performance at school. Children who have received cranial radiation and intrathecal chemotherapy need regular scholastic evaluations. Be alert for signs and symptoms that could indicate a secondary tumor. Periodic laboratory studies will be performed. Ask the parents about insurance coverage and other financial difficulties during ongoing care.

Plan care to assist the family to manage any long-term effects of cancer treatment. This may involve physical rehabilitation, support related to visual impairment, or treatment for cardiac or musculoskeletal abnormalities. Provide resources for information and support. Facilitate periodic evaluations in a healthcare agency so that serious outcomes of treatment can be identified early.

The accompanying *Nursing Care Plans* include several diagnoses that may be appropriate for the child with cancer who is receiving care in the hospital or at home. Among the many other diagnoses that may be appropriate for a child with cancer are the following (NANDA-I © 2014):

- ***Diarrhea*** related to radiation therapy and toxins
- ***Urinary Elimination, Impaired,*** related to chemotherapy
- ***Tissue Integrity, Impaired,*** related to the effects of chemotherapy and radiation therapy on oral mucosa
- ***Skin Integrity, Impaired,*** related to altered nutritional state, effects of medication, radiation, and immobilization
- ***Coping, Ineffective,*** related to situational crisis of chronic and acute illness
- ***Caregiver Role Strain*** related to anxiety and disruption in family roles and patterns
- ***Sleep Pattern, Disturbed,*** related to biochemical agents, anxiety, and unfamiliar surroundings
- ***Body Image, Disturbed,*** related to chronic illness and treatments
- ***Knowledge, Deficient (Child or Parents),*** related to lack of exposure to disease or treatments
- ***Grieving*** related to actual or potential loss

Nursing Care Plan: Hospital Care of the Child With Cancer

1. Nursing Diagnosis: *Pain, Acute,* related to tissue injury (NANDA-I © 2014)

GOAL: The child will report reduced pain that is manageable.

INTERVENTION	RATIONALE
• Give analgesics as ordered.	• Adequate medications can reduce pain.
• Teach relaxation techniques, deep breathing, and distraction.	• Nonpharmacologic methods work with the medication to reduce pain.
• Insert pain management techniques appropriate for developmental age (see Chapter 15).	• Developmental level determines the pain assessment method that should be used, as well as the most appropriate intervention methods, from rocking, to distraction, to providing information.

EXPECTED OUTCOME: Child will experience pain reduced to the level that allows the child to interact appropriately and gain rest.

2. Nursing Diagnosis: *Nutrition, Imbalanced: Less than Body Requirements,* related to inability to ingest or digest food or absorb nutrients (NANDA-I © 2014)

GOAL: The child will maintain adequate nutritional intake. The child will experience reduced effects of chemotherapy (i.e., nausea and vomiting).

INTERVENTION	RATIONALE
• Offer small feedings. Encourage favorite foods. Refer to dietitian for special meals. Weigh daily.	• Measures can increase caloric intake. Taste changes and mouth sores alter desire for food.
• Teach the child distraction and relaxation techniques. Give antiemetics according to orders.	• Pharmacologic and nonpharmacologic methods are effective in helping to reduce nausea.

EXPECTED OUTCOME: Child will maintain admission weight or preillness weight. The child will have minimal side effects of nausea and vomiting.

3. Nursing Diagnosis: *Fluid Volume: Excess or Deficient* related to medications (NANDA-I © 2014)

GOAL: The child will be adequately hydrated.

INTERVENTION	RATIONALE
• Record all intake and output. Monitor intravenous rate and solution as appropriate. Monitor output from urine and other output routes such as vomiting or diarrhea.	• Some drugs (e.g., cyclophosphamide) necessitate a high level of fluid intake to prevent complications. Careful balance of intake and monitoring of output are required.
• Test specific gravity of urine daily.	• Renal function may be affected by chemotherapy.

EXPECTED OUTCOME: Child will demonstrate adequate hydration. Mucous membranes will be hydrated. Specific gravity will remain within normal range.

4. Nursing Diagnosis: *Infection, Risk for,* related to immunosuppression, invasive procedures, malnutrition, or pharmaceutical agents (NANDA-I © 2014)

GOAL: The child will remain free of infection.

INTERVENTION	RATIONALE
• Wash hands often. Maintain in isolation if needed.	• Hand hygiene is effective to reduce organisms. Transmission-based precautions may be needed to safeguard child.
• Monitor temperature. Use a noninvasive method such as tympanic; report method used when recording temperature. Report elevation to healthcare provider.	• Elevated temperature is a sign of infection. Children with oral or intestinal mucositis should not have temperature taken in these mucous cavities since it may cause increased irritation.

EXPECTED OUTCOME: Child will remain infection-free.

(*continued*)

Nursing Care Plan: Hospital Care of the Child With Cancer (*continued*)

GOAL: The child will return to normal, uninfected state.

INTERVENTION	RATIONALE
• Administer intravenous antibiotics as ordered. Monitor temperature. Use cooling mattress as ordered. Report elevations over 38°C (101°F) to healthcare provider.	• Multiple antibiotics are needed to deal with bacterial and fungal infections during neutropenia. Blood cultures may be taken to identify organism.

EXPECTED OUTCOME: The child with an infection will be effectively treated.

5. Nursing Diagnosis: *Coping, Ineffective,* related to situational crisis (NANDA-I © 2014)

GOAL: The child will demonstrate normal adaptive coping methods.

INTERVENTION	RATIONALE
• Encourage drawings and other therapeutic play for expression of feelings. Allow for expression of angry feelings, such as hitting dolls and throwing sponge balls. Discuss how to behave during treatments.	• Expression of feelings helps identify avoidance coping for further intervention. Play is a normal way for the child to express self and ideas. Misinterpretations can be corrected. Knowledge of appropriate and helpful behaviors supports self-esteem.

EXPECTED OUTCOME: Child will continue to use usual coping strategies expected for developmental stage.

Planning and Implementation

Nurses have many resources to assist in planning and implementing nursing care for the child with cancer. Oncology Nursing Society and the Association of Pediatric Hematology and Oncology Nurses are examples of organizations helpful to nurses. The nursing care of children newly diagnosed with cancer and their families includes immediate physiologic and psychologic support, along with anticipatory guidance about imminent and future medical interventions. Assist and support the family as they make decisions about types of treatment that are appropriate for the child.

Nursing care of the hospitalized child with cancer and the child receiving ongoing therapy at home is summarized in the accompanying *Nursing Care Plans*. These care plans are designed for the child who has progressed beyond cancer diagnosis and is receiving chemotherapy.

Physiologic care of the hospitalized child focuses on providing support during treatment. This includes ensuring optimal nutritional intake, administering medications, managing the multiple side effects of chemotherapy and radiation, ensuring adequate hydration, preventing infection, and managing pain during diagnostic procedures and treatment.

Nursing Care Plan: Home Care of the Child With Cancer

1. Nursing Diagnosis: *Health Management, Family, Ineffective,* related to complex chemotherapeutic therapy (NANDA-I © 2014)

GOAL: The family and child will comply with the child's medication regimen.

INTERVENTION	RATIONALE
• Educate parents and child about the importance of taking medication as prescribed.	• Understanding can assist parents and child in placing importance on medication intake.
• Set up calendar with dates, times, and medications clearly labeled.	• Visual reminders can help them recall instructions.
• Reward the child for taking medications.	• Reinforcing desired behaviors through rewards is effective with children.

EXPECTED OUTCOME: Child will take all medications according to prescription.

2. Nursing Diagnosis: *Development: Delayed, Risk for,* related to serious illness (NANDA-I © 2014)

GOAL: The child will demonstrate normal physical, emotional, and cognitive development.

INTERVENTION	RATIONALE
• Encourage play appropriate to age.	• Normal activities support self-esteem and self-knowledge.
• Encourage the child to attend school when able to do so. Arrange for tutors at home when unable to attend.	• School is the work of the child and promotes cognitive and social growth.
• Encourage seeing peers when unable to attend school.	• Peer contacts help the child in normal developmental tasks.
• Work with teachers to support reentry to school. Use puppets, videotape, and discussion with classmates.	• Classmates need to understand what has happened to their friend without asking the child directly.

EXPECTED OUTCOME: Child will continue to develop physically, emotionally, and cognitively at a normal pace.

3. Nursing Diagnosis: *Fatigue* related to disease state (NANDA-I © 2014)

GOAL: The child will maintain energy levels necessary for normal activities.

INTERVENTION	RATIONALE
• Problem solve ways to save energy for play and school.	• The child and parents are assisted to see school and play as important.
• Plan with child for quiet activities during low-energy times.	• The child is empowered to select and plan own activities.

EXPECTED OUTCOME: Child will plan use of time effectively to maintain energy for school and play. The child conserves energy during times of increased fatigue.

ENSURE OPTIMAL NUTRITIONAL INTAKE

The high metabolic rate of cancer growth depletes the child's nutritional stores. In addition, the catabolic effect of chemotherapy and radiation on normal cells necessitates additional cellular replacement. The child needs increased nutritional intake at a time when nausea and vomiting are occurring as drug side effects, and when decreased activity, treatment protocols, and general health status result in diminished appetite. This often leads to extreme concern on the part of parents, and they may focus excessive attention on the child's intake.

Administer antiemetic drugs to lessen nausea from chemotherapy. Integrate feeding methods and foods that the family and the child find most helpful for ensuring adequate intake. Allow the family to bring the child's favorite foods to the hospital. Ask the family what treatments they use to decrease the child's nausea and vomiting. Perform 24-hour dietary recalls to assess the child's intake, and evaluate height and weight regularly. Special nutritional products may be given orally, nasogastric or nasoduodenal tube feedings may be given, or total parenteral nutrition may be necessary.

ADMINISTER MEDICATIONS

An important intervention of the oncology nurse is administering medications safely. Most chemotherapeutic drugs are prescribed and calculated as dose per meter squared (dose/m^2), with m^2 being calculated from the child's height and weight. (See the *Clinical Skills Manual* SKILLS.)

A number of chemotherapeutic drugs are commonly used in combinations. These drugs are prepared with special techniques under laminar flow devices to minimize potential toxic effects on healthcare providers. Gloves and other hazardous drug protocols are used. The Occupational Safety and Health Administration (OSHA) publishes an instruction manual entitled *Controlling Occupational Exposure to Hazardous Drugs* that outlines general guidelines, protective equipment, and procedures. Care must be taken to protect the patient as well; the nurse should avoid **extravasation** of intravenous drugs (leakage into the soft tissue around the infusion site) because permanent tissue damage can result.

In addition to chemotherapeutic drugs, the nurse administers other medications, such as antiemetics to control nausea, vitamin supplements, and antibiotics. Antiemetics such as ondansetron are given prophylactically when a cancer agent is administered that has known emetic effects. Ask parents about complementary therapy and medications they are obtaining from other sources and using at home. All medications must be safely administered and the child should be monitored for side effects. **Polypharmacy** (the use of several drugs at one time to treat multiple health conditions) can lead to multiple side effects and can challenge the body's ability to metabolize and excrete drugs.

Some children receive fluids and medications at home via central lines or by intramuscular or subcutaneous injection. Consider referral to home healthcare infusion agencies for monitoring of these treatments and provision of supplies for home use.

Families Want to Know

Nutrition and the Child With Cancer

Because of the effects of cancer and chemotherapy or other treatment, the child often has a poor appetite. Mucosal sores lead to difficulty chewing and swallowing. Parents can enhance the nutritional intake of the child in a variety of ways:

- Provide frequent small feedings rather than three meals daily.
- Integrate the child's favorite foods and the cultural foods common to the family into daily menus.
- Have nutritious snacks available for times when the child feels like eating.
- Sprinkle dried milk on top of cereals and other foods.
- Smooth, soft foods are usually preferred. Avoid acidic or spicy foods. Milkshakes with added peanut butter, puddings, and soft casseroles may be well tolerated. Try a variety of liquid protein-calorie supplements to find those the child likes.
- Avoid making food an area for disagreement. Do not force foods but rather make them readily available.
- If therapy is causing the child to vomit, do not encourage food at that time. The child may develop food aversions to foods that are vomited.
- Administer antiemetics as ordered during therapy since they can prevent nausea and vomiting.
- Report weight loss and increased fatigue.
- Bring the child in for scheduled health visits so growth, development, and effects of therapy can be monitored.
- Some children need a temporary feeding tube to ensure adequate nutrition. Feedings at night can often increase intake and promote health. Occasionally, a central line is inserted to provide total parenteral nutrition.
- Supplements and tube feedings will usually be covered by insurance if the healthcare provider writes an order for them.

MANAGE TREATMENT OF SIDE EFFECTS

All cancer treatments affect some normal body cells as well as cancer cells, causing a wide variety of side effects. Know all side effects of specific drugs administered and monitor for them. A frequent occurrence is **myelosuppression**, or suppression of blood cell production in the bone marrow. Be alert for signs of a decreased white blood cell count, such as infections. **Neutropenia** is present when the absolute neutrophil count is less than 500 cells/mm^3 or if between 500 and 1000 cells/mm^3 when chemotherapy is being given and falling levels are anticipated. At these levels, children will be given a broad-spectrum antibiotic; granulocyte colony-stimulating factor (G-CSF) may be given (refer to *Medications Used During Cancer Treatment: Colony-Stimulating Factors* earlier in the chapter). Take the child's temperature, isolate the child from others with infections, and perform serum laboratory studies as ordered. Although an elevated temperature generally indicates infection, in a child with immunosuppression, the temperature may be low even in overwhelming infection. A colony-stimulating factor for white cell production may be administered if necessary. A treatment known as *leucovorin rescue* is used in conjunction with high-dose methotrexate chemotherapy. Leucovorin (citrovorum factor) is a form of folic acid that helps protect normal cells from the destructive action of methotrexate. It is started within 36 hours of methotrexate administration and is given along with hydration therapy (Cohen & Wolff, 2013).

Protect the child from bruises and be alert for hemorrhage or signs of bleeding such as petechiae or the presence of blood in vomit and urine. These are all effects of **thrombocytopenia**, or decreased platelets. When thrombocytopenia occurs, minimize needlesticks and other intrusive procedures. Be ready to deal with nosebleeds and watch for bleeding gums. Report any bleeding episodes to the oncology specialist. Be sure parents know that the child should avoid contact sports or other rough activities and that any healthcare provider, such as a dentist, should be informed of the child's treatment and condition. Infusions to increase platelets are sometimes administered.

Inadequate red blood cell production can result in anemia. Encourage the child to eat iron-rich foods, and administer nutritional supplements as needed. Blood transfusions are sometimes needed to treat severe anemia.

Chemotherapy affects all rapidly growing cells in the body, but especially those of the mucous membranes. Provide good oral hygiene with a soft toothbrush, foam wand, or water irrigation device. Report oral breakdown promptly. See *Families Want to Know: Oral Care* for common techniques to manage oral hygiene. Be alert for blood in vomit and stool or dark-colored stools, all of which can indicate bleeding in the gastrointestinal tract. Blood in the urine may also occur. Know all side effects of specific drugs administered and monitor for them. Some side effects are late and may be seen after therapy is completed. Emphasize importance of all follow-up visits scheduled in the future for monitoring of late effects.

Radiation can cause burns to the skin. Examine the skin daily during hospitalization or weekly when making home visits. Leave the marks on the skin that outline the radiation target area. Avoid use of lotions, powders, and soaps on the target skin area. Some children may need to be anesthetized to ensure correct positioning for radiation; postanesthesia care will then be needed.

ENSURE ADEQUATE HYDRATION

Hydration management can be a challenge because the child may not be thirsty but is excreting large numbers of cell fragments and other substances as a result of treatment. Offer frequent small amounts of fluid. Include frozen ice pops or other fluid-containing foods such as Jell-O. Measure intake and output. To ensure adequate excretion, a number of chemotherapeutic drugs are given with intravenous fluids. It is important to administer fluids as ordered and ensure that the recommended urinary output excretion rate is maintained after drug administration.

Families Want to Know

Oral Care

Since cancer treatment and poor nutritional status can adversely affect the oral status of children, families need help to plan and carry out prophylactic and treatment measures. Children continue to lose teeth, have new teeth erupt, and require nutrients to help in building teeth not yet erupted even during cancer treatment. Some suggestions are:

- Provide a visit to the dentist early in treatment for assessment, treatment of dental disease, and establishment of a prevention plan.
- Brush teeth twice daily with a soft bristle brush and rinse with water.
- When granulocyte counts fall below 500/mm^3 or platelets fall below 40,000/mm^3, toothettes or gauze can be used to clean the teeth. Avoiding brushes will help to prevent bleeding and infection.
- Toothpaste can be used unless it causes discomfort.
- Medications may be used to prevent infection. They may include antibacterial mouthwash, nystatin, or fluconazole. Continue oral fluoride if it is not present in the drinking water.
- If bleeding, infection, or other oral care needs emerge, consult with the dentist and pediatric oncologist to develop a treatment plan.

PREVENT AND TREAT INFECTION

Children with cancer have an altered immune system, both from the disease and from the effects of immunosuppressant drugs, and must be kept away from persons with known infections. Teach parents to avoid taking the child to places that attract large gatherings of people, such as department stores, once the child returns home. Teach administration of any drugs being used to prevent infection such as pentamidine or sulfa preparations for *Pneumocystis* pneumonia prophylaxis. Emphasize the need to report any exposure to contagious diseases, especially chickenpox. Some drugs may mask signs of infection, so be alert for any signs of mild infection. Fever, malaise, and mild respiratory infection must all be reported promptly (see *Families Want to Know: Reportable Events for Children Receiving Chemotherapy*). Keep the child's immunization record so immunizations that have not been given yet can be administered in regular clinic visits after therapy is complete, using Centers for Disease Control and Prevention (CDC) recommendations for timing after treatment. Follow recommendations for the immunization of children with cancer as published by the CDC and the American Academy of Pediatrics (AAP). Usually, no immunizations are given to the child until 6 months after completing chemotherapy.

Management of infections is critical. Children are often hospitalized and central lines are used for antibiotic administration. Blood cultures and cultures of infected body parts help to establish the causative organisms. Because of lowered immune status, unusual agents are sometimes identified. Administer medication treatment on time and as ordered. Ensure standard precautions and transmission-based precautions are followed. Temperature and vital signs are taken and all body systems are assessed at admission and at least every 4 hours.

MANAGE PAIN

The child with cancer may experience pain from the disease itself and from the medical interventions, such as lumbar puncture, bone marrow aspiration, and frequent intravenous infusions and blood draws. Use all possible pain management techniques

Families Want to Know

Reportable Events for Children Receiving Chemotherapy

Parents require verbal and written instructions about signs and symptoms to report to the child's oncologist while the child is receiving chemotherapy. Have parents report the following events to the child's oncologist if they occur while the child is receiving chemotherapy:

- Temperature above 38°C (101°F)
- Any bleeding, such as nosebleeds, blood in stool or urine, petechiae, bruising
- Pain or discomfort with urination or defecation
- Sores in the mouth
- Vomiting or diarrhea
- Persistent pain anywhere, including headache
- Signs of infection, such as cough, fever, runny nose, tugging at ears
- Signs of infection in central lines, such as redness, drainage, or tenderness
- Exposure to communicable diseases, especially varicella (chickenpox)

Parents should also inform dentists and other healthcare providers that the child is receiving chemotherapy prior to procedures. Prophylactic antibiotics should be given before and after dental care.

Source: Adapted from Bindler, R. M., & Howry, L. B. (2005). *Pediatric drug guide*. Upper Saddle River, NJ: Prentice Hall.

to keep the child comfortable because this encourages cooperation throughout the long treatment period. Whenever possible, include the parents in comforting the child after painful procedures. (See Chapter 15 for suggestions on methods of pain management.) Nurses must examine research on effective pain management for children and integrate findings into practice (Fielding, Sanford, & Davis, 2013).

Sedation for diagnostic and therapeutic procedures (see Chapter 15) may be used for pain management. Administer sedation as ordered for young children who are undergoing lumbar punctures, radiation, and other procedures, and monitor them after the procedure. Coordinate other painful or intrusive tests so they can be done while the child is sedated for radiation.

Topical anesthetics such as eutectic mixture of local anesthetic (EMLA) cream may be used to numb the skin before an intravenous start, lumbar puncture, or bone marrow aspiration. Do not use EMLA on infants who are a gestational age of less than 37 weeks. Doses are individualized for infants and young children; follow guidelines for drug administration. For all infants, be certain that parents realize the importance of limiting the area and duration as ordered and to keep the cream in a safe place to avoid ingestion by any children. Other pain-prevention measures include fast-acting sprays, intradermal injection of anesthesia with lidocaine, iontophoresis (local anesthetic and electrical current), and sedation. Follow sedation monitoring protocols. (See the *Clinical Skills Manual* SKILLS.) Additional pain management techniques such as relaxation training and hypnosis may be beneficial. Having parents or other support persons present is helpful to most children.

PROVIDE PSYCHOSOCIAL SUPPORT

A diagnosis of cancer brings with it many emotions for the family. Initially, parents experience shock and anger. They need basic information about the disease and the purpose of the tests that will be performed. Instructions often need to be repeated as parents may not process information the first time it is presented because of their increased stress levels. Help the parents plan how and when to tell the child the diagnosis. What the child needs to know is based on the child's developmental level and understanding.

When family members have progressed from their initial state of shock about the diagnosis, they need to learn more about the disease. They may be interested in the pathophysiology, treatment, and expected outcome or the prognosis. Clarify their understanding of these areas and ask what questions they have. Provide verbal explanations and written material. Parents may talk with friends, purchase books, or search the Internet for information. Find out where they are getting information and provide additional resources when appropriate. Correct misconceptions and misinformation.

The family needs many strategies to deal with the challenge of long-term treatment for cancer. As the child experiences remissions and exacerbations or complications, the family feels alternately hopeful and discouraged. Identify the family's support systems and intervene as needed to enhance these systems. Facilitate contact with extended family members who might be of help, religious or spiritual connections, social service agencies, and other resources such as Internet and parent support groups. For parents who are concerned about job obligations and financial concerns, help them identify sources of financial assistance, respite from child care, and ways to take time for themselves.

Children undergoing treatment for cancer need support appropriate to their developmental stage and cognitive level. (See Chapters 4 and 11 for developmental levels and effective support strategies for children of different ages.) Younger children primarily need support during painful procedures and separation from parents. Older children need intervention strategies to help work

EVIDENCE-BASED PRACTICE | Cancer, Sleep, and Fatigue

Clinical Question

Inadequate amounts and quality of sleep are common problems among youth. Busy schedules and use of screen technologies contribute to poor sleep habits. Daytime sleepiness and other outcomes can result (Bartel, Gradisar, & Williamson, 2014). The child or adolescent with cancer is even more likely to have disturbed sleep, due to the cancer itself, the treatment protocols, and associated symptoms. What assessments and interventions should the nurse implement to understand sleep needs in the child with cancer?

The Evidence

A systematic review by nurses examined the measurement of sleep in adolescents with cancer by measures such as questionnaires, sleep diaries, and actigraphy (a watchlike device that measures movement and accurately displays sleep time). Primary reasons for disturbed sleep in cancer treatment included pain, frequent awakenings or fragmented sleep, and symptoms such as nausea (Erickson et al., 2011). Both mothers and children with acute lymphoblastic leukemia had disturbed sleep patterns, difficulty falling asleep, and fatigue (Matthews, Neu, Cook, et al., 2014).

Sleep disturbance may even continue after cancer treatment is completed because of brain changes that resulted from a tumor, or from treatment such as radiation or chemotherapy. In over 1400 survivors of childhood cancer, fatigue and poor sleep quality were identified (Clanton et al., 2011).

Best Practice

Cancer interfaces with normal developmental progression in several ways, one of which is sleep. Question sleep patterns at each oncology visit, provide suggestions for sleep hygiene, and refer the child and parents for sleep intervention as needed. Inquire about daytime sleepiness and fatigue. Have the family remove televisions and cell phones from the youth's bedroom, arrange for rest periods each day, and maintain routines that enable sleep.

Clinical Reasoning

Plan a series of questions to ask children and teens with cancer about the amount of sleep obtained on weekdays and weekends, patterns of sleep, and any changes in sleep since the cancer was diagnosed. Inquire about how the disease and its treatment have influenced sleep in the parents. What sleep hygiene measures can assist in acquiring needed sleep time and quality?

Figure 24–8 **A child in a pediatric oncology clinic giving injections to a doll. This type of play therapy helps the child deal with fear, thus lowering her stress level.**

through feelings about treatments (Figure 24–8). A major developmental task of adolescence is to attain independence and control, but cancer often interferes with adolescents' ability to achieve this task. Therefore, plan nursing strategies that empower adolescents as much as possible. Introduce them to other teens with similar diagnoses and allow them to make decisions and choices independent of parents when possible. An adolescent can decide which type of medication port would be best (e.g., an implantable port under the skin or a venous access device with tubing outside the body). Making this choice enables the teen to feel more in control of the disease and treatment. (See *Evidence-Based Practice: Cancer, Sleep, and Fatigue*.)

Talk with the child's teachers before the return to school after treatment to explain the child's condition. Ask them to notify the family immediately of diseases or infections in other children so the child with cancer treatment who is immunocompromised can be kept home. Arrange for tutors if necessary to assist the child with schoolwork during hospitalization and home care. Explore the option of summer camp for children with cancer. The Make-A-Wish Foundation strives to make dreams come true for ill children by sponsoring them for a desired activity or outing. Refer the child to this foundation if appropriate.

The siblings of a child who has cancer may grieve over the ill brother or sister and may feel sad and depressed. Inquire about what they know about the child's condition and their reactions or behavior changes. Consider the impact on siblings when a child is being treated for cancer. They may alternately resent and feel guilty for the sibling's illness. They may not understand the treatments or disease. School progress may be slowed and teachers may not be aware of the sibling's stress. Ask the parents if the siblings are demonstrating symptoms such as depression, behavioral changes, or decrease in school performance and suggest interventions as appropriate. Find out who is caring for siblings and whether their teachers have been informed about the family situation. Invite them to play therapy sessions and recreational activities with the ill child. They may benefit from speaking with a school counselor or can be referred to a support group for siblings of children with cancer. Some cancer summer camps welcome siblings as well as children with cancer.

Chapter 13 offers strategies to help the family of a child with cancer cope with the stressor of a life-threatening illness. For some types of cancer, the child may experience a remission with treatment, but a recurrence of disease later as cancer cells grow again. The family may become angry or depressed about the relapse. Repeated treatments challenge the family's support systems. Waiting for the outcome of diagnostic tests can be an especially challenging time. Provide information as soon as possible. If the child's illness progresses, refer the family to hospice to help them care for the terminally ill child and work through the grieving process. Explore cancer support groups and share this information with families.

DISCHARGE PLANNING AND HOME CARE TEACHING

Preparation for home care centers on creating a normal environment while supporting the child's physiologic and psychosocial responses to the cancer and treatments. Education is the primary focus of discharge planning. Teach the parents how to ensure adequate nutritional intake, to be alert for signs of infection, to protect the child from exposure to communicable diseases during times of neutropenia, to administer medications at home, and to handle vomiting and pain. Help the parents and child deal with any obstacles to normal development and functioning. Teach the parents and family about symptoms that need to be treated immediately.

Home management of a vascular access device or central line, such as a Broviac catheter, initially challenges parents (Figure 24–9). An implanted port, which allows the child freedom to swim and engage in other activities, may be used. Parents will need information about whatever device the child has received. Demonstrate details about cleaning the site, instilling heparin in the line or reservoir, and other needed care. After teaching the parents, observe them performing the procedure before the child is discharged.

Emphasize the need for the child and family to have fun and be as normal as possible. Play distracts the child and is essential in reducing fears. Children, parents, and siblings often benefit from

Figure 24–9 **Comfort and convenience. A vascular access device allows chemotherapeutic agents to be administered without the need for repeated "sticks" to the child.**

participation in cancer support groups and cancer summer camps. These activities create additional support systems, build the child's self-esteem, and enhance coping skills through role modeling. (See *Families Want to Know: Cancer Therapy* earlier in this chapter.)

Make home visits to evaluate the family's strengths and needs in the home setting. Be sure that the family has adequate support from hospice and other end-of-life services when a child's condition is terminal.

Most children are treated for cancer over a period of 2 to 3 years. Since normal developmental stages progress during this time, health promotion and health maintenance visits should still occur. Some usual care may have to be altered, but many of the same developmental concerns of all children should be addressed. Help parents to view the child as a "normal" child who is ill for a period of time, but still needs to have limits set on behavior, to develop healthy lifestyles, and to have environmental stimulation to learn to talk, read, or perform motor and cognitive tasks.

Evaluation

Expected outcomes of nursing care for the child with cancer relate to the specific disease, treatments, and responses. Some examples of outcomes include the following:

- The child demonstrates adequate intake to promote normal growth.
- Hydration is adequate to support body processes and ensure drug and cancer cell product elimination.
- Treatment side effects are promptly identified.
- Pain is managed to a level of comfort satisfactory to child and family.
- Family uses resources to provide necessary support during hospitalizations and treatments.
- Family demonstrates knowledge of management and treatment regimens.

Solid Tumors

Brain Tumors

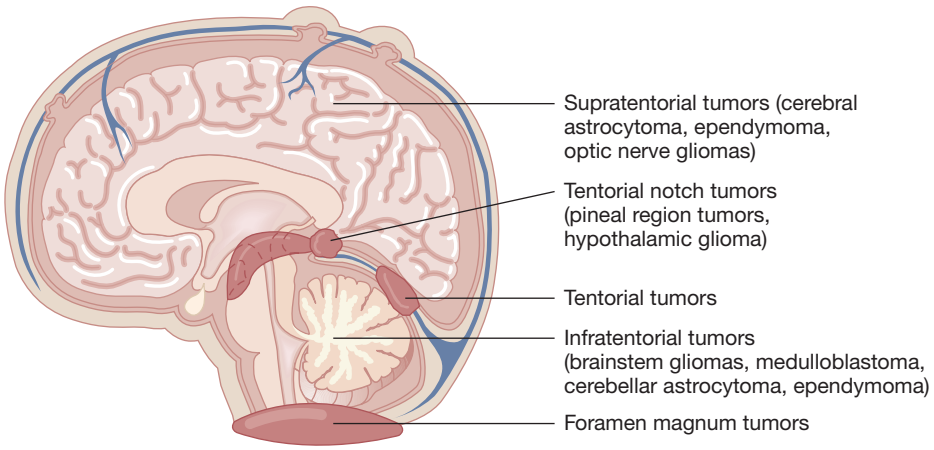
Central nervous system (CNS) or brain tumors are the most commonly occurring solid tumors in children and the second most common malignancy, after leukemia. Each year approximately 1300 children under 5 years of age and 2200 youth up to 20 years of age are diagnosed with tumors of the brain and CNS, accounting for one in five childhood cancers; the overall survival rate is 70% ("Brain Tumor Incidence," 2011; Kuttesch, Rush, & Ater, 2011; McLendon, Adekunle, Rajaram, et al., 2011).

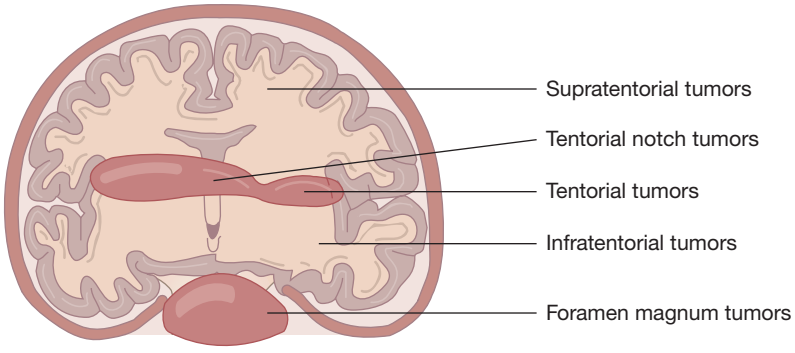
ETIOLOGY AND PATHOPHYSIOLOGY

The cause of most brain tumors is unknown. About 5% to 10% of brain tumors are genetic in origin. Exposure to radiation is a known risk factor, such as CNS radiation used for treatment of some other cancers. There is a higher incidence in children than adults with certain other cancers or diseases such as retinoblastoma, renal tumors, neurofibromatosis, tuberous sclerosis, or endocrine syndromes (Faria, Rutka, Smith, et al., 2011; Pollack & Jakacki, 2011).

Brain tumors in children usually occur below the roof of the cerebellum and involve the cerebellum, midbrain, and brainstem (see *Pathophysiology Illustrated: Brain Tumors*). In contrast, brain tumors in adults are usually located above the areas between the cerebrum and cerebellum.

Pathophysiology Illustrated: **Brain Tumors**





Approximately 1700 children under the age of 14 years are diagnosed annually as having tumors of the brain and CNS. The four most common brain tumors in children are medulloblastoma, cerebral astrocytoma, ependymoma, and brainstem glioma ("Brain Tumor Incidence," 2011; Kuttesch et al., 2011; McLendon et al., 2011).

Health Promotion The Child Receiving Cancer Treatment

Cancer treatment often extends for several years, so the child needs to continue health promotion and health maintenance visits.

Growth and Development Surveillance

- The child is assessed for height, weight, and body mass index. This provides information about growth patterns, which may be altered by cancer treatment. If indicated, 24-hour diet recalls and other nutritional assessments are performed.
- Teaching is provided about age-appropriate foods. Since appetite may be impaired during periods of treatment, the child may be lacking fruits, vegetables, or other foods, as well as the nutrients they include. Encourage parents to be sure the child has a well-balanced diet during periods of remission.
- Perform developmental screening of young children. Provide suggestions for parents about the stimulation that is appropriate for the child's age. Include quiet activities that can be used when the child is fatigued or receiving therapy. These might include reading books, listening to tapes and music, and working on a computer. Have the parent plan for these activities on days that the child goes for chemotherapy or other treatment.
- Ask about the school-age child's progress in school. Performance may be altered because of neurologic effects of treatment as well as missing school. Plan for the family to partner with the school personnel for provision of tutors, computer programs, or other needed assistance.
- Encourage continued social contact with peers when blood counts are adequate to prevent infection.

Physical Assessment and Screening

- Careful physical assessments are performed to identify any abnormalities that may result from cancer or its treatment. Cardiopulmonary and neuromuscular assessments are particularly important. Vision and hearing should be assessed prior to treatment and periodically throughout. Include measurements of fine and gross motor activity.

Elimination

- Toddlers may have an interruption in toilet training during periods when they do not feel well. Help parents understand this regression and encourage them to start again when the child is feeling better.
- Some medications cause diarrhea or constipation, so evaluate bowel patterns and provide guidance as needed. Skin care instruction may be needed if the child has diarrhea and is relatively immobile. Increasing fluids and fiber foods may be needed for constipation.
- Evaluate urinary output since many medications have effects on kidney function. Encourage adequate fluids for age to ensure elimination of medications.

Sleep and Fatigue

- Children undergoing treatment often have disturbed sleep patterns. Parents of young children may become exhausted working all day, getting the child to treatments, and having disturbed sleep at night. Assess both the child's sleep patterns and the family's experiences. Encourage plans for respite care to enable rest periods. Provide cots, rocking chairs, and other comfortable settings for child and family members during treatments.
- Both child and parents may not expect or understand the profound fatigue that occurs during cancer treatment. They can be helped to plan for providing quiet times, and replenishing energy through naps, massage, relaxing baths, and spending time with family.

Physical Activity

- Because the child has periods of fatigue, patterns of physical activity may decrease. Emphasize the importance of integrating physical activity when the child feels well, since it is needed for learning gross motor skills, facilitating blood flow, improving mental status, and setting patterns for the future.

Disease and Injury Prevention Strategies

- The child with cancer has the same safety hazards as other children of the same age, and such topics as car safety seats, fire prevention, water safety, and violence prevention should be addressed.
- An important hazard for children with cancer is infection due to decreased immune response. Keep records of immunization status. Follow the recommendations of the CDC and AAP for other immunizations. Teach about the hazards of large groups when the child's immune system is compromised. Discuss the care of central lines and other potential sources of infection. Have families report signs of infection and exposure to known illnesses promptly.

Mental and Spiritual Health

- Evaluate the child and family for signs of anxiety and depression. Ask how they are managing the cancer treatment and what poses the greatest challenges. Refer to other families with similar circumstances for support.
- Ensure that the child has contact with friends through child care, school, or via phone, letters, and a computer.
- Find out the impact of the child's cancer on the parent's jobs. Ask how the siblings have been coping, what changes there are in school performance, and whether teachers and others are aware of the stress the sibling may be experiencing.

Transitional Care

- As the child's treatment ends, instruct the child's parents about needed periodic follow-up with the oncologist. Continue to perform neurologic examinations and ascertain school performance. Be alert for signs of secondary tumors.
- Ask about worries regarding the future. As teens grow older, have them take over more responsibility for informing healthcare providers of their cancer history and assist them to transition to adult healthcare providers.

TABLE 24–5 Clinical Manifestations of Brain Tumors

TUMOR	ETIOLOGY	CLINICAL MANIFESTATIONS	CLINICAL THERAPY
Medulloblastoma	External layer of cerebellum	Headache, vomiting, ataxia	Surgery; chemotherapy with lomustine, vincristine, cisplatin; radiation
Astrocytomas	Glial cells, supratentorial or infratentorial	Seizures, visual disturbances, increased intracranial pressure, vomiting	Surgery; chemotherapy with vincristine, dactinomycin; radiation
Ependymoma	Fourth ventricle, posterior fossa	Hydrocephalus	Surgery, radiation
Brainstem gliomas	Pons	Cranial nerve (VI + VII) tract signs, nystagmus, ataxia, motor symptoms	Surgery, radiation

CLINICAL MANIFESTATIONS

Children with brain tumors can manifest behavioral and nervous changes. These are often a result of increased intracranial pressure and may occur either rapidly or slowly and subtly. Some common symptoms include headache, nausea, vomiting, abnormal gait, dizziness, change in vision or hearing, fatigue, and mental status changes such as educational or behavioral problems.

Brainstem tumors can present with weight deficits and may be mistakenly diagnosed as an eating disorder of infancy and childhood (failure to thrive). This may delay proper treatment. See Table 24–5 for common manifestations of certain types of brain tumors.

Medulloblastomas are brain tumors in the external layer of the cerebellum. They account for 35% to 40% of childhood brain tumors, and commonly occur in children 5 to 6 years of age. *Astrocytomas* arise from glial cells and can be either above or below the area between the cerebrum and cerebellum. They account for 35% to 40% of childhood brain tumors. The presenting symptoms vary depending on the location of the tumor. Endocrine, vision, and behavioral changes are all possible, as well as increased intracranial pressure and seizures. *Ependymomas* commonly occur in the fourth ventricle of the posterior fossa and comprise 10% to 15% of childhood brain tumors. Impaired growth, hydrocephalus, seizures, and cranial nerve impairments are the most common manifestations. *Brainstem gliomas* are located in the pons and typically spread into the surrounding tissue. They account for 10% to 15% of childhood brain tumors (Kuttesch et al., 2011).

CLINICAL THERAPY

Brain tumors are diagnosed with computed tomography (CT), magnetic resonance imaging (MRI), positron emission tomography (PET), single-photon emission computed tomography (SPECT), myelography, and angiography. New technologies combine imaging with angiography to more specifically image the lesion. Examples include magnetic resonance angiography (MRA), magnetic resonance spectroscopy (MRS), perfusion and diffusion imaging, digital subtraction angiography (DSA), and CT angiography (CTA) (Paldino, Faerber, & Poussaint, 2011). Neurophysiologic tests (electroencephalography and brainstem evoked potentials) are used to assess sensory pathway integrity and disease-related or drug-related sensory dysfunction. Other tests that may be performed are tumor markers and cerebrospinal fluid cytology. Lumbar puncture identifies abnormal cells in the cerebrospinal fluid. Bone marrow aspiration and bone scans identify extracranial primary neoplastic growth since cancers in other sites can metastasize to the brain.

Treatment depends on the type of brain tumor. Surgery is common. It may be performed to obtain a biopsy specimen, to debulk (reduce the tumor by partial removal) or excise the tumor, or to treat any hydrocephalus that may be present. During surgery, radiologic images allow the neurosurgeon to see computerized images of the brain while stimulating nerves to determine their functioning. These techniques provide rapid feedback to the neurosurgeon. Laser surgery, which has delicate precise control and accuracy, is used when tumors are close to sensitive neural or vascular structures.

Use of radiation after surgery and chemotherapy has improved the survival of children with medulloblastoma and ependymoma. High-dose chemotherapy is often used, and this modality has improved the survival of children with CNS tumors. Low-dose chemotherapy can shrink and help manage some tumors. Intrathecal administration of chemotherapy is useful in some cases. An Ommaya reservoir, a dome-shaped device with a catheter, may be surgically placed under the scalp to administer chemotherapy directly to the central nervous system.

However, the blood–brain barrier reduces the effectiveness of chemotherapy for children with brain tumors. For example, when methotrexate is administered intrathecally (in the spinal canal), only a small amount crosses normal brain capillaries. Radiation is not used in children under 3 years old because of resultant damage to brain cells. Hematopoietic stem cell transplantation is increasingly used. Numerous new approaches are being investigated and will be used increasingly in the years ahead. New combinations of chemotherapeutic agents, precision-guided delivery of medications and radiotherapy, gene therapy, cytokine-producing therapy to activate the immune system, molecular analysis and epigenetic markers to guide treatment, and blood–brain barrier disruption are examples of emerging treatments (Faria et al., 2011; Pollack, 2011).

Clinical Tip

The following are examples of drugs that may be used to treat brain tumors (Kuttesch et al., 2011):

- Cyclophosphamide
- Ifosfamide
- Lomustine
- Methotrexate
- Vincristine
- VP-16
- Cisplatin
- Carboplatin
- Nitrosourea
- Temozolomide

Complications of treatment for children with brain tumors are significant. They include severe infections (associated with high-dose chemotherapy), seizure activity, sensorimotor defects, hydrocephalus, and growth problems. Care is taken to treat infections early and aggressively. If a cerebrospinal shunt is used,

infection or blockage can occur. (See Chapter 27 for further discussion of cerebrospinal shunts in children.) Anticonvulsants are commonly given prophylactically after surgery. Endocrine problems, such as growth hormone changes, hypothyroidism, and panhypopituitarism, may occur when the tumor is in the hypothalamic–pituitary area. Treatment may also lead to impaired cognitive function and emotional or behavioral problems in some children. Memory deficits and selective attention deficits are the most common problems.

Diabetes insipidus is a special consideration in children with midline brain tumors, such as those that compress the hypothalamus, pituitary stalk, or posterior pituitary gland. Manifestations of diabetes insipidus include voiding of large amounts of dilute urine with a specific gravity of less than 1.005 to 1.010 (see Chapter 30).

Nursing Management

For the Child With a Brain Tumor

Nursing Assessment and Diagnosis

The focus of physiologic assessment of the child with a brain tumor is determined by its presentation (Table 24–6). Presenting signs can be categorized as follows:

- Nonspecific signs related to increasing intracranial pressure
- Secondary signs related to displacement of intracranial structures
- Focal signs suggesting direct involvement of the brain and cranial nerves

Thorough neurologic examination before surgery is essential to provide a record of baseline functioning. The neurologic examination also allows the evaluation of the child's changing physiologic status before surgery. Ask if the child has manifested slow changes over time or has had quickly developing symptoms. Measurement of head circumference and assessment of the anterior fontanelle are necessary in children under the age of 18 months.

Perform developmental screening on young children using the Denver II or other developmental test (see Chapter 6). Ask about the child's social interactions, school performance, and any behavior changes that have occurred.

Several nursing diagnoses can be identified for the child with a brain tumor depending on the type and location of the tumor. Some common examples follow (NANDA-I © 2014):

- ***Nutrition, Imbalanced: Less than Body Requirements,*** related to loss of appetite
- ***Mobility: Physical, Impaired,*** related to tumor pressure on coordination centers
- ***Development: Delayed, Risk for,*** related to effects of disability
- ***Memory, Impaired,*** related to neurologic disturbance
- ***Pain, Acute,*** related to compression of brain tissue

TABLE 24–6 Physiologic Assessment of Brain Tumors

CLINICAL MANIFESTATIONS	ASSESSMENT
Nonspecific signs: headache, morning vomiting, somnolence, irritability	Level of consciousness, pupil response, pupil shape and size
Secondary signs: disturbances of cranial nerves; other signs depend on site of tumor	All cranial nerves
Focal signs: truncal ataxia (midline brain tumors), general nystagmus, head tilting	Motor ability, head positions when watching television or looking at people (double vision, sixth cranial nerve involvement)

Planning and Implementation

The child with a brain tumor requires multidisciplinary care by, among others, a neurologist, neurosurgeon, pediatrician, dietitian, and social worker. Other specialists are also often needed. The nurse can act as a case manager to coordinate the complex care needed by the child.

For the nursing care of children immediately following surgery, refer to Chapter 11. In addition, close monitoring of neurologic status is needed postoperatively (refer to Chapter 27). Be especially alert for signs of increased intracranial pressure and infection. Observe for seizure activity. Administer drugs such as antibiotics and anticonvulsants as ordered.

Signs and symptoms of diabetes insipidus may occur following brain surgery (see Chapter 30 for a description of diabetes insipidus). Nursing care includes hourly measurement of intake and output, measurement of serum sodium levels every 4 to 6 hours, accurate fluid replacement, and frequent assessment of neurologic status. An indwelling urinary catheter is useful for accurate measurement of urinary output.

DISCHARGE PLANNING AND HOME CARE TEACHING

Teach the parents to watch for an increase in the child's voiding of dilute urine. Be sure they can recognize the signs of infection and changes in the child's neurologic status. Once the child is ready for discharge, chemotherapy or radiation may begin; tell parents the reason and potential side effects of these treatments. Help the family get any special equipment they may need to care for the child at home, such as a wheelchair, bed rails, or dressings. The American Cancer Society is a potential resource for assistance with these needs.

Children with brain tumors, especially those who have received radiation, often have some permanent sequelae. They may have slowed development, incoordination, learning disabilities, or other effects. These sequelae are most common in children who are 3 years of age or younger at the time of radiation therapy. Perform accurate height and weight measures at each healthcare visit. Assess developmental milestones. Ask about progress in school and any special services that might be needed. Perform thorough neurologic assessments. Support the family as they learn to deal with unknown or changed expectations for the child's performance.

Evaluation

Expected outcomes of nursing care for the child with a brain tumor depend on the site of tumor, clinical therapy, and medical outcome. Some outcomes might include the following:

- Nutritional intake is adequate to support growth and prevent malnutrition.
- A safe environment is maintained for the child.
- Physical mobility is maintained to the limits of developmental level and alterations of disease.
- An environment that supports normal developmental milestones within the capability of the child is maintained.
- Pain is managed to a level of comfort.
- Parents understand the diagnosis and treatment plan.

Neuroblastoma

Neuroblastoma is the solid tumor most commonly occurring outside the cranium of children. It is responsible for 8% to 10% of childhood cancers and 15% of cancer deaths in children. The average age at diagnosis is 17 to 22 months; it is the most common tumor in infants during the first year of life. Nearly all cases (90%) are diagnosed before 5 years of age (Zage & Ater, 2011). Prognosis varies, depending on the staging of the tumor (Table 24–7) and the age of the child, with more favorable outcomes in infants under 1 year of age and in presenting sites in the pelvis or thorax. Less favorable outcomes are associated with the presence of N-*myc* oncogen amplification. Survival rates are 90% for stages 1 and 2, but drop to 25% to 35% for stage 4 (Zage & Ater, 2011). As compared to White, Hispanic, and Asian children, more Black and Native American children have advanced disease upon diagnosis and therefore lower survival rates (Henderson et al., 2011). It is unknown if genetic differences or lack of consistent primary care contributes to this disparity.

Neuroblastoma is commonly a smooth, hard, nontender mass that can occur anywhere along the sympathetic nervous system chain. A frequent location is the abdomen, although other sites are the adrenal, thoracic, and cervical areas.

ETIOLOGY AND PATHOPHYSIOLOGY

Neuroblastoma originates in primitive neurocrest cells that form the adrenal medulla, paraganglia, and sympathetic nervous system of the cervical sympathetic chain and the thoracic chain. Approximately 50% of neuroblastomas develop in the adrenal medulla; 30% develop in the cervical, thoracic, or pelvic ganglia; and the remaining are elsewhere along the sympathetic chain (Zage & Ater, 2011). Lymph node metastasis is common because of the proximity of the tumor origin to the lymph system drainage.

TABLE 24–7 International Neuroblastoma Staging System

STAGE	DESCRIPTION
1	Localized tumor confined to the area of origin; complete gross excision, with or without microscopic residual disease; identifiable ipsilateral and contralateral lymph nodes negative microscopically
2A	Unilateral tumor with incomplete gross excision; identifiable ipsilateral and contralateral lymph nodes negative microscopically
2B	Unilateral tumor with complete or incomplete gross excision; with positive ipsilateral regional lymph nodes; identifiable contralateral lymph nodes negative microscopically
3	Tumor infiltrating across the midline with or without regional lymph node involvement; or unilateral tumor with contralateral regional lymph node involvement; or midline tumor with bilateral regional lymph node involvement
4	Dissemination of tumor to distant lymph nodes, bone, bone marrow, liver, and/or other organs (except as defined in stage 4S)
4S	Localized primary tumor as defined for stage 1 or 2 with dissemination limited to liver, skin, and/or bone marrow; bone marrow involvement should be minimal (less than 10% of cells); if greater it is stage 4 disease

Source: Data from National Cancer Institute. (2011e). *Stages of neuroblastoma*. Retrieved from http://www.cancer.gov/cancertopics/pdq/treatment/neuroblastoma/HealthProfessional/page2

The cause of neuroblastoma is unknown. A genetic defect found in many cases of neuroblastoma is a deletion of the short arm of chromosome 1 (1p del); other abnormalities include 11q, 14q, and 17q. Amplification of the proto-oncogene N-*myc* or mutation of *Phox2B* and *ALK* genes may be seen (Shuangshoti et al., 2011; Zage & Ater, 2011).

CLINICAL MANIFESTATIONS

The location of the mass determines the symptoms. A retroperitoneal mass causes altered bowel and bladder function; characteristic signs are weight loss, abdominal distention, enlarged liver, irritability, fatigue, and fever. Dyspnea or infection may occur when the tumor is mediastinal. Neck and facial edema may result from vena cava syndrome if the tumor is mediastinal and large. Intracranial lesions may be present with periorbital ecchymosis. Malaise, fever, and a limp can occur if there has been metastasis to the bone. Bone marrow disease can manifest as **pancytopenia** (abnormal depression of all cellular blood components) with neutropenia (causing infections) and anemia (causing fatigue). Metastatic spread can result in an array of symptoms affecting multiple organs.

CLINICAL THERAPY

The International Neuroblastoma Staging System (INSS) recommends different diagnostic and laboratory evaluations for diagnosis of the primary disease and of metastases (see Table 24–7). Biopsy of the tumor is used for initial diagnosis, and metastases are diagnosed by bone marrow biopsy, radiolabeled scanning, x-ray, CT, and MRI. Tumor markers include vanillylmandelic acid (VMA), homovanillic acid (HVA), dopamine, ferritin, NSE (an enzyme in neural tissue), lactic dehydrogenase (LDH), and a ganglioside GD2 (a sugar and lipid molecule on the surface of neural cells). VMA and HVA are by-products of adrenal hormones, and their levels are usually elevated in the urine and blood (see Appendix D for normal values). Areas of necrosis and calcification are readily identifiable with radiologic tests. These tests also help in the staging of the disease by identifying metastases. Urinary catecholamines are often increased.

Routine blood cell counts are needed, including CBC with differential. The test may reveal anemia and thrombocytopenia. There is no classic WBC response, although thrombocytopenia may occur in association with disseminated intravascular coagulation. **Leukocytosis** (higher than normal leukocyte count) and **leukopenia** (lower than normal leukocyte count) have been observed with bone marrow involvement. Serum electrolytes, liver function studies, LDH, coagulation studies, and urinalysis are performed. Elevations in dopamine, ferritin, NSE , LDH, and GD2 are seen. All of these laboratory findings are used initially to diagnose the disease and later to follow its progress. A biopsy or surgical removal of the tumor will be followed by analysis of its type and genetic abnormalities. Areas of necrosis and calcification in major organs are readily identifiable with radiologic tests and MRIs. These tests also help in the staging of the disease by identifying metastases.

The stage of the tumor determines the treatment protocol. Surgical excision of the mass is performed and may be the only treatment in low-risk stages. With higher risk, surgery is followed by chemotherapy with a combination of drugs. Radiation is often used, especially in disseminated disease or when tumors are not receptive to chemotherapy. Autologous stem cell transplantation may be performed for advanced disease, sometimes followed by the biologic modifier *cis*-retinoic acid and fenretinide (to promote apoptosis) (Zage & Ater, 2011).

Clinical Tip

The following are examples of drugs that may be used to treat neuroblastoma:

- Cyclophosphamide
- Cisplatin
- Ifosfamide
- Teniposide
- Etoposide
- Carboplatin

Nursing Management

For the Child With Neuroblastoma

Nursing Assessment and Diagnosis

Assess the presenting site of the tumor, such as the neck or abdomen, by observation and inspection. Palpation is contraindicated to avoid seeding tumor cells. Carefully document related functioning, such as bowel and bladder function. Take vital signs to watch for elevated temperature and vital sign changes caused by a thoracic mass. Observe gait and coordination. Take weight and height and compare to earlier percentiles for the child. Specific assessments during treatment will depend on the treatment methods used (refer to the earlier discussions of chemotherapy and radiation treatment). Psychosocial assessment and emotional assessment of the family are needed.

A variety of nursing diagnoses may be appropriate for the child with neuroblastoma, depending on the location and extent of the presenting disease. Some common diagnoses might include the following (NANDA-I © 2014):

- ***Gas Exchange, Impaired,*** related to ventilation-perfusion imbalance
- ***Mobility: Physical, Impaired,*** related to neuromuscular impairment
- ***Pain, Acute or Chronic,*** related to tumor pressure and injury
- ***Grieving (Family)*** related to potential loss of significant person

Planning and Implementation

The nursing management of the child with neuroblastoma can encompass the three phases of medical treatment: chemotherapy, surgery, and radiation. Specific postsurgical care depends on the size and site of the tumor. Normal postoperative care includes providing fluid support and respiratory care and preventing infection.

Nursing care during the chemotherapy phase includes minimizing side effects, preventing infection, teaching parents about the medications their child is receiving, and monitoring physical and emotional growth and development of the young child. When radiation is part of the treatment, use common nursing measures described earlier in the chapter.

Topics for parent and family teaching and discharge planning are presented in *Families Want to Know: The Child With a Neuroblastoma*. Ongoing support and connection to resources to assist in management of the child's treatment at home will be needed. When the prognosis is poor, parents may appreciate referrals to hospice, to other parents who have experienced similar child illnesses, and to other community resources. See Chapter 13 for additional nursing care for the end of life.

Evaluation

Expected outcomes of nursing care for the child with neuroblastoma include the following:

- Ventilatory exchange is adequate to support daily activities.
- Physical mobility is maintained to the level possible considering developmental age.
- Sensory/perceptual alterations are managed to provide for safety and sensory input.
- Pain is managed to a level of comfort.
- Family members accept and integrate the diagnosis.

Wilms Tumor (Nephroblastoma)

Nephroblastoma, an intrarenal tumor of which the most common type is Wilms tumor, is a common abdominal tumor of childhood and accounts for 6% of all childhood tumors. The incidence

Families Want to Know

The Child With a Neuroblastoma

Surgery Phase

- Teach the parents to observe for signs of infection at the wound site and to take the child's temperature, if necessary.
- Assist the family in providing pain management, including medication administration and various comfort measures.
- Teach the parents the importance of keeping accurate records of urine output and bowel movements and to notify the healthcare provider if the child does not have a bowel movement at least every 3 days.
- Continue with progression to a regular diet.

Chemotherapy Phase

The child frequently has a central line placed early in the chemotherapy phase. The central line greatly reduces the emotional trauma associated with chemotherapy and blood tests.

- Teach the child how to help the parents with cleaning of the central line.
- Teach the child how to protect the central line.
- Teach the parents how to clean and dress the site of the central line.
- Have the parents practice central line care with a model and then on the child before discharge to increase the parents' confidence.
- Give the parents written and illustrated information about care of a central line.
- Arrange for home care dressing supplies before discharge.
- Give the parents detailed chemotherapy information.
- Teach the administration of any medications that the parent will administer via central line or other routes.
- Refer the family to the American Cancer Society for coloring books for children receiving chemotherapy.

is approximately 7.6 cases per million children annually. Wilms tumor occurs most frequently between 2 and 3 years of age, with young ages being more commonly associated with bilateral disease (Buckley, 2011).

ETIOLOGY AND PATHOPHYSIOLOGY

Wilms tumor is associated with several congenital anomalies: aniridia (absence of the iris), hemihypertrophy (abnormal growth of one half of the body or a body structure), genitourinary anomalies, nevi, and hamartomas (benign, nodule-like growths). These connections suggest a genetic link; chromosomal deletions at 11p13 and 11p15 (locations for *WT1* and *WT2* genes) have been associated with Wilms tumor. It has a high incidence in Beckwith-Wiedemann syndrome, which is characterized by macroglossia and hypoglycemia. However, most children with Wilms tumor have no other abnormalities. Wilms tumor grows very quickly, doubling its size in 11 to 13 days. Such fast growth generally contributes to a large tumor by the time of diagnosis. However, chemotherapeutic drugs have significantly increased survival rates for children with Wilms tumor, with 90% survival rates (Anderson, Dhamne, & Huff, 2011; Buckley, 2011; Huff, 2011).

CLINICAL MANIFESTATIONS

Wilms tumor is usually an asymptomatic, firm, lobulated mass located to one side of the midline in the abdomen. Often a parent discovers the mass during the child's bath. Hypertension caused by increased renin activity related to renal damage is reported in 25% of cases. Hematuria or abdominal pain is sometimes present.

CLINICAL THERAPY

The diagnosis of Wilms tumor is based on an ultrasound study of the abdomen and an intravenous pyelogram. CT scanning or MRI of the lungs, liver, spleen, and brain may be performed to identify any metastasis. This information is used in staging the tumor (Table 24–8). A complete blood count is obtained, as well as BUN and creatinine levels. Liver function tests are performed.

Treatment is multifaceted and increasingly successful; about 90% of early stages and 70% of metastatic cases have long-term survival (Anderson et al., 2011). Surgery is performed to remove the affected kidney, to examine the opposite kidney, and to look for other sites of metastasis. Chemotherapy or radiation therapy, alone or in combination, is sometimes used before surgery to reduce the size of the tumor. Radiation, chemotherapy, or both may also follow surgery. Children whose tumors are almost completely excised and who have a favorable prognosis do not require irradiation of the tumor bed and may receive limited chemotherapy.

Long-term complications of treatment include liver damage, portal hypertension, and mild cirrhosis, which may occur in children treated for right-sided Wilms tumor. Radiation damage (such as thinning or weakening) of the skeleton, pelvis, and thorax has been reported. Kyphosis and scoliosis may occur from irradiation of vertebral bodies and the pelvis. Glomerular damage to the remaining kidney may also occur. Second malignancies in the original radiation field have occurred with orthovoltage radiation, but recent changes in radiation therapy have reduced this risk.

Clinical Tip

The following are examples of drugs that may be used to treat Wilms tumor:

- Vincristine
- Actinomycin D
- Doxorubicin
- Cyclophosphamide

TABLE 24–8 National Wilms Tumor Study Staging System

STAGE	DESCRIPTION
I	The tumor is limited to the kidney and completely excised. The surface of the renal capsule is intact. The tumor is not ruptured before or during removal. No residual tumor is apparent beyond the margins of the excision.
II	The tumor extends beyond the kidney but is completely excised. Regional extension of the tumor is present (i.e., penetration through the outer surface of the renal capsule into the perirenal soft tissues). Vessels outside the kidney substance are infiltrated or contain tumor thrombus. Biopsy may have been performed on the tumor, or local spillage of tumor confined to the flank has occurred. No residual tumor is apparent at or beyond the margin of excision.
III	Residual nonhematogenous tumor is confined to the abdomen. Any of the following may occur: • Lymph nodes on biopsy are found to be involved in the hilus, the periaortic chains, or beyond. • Diffuse peritoneal contamination by the tumor has occurred, such as by spillage of tumor beyond the flank before or during surgery, or by tumor growth that has penetrated through the peritoneal surface. • Implants are found on peritoneal surfaces. • The tumor extends beyond the surgical margins either microscopically or grossly. • The tumor is not completely resectable because of local infiltration into vital structures.
IV	Hematogenous metastasis: deposits are present beyond stage III (e.g., lung, liver, bone, and/or brain).
V	Bilateral renal involvement is present at diagnosis. An attempt should be made to stage each side according to the above criteria on the basis of extent of disease before biopsy.

Nursing Management

For the Child With Wilms Tumor (Nephroblastoma)

Nursing Assessment and Diagnosis

Perform a thorough baseline assessment of the child. Do not palpate the abdomen because of the potential for spreading the cancerous cells. Monitor the child's blood pressure carefully because hypertension is a common finding that may require treatment.

Nursing diagnoses for a child with Wilms tumor will differ depending on the phase of treatment. Some common nursing diagnoses might include the following (NANDA-I © 2014):

- ***Infection, Risk for,*** related to inadequate defenses
- ***Urinary Elimination, Impaired,*** related to anatomic obstruction
- ***Tissue Perfusion: Cardiac, Risk for Decreased,*** related to hypertension caused by mechanical reduction of blood flow
- ***Caregiver Role Strain, Risk for,*** related to child's illness severity
- ***Home Maintenance, Impaired,*** related to child's disease

Planning and Implementation

Nursing management can be divided into two phases: the postrenal surgery phase and the chemotherapy phase. (See Chapter 11 for general care of the child after surgery.) Drawings and special teaching dolls with removable kidneys can be used to teach young children about the surgery. Although chemotherapy may occur at two different times, before and after surgery, nursing management considerations remain the same.

Nursing care during the postrenal surgery phase focuses on pain management and close monitoring of fluid levels. A large incision is necessary to remove the kidney, and the resultant postoperative shift of organs and fluid in the abdominal cavity may create discomfort for the child. Frequently reposition the child and use noninvasive and pharmacologic pain interventions to improve the child's comfort. Gentle handling is important. Monitor fluids closely following surgery to prevent hypovolemia and to assess the shift of fluids out of the third space and out of the body. Assess daily weight, intake and output (I&O), and urine specific gravity. Monitor the function of the remaining kidney. Take blood pressure frequently to watch for signs of shock and to assess the functioning of the remaining kidney.

SAFETY ALERT!

If you feel a mass during palpation of a child's abdomen, stop palpating immediately and report the finding to the child's primary healthcare provider. Never palpate the liver or abdomen of a child with Wilms tumor as this could cause a piece of the tumor to dislodge. Place a sign on the child's bed and in the chart alerting healthcare providers not to palpate the abdomen.

During the chemotherapy phase, monitor the child for side effects of drugs, the potential for infection from the central line site, and the function of the remaining kidney. Advise parents about home care needs, administration of medications, and monitoring for drug side effects and ongoing needs for healthcare monitoring. A long-term complication in children who receive doxorubicin treatment is congestive heart failure, so ongoing periodic healthcare evaluations are needed. Be sure care is well coordinated among all healthcare providers.

Evaluation

Desired outcomes for nursing care of the child with nephroblastoma include balanced intake and output, normal vital signs, recovery from surgery, and successful family management of postsurgical care and ongoing treatments.

Bone Tumors

Osteosarcoma

Osteosarcoma is the most common tumor affecting the skeleton of children, with an incidence of seven cases per million children. Its peak incidence is during the rapid growth years, at age 13 years for girls and age 14 years for boys (Arndt, 2011b). The tumor is usually located at the metaphysis of the distal femur, proximal tibia, or proximal humerus.

ETIOLOGY AND PATHOPHYSIOLOGY

Bone tissue produced by osteosarcoma never matures into compact bone. Although the cause of osteosarcoma is unknown, radiation exposure (either environmental or treatment related) is associated with its development. Survivors of retinoblastoma have a greatly increased incidence of osteosarcoma. An abnormality of gene *p53* has been noted in some cases of this cancer, leading to oncogene malformations and possibly to an absence of tumor suppressor genes (Chen et al., 2014).

CLINICAL MANIFESTATIONS

The common initial symptoms are pain, swelling, and a limp. The pain can be referred to the hip or back, which can delay diagnosis. Deep bone pain causing night awakenings should be investigated (Arndt, 2011b). Pulmonary metastasis occurs in 20% of cases. Other metastatic sites include kidney, adrenals, brain, and pericardium. When lung metastasis is the only site, lung resection may be successful for treatment. Disseminated metastases and bone lesions have poorer prognoses.

CLINICAL THERAPY

Diagnosis is made through radiographic studies of the affected area, bone scan, CT or MRI scans of involved bone, blood test for serum alkaline phosphatase and lactic dehydrogenase (levels may be elevated), and tumor biopsy (to confirm the diagnosis). Arteriography may be performed if limb-sparing surgery is contemplated. Complete blood count, liver studies, and renal studies are performed for information about possible metastases.

Clinical Tip

The following are examples of drugs that may be used to treat osteosarcoma:

- Methotrexate with leucovorin rescue
- Doxorubicin
- Cisplatin
- Ifosfamide with mesna

Treatment involves both surgery and chemotherapy. The surgery is either a limb-salvage procedure or limb amputation. In limb-salvage procedures, the tumor is removed and a bone graft or internal prosthesis is inserted. A limb-salvage procedure is often possible if bone growth has taken place and a neurobundle (area where several nerves converge) is not involved in the tumor (Manfrini, Tiwari, Ham, et al., 2011). Other criteria such as joint involvement and possibility of prosthetic use in the future are weighed in the decision about a salvage procedure or amputation. Physical rehabilitation will be needed after either amputation or limb-salvage procedure. Aggressive chemotherapy following surgery has improved the survival rate. At the time of diagnosis, most children have metastases (even though they may not be identifiable), so chemotherapy is needed. Chemotherapy is started before surgery to shrink the tumor, especially when limb-salvage surgery is planned. It is also given postoperatively to treat and prevent metastasis.

Ewing Sarcoma

Ewing sarcoma is a malignant, small, round cell tumor usually involving the diaphyseal (shaft) portion of the long bones. The most common sites are the femur, pelvis, tibia, fibula, ribs, humerus, scapula, and clavicle, but any bone may be involved. Ewing sarcoma occurs in two children per million, is most common in White and Hispanic children, and is rare in African American and Asian American children. The incidence is highest in children between the ages of 5 and 20 years (HaDuong, Martin, Skapek, et al., 2015; Moore & Haydon, 2014).

Translocations on chromosomes 11 and 22 have been identified in children with Ewing sarcoma; these are t(11;22)(q24;q12). In addition, these tumors express a proto-oncogene, c-*myc*.

The symptoms are similar to those of osteosarcoma and may include pain, swelling, fever, an elevated WBC count, an elevated erythrocyte sedimentation rate, and elevated C-reactive protein. Some children present with a fracture of the affected bone. A tumor biopsy is necessary for diagnosis. Diagnostic tests are the same as those for osteosarcoma.

Initial treatment for Ewing sarcoma is chemotherapy to reduce the tumor, followed by radiation and surgical removal of the tumor and/or bone. Limb-salvage procedures are now commonly performed rather than amputation. Chemotherapy is always used after initial treatment because undetectable metastases are nearly always present.

Clinical Tip

The following are examples of drugs that may be used to treat Ewing sarcoma (Meyer & Grier, 2014):

- Vincristine
- Cyclophosphamide
- Dactinomycin
- Doxorubicin
- Ifosfamide
- Irinotecan
- Etoposide
- Temozolomide
- Topotecan

Nursing Management

For the Child With a Bone Tumor

Nursing Assessment and Diagnosis

Carefully evaluate any child or adolescent who has a limp or complains of pain in an extremity. Confirm the onset and whether the symptoms were associated with injury. Refer for further evaluation if the discomfort persists or is not associated with injury. Physiologic assessment of the child with a bone tumor includes assessment of the site before surgery. Assess the child's pain or discomfort, mobility, and gait. Take careful vital signs, especially noting temperature and respirations. Psychologic assessments of the child and family are needed, especially if amputation is planned. Loss of a limb causes body image disturbances, particularly with school-age children and adolescents. Assess the child's understanding of the treatment and of care after surgery. Find out what support systems are available to the family.

Observe the wound postoperatively for infection and hemorrhage. Assess circulation above and below the operative site. If edema is found, elevate the limb. If a limb-salvage procedure is performed, the child's extremity will remain, but it will not function as before because muscle insertion sites and mass have been removed with the tumor during surgery. Detailed charting of the condition of the surgical site and limb function is important.

If the limb has been amputated, assess the child for the following signs indicating a disturbed body image:

- Refusal to look at or touch the altered or missing body part
- Preoccupation with loss or change
- Feelings of shame or embarrassment, either verbalized or demonstrated
- Distorted perception of normal body (easily seen in the child's drawings of the body)
- Fears of rejection or unwanted attention from others
- Overexposure or hiding of the affected body part
- Actual or perceived change in the structure and function of the body or body parts

Psychosocial assessment of the child and family is discussed in more detail earlier in the general section titled *Childhood Cancer*.

Nursing diagnoses for the child with a bone tumor are based on the treatment and needs of each child. The nursing diagnoses that might be appropriate include the following (NANDA-I © 2014):

- ***Infection, Risk for,*** related to amputation or limb-salvage procedure
- ***Skin Integrity, Impaired,*** related to mechanical forces of prosthesis
- ***Mobility: Physical, Impaired,*** related to musculoskeletal impairment
- ***Body Image, Disturbed,*** related to treatment and injury
- ***Pain, Acute,*** related to physical injury of tissues

Planning and Implementation

Care of the child after surgery involves general postoperative care (see Chapter 11). The child who has had an amputation has special needs regarding skin care and rehabilitation. Inspect the tissue at the surgical site, using sterile technique, and turn the child at least every 2 hours. The site needs to heal completely before chemotherapy can begin and a prosthesis can be made. Pain management is a major nursing care need. When amputation has occurred, the adolescent will often experience phantom pain. This is pain that feels as if it were occuring in the amputated extremity and is caused by trauma to the nerves in the area of the amputation. Acknowledge that the pain is real since the nerve endings are intact and the patient is perceiving real discomfort. Medicate adequately and use additional pain control measures such as repositioning the limb using gentle movement, supporting the limb, and using distraction or deep breathing.

Discuss insurance and other financial arrangements with the parents, as prosthetics can be costly. Physical therapy will be needed as well. Referral to a Shriners Hospital is an option for some families.

Implement plans to help the child deal with body image disturbance. Plan for a visit from another child who is well adjusted to a prosthesis. Help the child gradually learn how to care for the stump. Slow progress may be made as the child first looks briefly, then for longer periods, and finally is willing to touch the stump. Show the child how it is possible to continue with sports such as baseball, skiing, or biking with a prosthesis. A discussion group with others can be very useful for adolescents. Plan with the child how to tell friends about the surgery and what issues the child may face upon return to school. Make plans for elevator access if needed and emergency evacuation procedures. Some children or adolescents may need referral for counseling to assist in dealing with body image disturbance.

The child will receive physical rehabilitation while hospitalized and after discharge. When the child is discharged, explain to the family the importance of bringing the child for outpatient chemotherapy and physical rehabilitation visits. Special arrangements may be needed at the child's school to accommodate a wheelchair, crutches, or ambulation with a new prosthesis. Call

or visit the school to see whether there are buttons to open doors, wide doorways to facilitate passage, and any limitations of the building. Contact school personnel to plan the child's return.

Follow-up care is needed to monitor for progress and to be alert for signs of metastases. Fracture may be a sign of recurrent tumor. All body systems such as lungs, heart, kidneys, and liver are monitored for signs of recurrence.

Evaluation

Expected outcomes of nursing care for the child with a bone tumor focus on the treatments required and adaptation to changes in lifestyle. Examples include the following:

- The surgical site heals with no signs of infection.
- The child adapts to changes in mobility status.
- The child successfully adjusts to changes required in school settings.
- Skin remains intact.
- Positive body image is achieved.
- Pain is managed to a level of comfort.

Leukemia

Leukemia is the most commonly diagnosed pediatric malignancy in children under 14 years of age. A cancer of the blood-forming organs, leukemia is characterized by a proliferation of abnormal white blood cells in the body. Several types of leukemia are differentiated depending on the blood cells affected. The main types are acute lymphoblastic leukemia (ALL), acute myelogenous leukemia (AML), and the rare chronic leukemias of childhood. Because chronic leukemias such as chronic myelocytic, chronic myelomonocytic, and chronic lymphocytic leukemia are rare in children, the following discussion will focus on ALL and AML.

The most common type of childhood leukemia is acute lymphoblastic leukemia, which accounts for 25% of all childhood cancer and 78% of leukemias in children. The peak age at onset is 2 to 3 years. ALL is more common in White children and in boys (Tubergen, Bleyer, & Ritchey, 2011). Subtypes of ALL are based on the French-American-British (FAB) system of classification. There are three types of ALL in the FAB system: L1, L2, and L3. Rasheed, the 12-year-old boy who is described in the chapter-opening scenario, has ALL.

Acute myelogenous leukemia refers to all leukemias from myeloid cells. About 17% of childhood leukemias are AML. It is most common in children younger than 2 years of age and in adolescents. It is more common in boys than girls and in Asians/Pacific Islanders, Hispanics, and Whites than in African Americans. There are several subtypes of AML in the FAB classification:

M0 = acute nonlymphocytic leukemia without maturation
M1 = acute nonlymphocytic leukemia with poor maturation
M2 = acute nonlymphocytic leukemia with maturation
M3 = acute promyelocytic leukemia
M4 = acute myelomonocytic leukemia
M5 = acute monocytic leukemia
M6 = erythroleukemia
M7 = acute megakaryocytic leukemia

Etiology and Pathophysiology

The causes of leukemia are not well understood. Some investigators theorize that exposure to infectious agents can predispose children to leukemia. Genetic factors are believed to play a role in some types of the disease. For instance, children with chromosomal defects such as Down syndrome, neurofibromatosis type I, Bloom syndrome, and Shwachman syndrome have an increased incidence of ALL (Messinger et al., 2012). Children with immune deficiency states, such as ataxia-telangiectasia, congenital hypogammaglobulinemia, and Wiskott-Aldrich syndrome, have an increased risk of ALL.

Ionizing radiation exposure when in utero and chemical agents such as treatment with chemotherapy for other cancers are thought to play some role in the development of AML. Several chromosomal and genetic abnormalities are associated with AML.

Leukemia occurs when the stem cells in the bone marrow produce immature WBCs that cannot function normally. These cells proliferate rapidly by cloning instead of normal mitosis, causing the bone marrow to fill with abnormal WBCs. The abnormal cells then spill out into the circulatory system where they steadily replace the normally functioning WBCs. As this occurs, the protective lymphocytic functions such as cellular and humoral immunity are reduced, leaving the body vulnerable to infections.

The malignant WBCs rapidly fill the bone marrow, replacing stem cells that produce erythrocytes (red blood cells) and other blood products such as platelets, thereby decreasing the amount of these products in circulation. The stem cells are replaced by leukemic clones, eventually resulting in anemia. Children with leukemia commonly experience abnormal bleeding, ecchymosis, or petechiae because of the reduced amounts of platelets.

Developing Cultural Competence Prevalence of Leukemia

African American, Hispanic, and Native American children have statistically poorer outcomes from leukemia treatment than do White and Asian children. Analysis of 5-year survival rates demonstrated poorer outcomes for African American children than for White children with AML (Bhatia, 2011). It is unclear whether racial and ethnic groups with poorer outcomes have particular genetic characteristics placing them at risk, do not obtain treatment as soon, have more complications from the disease, enroll less often in clinical trials, or have less access to care at oncology centers. Clearly, more research is needed to describe and then eliminate the racial and ethnic disparity in leukemia treatment outcomes.

Clinical Manifestations

Children with ALL and AML usually have fever, pallor, overt signs of bleeding, lethargy, malaise, anorexia, and large joint or bone pain. Petechiae, frank bleeding, and joint pain are cardinal signs of bone marrow failure. Enlargement of the liver and spleen (hepatosplenomegaly) and changes in the lymph nodes (lymphadenopathy) are common. If the leukemia has infiltrated the central nervous system (entered it by means of the circulatory or lymphoid system), the child may have signs such as headache, vomiting, papilledema, and sixth cranial nerve palsy (inability to move the eye laterally). These findings are caused by the leukemic cells massing and putting pressure on nerves. The testicles, spinal cord, and bone marrow are common sites for infiltration. The leukemic cells in the testicle become a mass that causes the testicle to enlarge, often painlessly.

Clinical Therapy

Diagnosis is based initially on blood counts and bone marrow aspiration. Blood counts commonly reveal a combination of abnormalities such as anemia, thrombocytopenia, and/or neutropenia. Bone marrow aspiration reveals immature and abnormal lymphoblasts and hypercellular marrow and is the differential test. The percentage of blast cells in marrow is measured. Other abnormal laboratory findings include elevated serum uric acid and hypocalcemia, as well as elevated potassium and phosphorus levels. Laboratory studies such as rapid flow cytometric assay are making the measurement of even very small numbers of leukemic cells possible, so that treatment can improve prognosis in children with minimal residual disease. Leukemic cells are examined and classified by FAB type, and DNA analysis may provide clues about genetic changes; all of these considerations are used to establish the protocol for treatment. Blood cells of children with ALL are B cell or T cell; these classifications are also used to establish treatment protocols.

Both ALL and AML are now approached by analysis of molecular targeting for the origin and type of disease identified (Masetti, Kleinschmidt, Biagi, et al., 2011; Pui, Carroll, Meshinchi, et al., 2011). Treatment of ALL involves radiation and chemotherapy (Rabin & Poplack, 2011). Radiation is used for central nervous system (CNS) disease, in T-cell leukemia, and for testicular involvement. Chemotherapy is commonly organized into four phases: (1) induction, (2) consolidation, (3) delayed intensification, and (4) maintenance of remission. Additional drugs may be used for treatment of CNS involvement. Maintenance therapy may continue for 2 to 3 years, causing decreased resistance to infection for this prolonged period. Treatment of AML involves use of a wide variety of drugs during the induction and consolidation phases.

Maximum cell death occurs during the *induction phase*. The cells that remain after this period are more resistant to treatment. After 3 to 4 weeks, bone marrow aspiration is reevaluated. Drugs are used in combination with CNS prophylaxis; cranial irradiation is used in some cases. During the *consolidation phase*, chemotherapy with L-asparaginase is administered. *Delayed intensification* uses additional drugs to target the leukemic cells that have survived. Treatment during the *maintenance phase* is aimed at destroying the remaining leukemic cells. Combinations of active drugs are used to prevent resistance. Occasionally, other drugs are added to the regimen, such as vincristine, prednisone, cyclophosphamide, intravenous methotrexate, cytosine arabinoside, doxorubicin, or anthracyclines.

The prognosis for children with leukemia is much improved with current therapy. An important factor is the initial leukocyte count; the higher the leukocyte count (over 50,000/mm^3) at diagnosis, the worse the prognosis. For children in the low-risk group, the probability of prolonged survival is as high as 90%; even higher risk ALL has a 75% to 80% cure rate with current treatments (Tubergen et al., 2011). Treatment methods and duration are adjusted for each child depending on that child's metabolic analysis and other risk factors (Rabin & Poplack, 2011).

Approximately 15% to 20% of children have a relapse within a year after completing treatment (Tubergen et al., 2011). Treatment for relapse consists of additional chemotherapeutic drugs. The prognosis is best if the relapse occurs late after the initial diagnosis and after the initial treatment is completed. Hematopoietic stem cell transplant (HSCT) is a treatment option for the child who has a relapse with ALL and who then achieves a second remission; the transplant is given when the child is in remission. Transplant is also used for children with AML; they do not need to be in remission for the transplant to be performed.

Clinical Tip

Following are the laboratory values in leukemia:

	Normal	Common Values in Leukemia
Leukocytes	Less than 10,000/mcL	Greater than 10,000/mcL
Platelets	150,000–400,000/mcL	20,000–100,000/mcL
Hemoglobin	12–16 g/dL	7–11 g/dL

Clinical Tip

The following are examples of drugs that may be used to treat acute lymphoblastic leukemia:

Induction Phase

- Prednisone
- Vincristine
- Intrathecal methotrexate (central nervous system prophylaxis)
- L-asparaginase
- Daunorubicin

Consolidation Phase

- L-asparaginase
- Doxorubicin

Delayed Intensification Phase

- Vincristine
- Ara-C
- Cyclophosphamide
- L-asparaginase

Maintenance Phase

- 6-Mercaptopurine or 6-thioguanine
- Methotrexate

Overall, 80% of children with leukemia are cured. Chemotherapy itself can create numerous complications, affecting all body organs. Secondary malignancies sometimes occur later in life. See the section on cancer survival earlier in this chapter.

Clinical Tip

The following are examples of drugs that may be used to treat AML:

Induction Phase

- Daunorubicin
- Doxorubicin
- Mitoxantrone
- Cytarabine

Consolidation Phase

- Etoposide
- Teniposide

Nursing Management

For the Child With Leukemia

Nursing Assessment and Diagnosis

Thorough physical assessment is important to ensure prompt identification of problems without injuring the child who has deficient coagulation and immune function. Perform assessments every 8 hours or more often depending on the chemotherapeutic regimen. Observe carefully for bruising, petechiae, and other signs of bleeding; assess for fever or other signs of infection. Once chemotherapy has begun, closely monitor renal functioning through specific gravity, intake and output, and daily weight measurements. Monitor dietary intake, nausea, vomiting, and constipation. Observe for mucosal ulcers in the mouth. A central line is usually in place for intravenous infusion of medications, so carefully assess the line for proper functioning and for signs

of infection. Ask the parents about any behavioral changes. CNS infiltration can affect the child's level of consciousness, causing irritability, vomiting, and lethargy. However, chemotherapeutic drugs and antiemetics can also induce these nonspecific signs. Frequent venipunctures, bone marrow aspirations, and lumbar punctures require pain assessment and an evaluation of the level of knowledge and coping skills of child and family.

Leukemia causes many changes in the body, and confirmation of the disease is difficult for families to face. Among the many nursing diagnoses that might be appropriate for the child with leukemia are the following (NANDA-I © 2014):

- ***Nutrition, Imbalanced: Less than Body Requirements,*** related to inability to ingest food
- ***Infection, Risk for,*** related to altered immune system functioning
- ***Injury, Risk for,*** related to bleeding
- ***Activity Intolerance*** related to generalized weakness
- ***Pain, Acute or Chronic,*** related to chemotherapy and disease process
- ***Sleep Pattern, Disturbed,*** related to chemotherapeutic drugs and disease process
- ***Anxiety (Child and Parent)*** related to change in health status

Planning and Implementation

Bone marrow suppression may necessitate transmission-based precautions. Instruct parents in the prevention of infection and use nursing care measures to prevent infection also. Perform careful hand hygiene; take temperature frequently; give mouth care with antibacterial mouthwashes; and inspect skin, mouth, rectal area, and central line site for any signs of infection. Care of mouth sores and other side effects of chemotherapy is presented in *Nursing Care Plan: Hospital Care of the Child With Cancer* earlier in this chapter.

Special attention to renal function is needed when the child receives cyclophosphamide. Gross hematuria is a side effect of this drug. Hydration with intravenous fluids to attain a specific gravity of less than 1.010 prevents or reduces the severity of hematuria. It also prepares the kidneys to manage products of tumor cell breakdown. To achieve the desired specific gravity, the child receives intravenous fluids at 1.5 times maintenance volume for at least 6 to 8 hours before and at least 1.5 hours after administration of the drug. Other chemotherapy drugs have different infusion times, and some do not require hydration prior to infusion. Check drug references carefully for recommendations with each drug. Evaluate the infusion site before and frequently during infusion. Although extravasation is not as common with central lines used in cancer treatment as in peripheral lines, it still can occur. Many chemotherapeutic agents are extremely toxic to tissues. In addition, lysis of the cancer cells can produce toxic side effects (see the *Oncologic Emergencies* section earlier in the chapter). Careful monitoring of intake and output is required to record the intravenous fluids, assess kidney functioning, and monitor excretion of by-products from destroyed tumor cells. Monitor specific gravity every 8 hours, as well as before and during administration of the drug, and when the intravenous fluids are reduced to maintenance volume levels. Daily weight measurements are important to assist in planning adequate hydration during chemotherapy, as well as to measure nutritional status.

Drug side effects may necessitate infusion of platelets or packed red blood cells. See the *Clinical Skills Manual* SKILLS for techniques to be used in these situations.

Many children are treated in an oncology clinic, staying in the hospital only on the day of intravenous drug administration and receiving oral medications at home. The time at the hospital is used to assess how the family is managing issues such as nutrition, sleep, medication administration, and obtaining psychosocial support. Careful teaching for the family is needed to ensure safe drug administration and identification of issues requiring further care.

Nurses play a key role in the long-term multidisciplinary treatment of children with leukemia. The impact of a diagnosis of leukemia and the long-term nature of treatment can severely stress the coping abilities of both the child and the family. Ongoing psychosocial assessment and emotional support are essential (see the general discussion of psychosocial assessment in the *Childhood*

Families Want to Know

Chemotherapy for Childhood Leukemia

Physical Care

- Have rest periods each day.
- Avoid exposure to people with illnesses.
- Drink generous amounts of water.
- Eat a healthy diet, using frequent, small, and nutritious meals to obtain enough nutrients.
- Take medicines prescribed to decrease nausea.
- Maintain good oral hygiene with a soft toothbrush and water irrigation device.
- Avoid sun exposure and check skin each day for any signs of bruises, pressure areas, cuts, or scratches.
- Allow time for and eat foods to promote bowel elimination.
- Promote bowel elimination through regular dietary and toileting practices.
- Report any signs of infection, changes in condition, or other concerns.

Emotional Care

- Be prepared for loss of hair with plans for hats, wigs, or other alternatives.
- Continue contact with friends via phone, Internet, and in person when possible.
- Try relaxation techniques to aid in sleep and management of treatments.
- Talk with clergy, teachers, parents, counselors, friends, or other supportive people about the experience of having leukemia.
- Keep a journal to record feelings and experiences.

Clinical Reasoning **Family Support During Childhood Cancer**

Sam is a 4-year-old boy recently diagnosed with acute lymphoblastic leukemia. He has been hospitalized for initial diagnostic work and the beginning of chemotherapy. Sam lives about 70 miles from the hospital and his parents have been taking turns staying with him. He has two older siblings at home who are 6 and 9 years old. What are the most urgent needs for the parents? The siblings? What information should you collect to begin planning for psychosocial support for the family?

Cancer section earlier in this chapter). Referral to support groups and social services may be beneficial. Help the family explore alternative therapies such as relaxation, imagery, and nutritional support that may aid the child. Be alert for any interactions that could occur between complementary therapies and the medical regimen.

Evaluation

Expected outcomes for nursing care of the child with leukemia include the following:

- Infection and other secondary complications of chemotherapy are prevented.
- Adequate hydration is maintained.
- Normal urinary output is maintained.
- Blood values are within normal limits.
- The family adapts successfully to parenting a child with chronic illness.
- Parents demonstrate adequate knowledge related to the disease process.

Soft-Tissue Tumors

Hodgkin Disease

Hodgkin disease, a disorder of the lymphoid system, usually arises in a single lymph node or an anatomic group of lymph nodes (see *Pathophysiology Illustrated: Hodgkin Disease*). Hodgkin disease rarely occurs before 10 years of age. It accounts for just 5% of cancers in children under 14 years, but 15% of cancer in youth from 15 to 19 years. The disease has a bimodal peak with higher incidence in the early 20s and after 50 years (Waxman, Hochberg, & Cairo, 2011). Three forms of the disease exist: young person form in those under 14 years, the young adult form in persons from 15 to 34 years, and the older adult form in those over 50 years. There is a slightly increased incidence in males, which is more pronounced in the disease manifested in younger children (Carbone, Spina, Gloghini, et al., 2011).

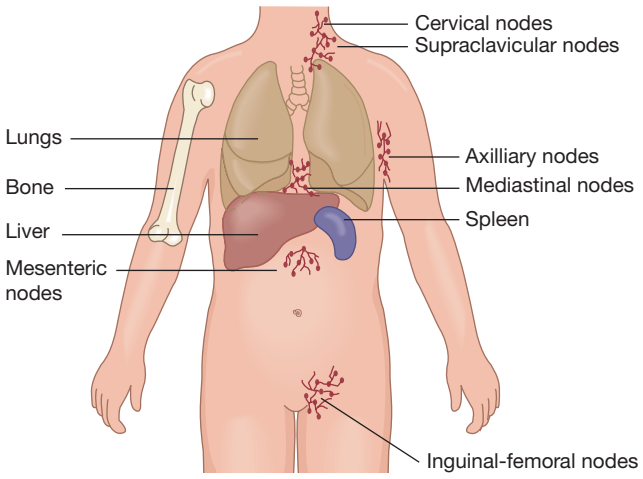
ETIOLOGY AND PATHOPHYSIOLOGY

Hodgkin disease occurs in clusters and has been reported in families. This suggests a possible genetic link as well as an infectious agent (such as Epstein-Barr virus) or environmental hazard (Waxman et al., 2011).

CLINICAL MANIFESTATIONS

The main symptom of Hodgkin disease is nontender, firm lymphadenopathy, usually in the supraclavicular and cervical nodes but occasionally in the mediastinal area. A mediastinal growth can cause respiratory difficulty because of pressure on the trachea or bronchi. A distinguishing large cell with multiple nuclei, called the

Pathophysiology Illustrated: **Hodgkin Disease**



Lymph nodes and organs affected in Hodgkin disease in children.

Reed-Sternberg cell, is characteristic of Hodgkin disease, although the cell is found also in infectious mononucleosis and some other lymphomas. Fever, night sweats, and weight loss occur in one third of children with Hodgkin disease and are associated with a more aggressive form of the disease. The leukocyte count and erythrocyte sedimentation rate (ESR) may be elevated.

CLINICAL THERAPY

Diagnosis is based on the presence of Reed-Sternberg cells in a lymph node biopsy. A staging classification is used to determine disease severity (Table 24–9). The basis for staging is data obtained from the history, physical examination, chest x-ray study (for metastasis), chest CT scan, CT or MRI scans of the retroperitoneal nodes, lymphangiogram if there is retroperitoneal involvement, laboratory studies (complete blood count, ESR, serum copper level, C-reactive protein, liver and renal function tests), and a radionuclide scan with gallium. Bone marrow biopsy, bone scan, or a staging laparotomy may be performed if advanced disease is suspected. Minimally invasive surgery can be used to biopsy or remove the spleen for diagnosis, avoiding the potential complications of major surgery (Waxman et al., 2011).

Clinical Tip

The following are examples of drugs that may be used to treat Hodgkin disease:

- Doxorubicin
- Bleomycin
- Vinblastine
- Dacarbazine
- Etoposide
- Prednisone
- Cyclophosphamide
- Procarbazine
- Methotrexate
- Mechlorethamine

TABLE 24–9 Staging System for Hodgkin Disease

STAGE	DESCRIPTION
I	Disease within a single lymph node region
IE	Disease within a single extralymphatic organ or site outside of lymphatic system (extralymphatic organ)
II	Disease within two or more lymph node regions on same side of diaphragm
IIE	Disease within extralymphatic organ, and of one or more lymph node regions on same side of diaphragm
III	Disease of lymph node regions on both sides of diaphragm; stage III(1) indicates involvement of upper abdomen above the renal vein, whereas stage III(2) indicates involvement of pelvic or other lower abdomen nodes
IIIE	Disease of lymph node regions on both sides of the diaphragm with involvement of extralymphatic organ
IIIS	As in III, plus disease within spleen
IIISE	As in III, plus disease in extralymphatic organs and spleen
IV	Disseminated disease within one or more lymphatic organs with or without lymph node involvement

Source: Data from National Cancer Institute. (2011a). *Childhood Hodgkin lymphoma treatment: Staging and diagnostic evaluation*. Retrieved from http://www.cancer.gov/cancertopics/pdq/treatment/childhodgkins/HealthProfessional/page4

Chemotherapy using a four-drug combination has been found to be the most effective drug treatment. Radiation is commonly added, with low doses for children who are still growing, and larger doses for those who are physically mature or those whose disease is more advanced at diagnosis. The 5-year survival rate is approximately 85% to 90%, depending on the stage of the disease at diagnosis.

Autologous stem cell or allogeneic stem cell transplant is a treatment option in children with advanced disease or relapse.

Non-Hodgkin Lymphoma

The four types of pediatric non-Hodgkin lymphoma (NHL) are (1) lymphoblastic lymphoma, (2) small noncleaved cell (Burkitt) lymphoma, (3) diffuse large B-cell lymphoma, and (4) anaplastic large cell lymphoma (Waxman et al., 2011). Lymphomas of all types are the third most common group of malignancies in children, following leukemia and brain tumors. Non-Hodgkin lymphomas are malignant tumors of lymphoreticular (internal framework of the lymph system) origin. The peak incidence for lymphomas occurs between the ages of 7 and 11 years, and they are three times more common in boys than in girls. The cure rate is 85% to 90% (Waxman et al., 2011).

Lymphoblastic non-Hodgkin lymphomas are caused by T-cell abnormalities. These abnormal T cells are diffuse, highly malignant, and very aggressive and do not mature. T-cell lymphomas produced by these cells often occur in children with congenital or acquired immunodeficiency states, chronic immune stimulation, or autoimmune disease. Some lymphomas have B-cell abnormalities, most specifically Burkitt lymphoma; 8q24 chromosomal translocation may be found in these cases (Waxman et al., 2011).

The incidence of lymphomas shows geographic variability. For example, a high incidence of Burkitt lymphoma is found in equatorial Africa, where it causes 50% of childhood cancers. Incidence in Hispanic children is higher than in White children, and African Americans have the lowest incidence. Boys are affected more than girls, and children with immune system compromise are most commonly affected. Epstein-Barr virus has been associated with Burkitt lymphoma, but in most cases of NHL, there are no known causes (Waxman et al., 2011).

Children with non-Hodgkin lymphoma frequently present with fever and weight loss. The lymph glands are usually enlarged or nodular, with the most frequent sites being the cervical, axillary, inguinal, and femoral nodes. However, the disease may be diffuse, without nodular glands. The anterior mediastinum is the primary site for T-cell lymphomas. Tumors that occur in this area may compress the airway (causing breathing difficulty) or superior vena cava (leading to swelling of the face, neck, or arms), and can cause pain. Jaw involvement is common in Burkitt lymphoma.

A complete blood count is performed; additional blood tests include renal and liver function, electrolytes, uric acid, and LDH. Bone marrow aspiration and lumbar puncture are performed. Chest x-ray, bone scan, gallium scan, CT, and MRI can help to isolate affected body organs. Tissue biopsy confirms the diagnosis.

A staging system is used to describe the tumor mass and extension to other body areas (Table 24–10). Treatment is tailored to the type of cancer and its stage. Stages I and II may be treated with drugs such as vincristine, cyclophosphamide, prednisone, and methotrexate for several months. Intrathecal medication is added if head and neck cancers are present. Stages III and IV are treated with additional drugs (up to nine total) for longer periods (1 to 2 years). Radiation is uncommonly used and may be helpful to treat a tumor that is impinging on a body part. Surgery is used to biopsy the tumor mass and treat any complications caused by the cancer. A hematopoietic stem cell transplant is used for children with recurrent disease.

Rhabdomyosarcoma

Rhabdomyosarcoma is the most common soft-tissue tumor diagnosed in children, and is especially common in children under 5 years of age. The 5-year survival rate is 70% (Egas-Bejar & Huh, 2014). It occurs most often in the muscles around the eyes (extraorbital), in the neck, and less commonly in the abdomen, genitourinary tract, and extremities (Figure 24–10).

The cause of rhabdomyosarcoma is unknown. However, it is more common in children with neurofibromatosis and Li-Fraumeni syndrome. Mutations in tumor suppressor gene *p53* are sometimes seen. The abnormal cells arise from mesenchyme that normally grows into muscle, fat, and bone.

Tumors close to the eye produce swelling, ptosis, visual disturbances, and eye movement abnormalities. When the tumor occurs in the genitourinary tract, the result can be urinary

TABLE 24–10 St. Jude Children's Research Hospital Staging Classification for Non-Hodgkin Lymphoma

STAGE	DESCRIPTION
I	Single tumor or node area involved; no tumor in abdomen or mediastinum
II	Single tumor with lymph node involvement; or two node areas or tumor on same side of diaphragm; or GI tumor in one site
III	Two tumors or node areas on different sides of diaphragm; or a primary mediastinal, intra-abdominal, or epidural tumor
IV	Any involvement with CNS or bone marrow metastases

Source: Adapted from National Cancer Institute. (2011b). *Childhood non-Hodgkin lymphoma treatment: Stage information*. Retrieved from http://www.cancer.gov/cancertopics/pdq/treatment/child-non-hodgkins/HealthProfessional

Figure 24–10 **Rhabdomyosarcoma can occur in soft tissue throughout the body. Although the areas around eyes and neck are common sites, soft tissue around genitalia, in extremities, and in other sites can also be affected. A biopsy was performed on the buttock of this infant, who will now undergo chemotherapy and surgical removal of the rhabdomyosarcoma tumor, followed by further chemotherapy.**

SOURCE: Dr. P. Marazzi/Science Source.

obstruction, hematuria, dysuria, vaginal discharge, and a protruding vaginal mass. Rhabdomyosarcoma occurring in the abdomen may be asymptomatic. There is rapid metastasis to the lungs, bones, bone marrow, and distant lymph nodes.

Diagnosis is confirmed by CT, MRI, PET, bone marrow aspiration, and biopsy. CBC, renal and liver studies, and urinalysis are performed. Lumbar puncture may be used in head and neck tumors. A useful biologic marker, desmin, allows differentiation of rhabdomyosarcoma from other round cell tumors. A significant number of children have metastatic disease at the time of diagnosis, so chest and lung CT scans, as well as regional lymph node biopsies are performed (Arndt, 2011b).

Treatment includes surgical removal of the tumor when possible. However, if the tumor involves other structures, removal may not be possible. Many children have metastasis at the time of diagnosis, so the primary tumor may not be removed. Surgery is followed by wide-field radiation and chemotherapy with a combination of drugs. Some commonly used drugs include the following:

- Vincristine
- Actinomycin
- Cyclophosphamide (VAC therapy)

Prognosis depends on the site, staging (Table 24–11), and histologic findings.

TABLE 24–11 Classification of Rhabdomyosarcoma

STAGE	DESCRIPTION
I	Localized tumor, completely resected disease
II	Total gross resection with regional microscopic spread
III	Locally extensive tumor with residual microscopic spread
IV	Any size primary tumor with distant metastatic disease present

Figure 24–11 **Retinoblastoma is characterized by leukokoria, a white reflection in the pupil.**

SOURCE: Custom Medical Stock Photo/Newscom.

Retinoblastoma

Retinoblastoma is an intraocular malignancy of the retina. It may be bilateral (20% to 30%) or unilateral. In 40% of children, the disease is inherited by an autosomal dominant gene. Family history is therefore important to collect, although many cases occur with no family history of the cancer (Zage & Herzog, 2011). The tumor arises from embryonic retinal cells. It may be a new mutation or may be passed on to offspring of affected individuals in an autosomal dominant manner. The retinoblastoma gene, *RB1*, is on chromosome 13q14.

The first sign of retinoblastoma is a white pupil, termed *leukokoria* or *cat's-eye reflex* (Figure 24–11). The red reflex is absent, asymmetric, or of a differing color in the affected eye. Other symptoms may include a fixed strabismus (a constant deviation of one eye from the other), orbital inflammation, glaucoma, and heterochromia (irises of different colors).

Retinoblastoma is usually diagnosed when the child is between 1 and 2 years of age. A family history should alert healthcare providers so that regular ophthalmologic examinations can be performed frequently on infants and young children in the family. The appearance of a unilateral tumor demands regular examinations of the healthy eye since bilateral disease can develop. In some children, a pineal gland tumor can also develop, causing CNS symptoms. The overall tumor-free survival rate is 95% (Zage & Herzog, 2011).

Diagnostic tests for the cancer include full ocular examination and CT or MRI scans of the eye orbit. All children with a history of retinoblastoma in the family should be examined by an ophthalmologist after birth, at 6 weeks, every 2 to 3 months until 2 years, every 4 months until 3 years, and then annually to aid in early diagnosis. Tumors are classified according to a staging system, from a very small localized tumor (group I) to tumors involving more than half the retina and with seeding into the vitreous (group V).

Treatment for retinoblastoma may include removal of the eye (enucleation) when there is permanent retinal damage or failure to respond to other treatment. Other surgical treatments involve cryotherapy or photocoagulation (argon laser therapy). Radiation is nearly always used, either as the sole treatment or before surgery to shrink the tumor. Chemotherapy is sometimes used but is frequently ineffective because the drugs often fail to penetrate sufficiently into the eye. Chemotherapeutic drugs include carboplatin, etoposide, vincristine, and cyclosporine. Multiple therapies are more commonly used in children with bilateral

retinoblastoma. Children with retinoblastoma are at increased risk of developing a secondary tumor, including another retinoblastoma or a sarcoma, most commonly osteogenic sarcoma. However, most young children who have been treated for the disease have good health and normal mental abilities several years after treatment. The most common sequela of retinoblastoma is decrease in visual acuity.

Nursing Management

For the Child With a Soft-Tissue Tumor

Nursing Assessment and Diagnosis

PHYSIOLOGIC ASSESSMENT

Physiologic assessment of the child with a soft-tissue tumor, such as Hodgkin disease, non-Hodgkin lymphoma, rhabdomyosarcoma, and other lymphomas, focuses on the child's general condition. Accurate height and weight measurements are essential to provide a baseline against which to measure the child's growth during treatment, as well as for calculation of chemotherapeutic drug dosages.

Observe the area of the tumor, such as the face, neck, and abdomen, and describe any changes. Monitor respiratory status if the tumor is in the face or neck. Report any changes in respiratory pattern to the oncology specialist. Avoid palpation of any tumor site or enlarged area; injudicious palpation and manipulation of a tumor site can influence metastasis. Notify the primary healthcare provider of a change in any lymph node or any other area of the body.

Gastrointestinal and genitourinary functions can be altered by the presence of a tumor and by treatment such as chemotherapy and radiation. Careful measurement of the child's intake and output is essential. Abdominal tumors may affect defecation, so charting of all bowel movements is important. Explain to the family and child why keeping accurate records is necessary.

Observe wounds closely for lack of healing as a result of chemotherapy or radiation. Examine the mouth and extremities for wounds or ulcers. Nutritional changes caused by treatment will affect the body's ability to support healthy cells and heal wounds.

A thorough eye examination is warranted for any child who has a family history of retinoblastoma or has undergone treatment for a prior tumor. Assess color and position of the iris and eye movements and perform the cover–uncover test and other eye tests described in Chapter 5. Ask whether the child has been evaluated by an ophthalmologist.

PSYCHOSOCIAL ASSESSMENT

Refer to the general discussion of psychosocial assessment in the *Childhood Cancer* section earlier in this chapter. Assessment of body image is needed when the child has a soft-tissue tumor affecting appearance of the head and neck.

The location and type of a soft-tissue tumor determine the specific nursing diagnoses for a particular child. Common nursing diagnoses might include the following (NANDA-I © 2014):

- ***Tissue Perfusion: Peripheral, Risk for Ineffective,*** related to interruption of blood flow
- ***Breathing Pattern, Ineffective,*** related to effect of tumor deformity on neck or chest wall
- ***Swallowing, Impaired,*** related to tumor or treatment
- ***Development: Delayed, Risk for,*** related to effects of treatment
- ***Body Image, Disturbed,*** related to illness and treatment

Planning and Implementation

Nursing management of children with soft-tissue tumors varies depending on the specific tumor. Children with lymphoma affecting the mediastinum may need respiratory support. Position the child so that the head is elevated. Administer chemotherapeutic drugs as ordered, maintaining adequate fluids to facilitate excretion of the resultant breakdown products. Monitor the central line used for chemotherapy administration, and teach parents how to take care of the central line when the child is at home.

For the child with a rhabdomyosarcoma involving the bladder, monitor urinary output carefully. Report hematuria and painful urination. Monitor the changes that occur during therapy. For example, in children with eye tumors, observe for a decrease in ptosis, which may indicate successful treatment. Administer pain medications as needed and use distraction and other techniques to decrease the child's discomfort. Emphasize to parents the need for follow-up CT and MRI scans after completion of treatment.

When the child with retinoblastoma undergoes removal of the eye, the parents and child will need detailed instructions on postsurgical care. Demonstrate to the parents care of the socket and use of a conformer to maintain the eye socket shape. When healing is complete and the child receives a prosthetic eye, instruct parents about its insertion and care. The child can gradually be taught to take over this care when old enough. Encourage periodic healthcare visits to monitor for signs of a tumor in the other eye. Interventions to encourage normal developmental milestones are adapted if sensory alteration has resulted.

Pay attention to the body changes associated with the cancer and its treatment. Children and adolescents may need suggestions to deal with hair loss, disfigurement, and living with serious illness. Referral to other children and teens with similar concerns may be helpful. Parents of all children need help to encourage normal development in the child with cancer.

The child with a soft-tissue tumor often receives chemotherapy or radiation, or sometimes both modalities. Nursing management during chemotherapy and radiation is discussed earlier in this chapter in the general sections on these treatment measures and in *Nursing Care Plan: Hospital Care of the Child With Cancer*. Generally, the family needs help to adjust to the diagnosis of a life-threatening disease and to the care of the ill child. Refer to Chapter 11 for a description of postsurgical care. Consult Chapter 19 for strategies to assist the child and family if the child has a visual impairment resulting from a retinoblastoma. Topics for parent and family teaching and discharge planning are similar to those previously presented.

COMMUNITY-BASED NURSING CARE

Reinforce with families the importance of long-term follow-up after treatment for a soft-tissue tumor. Increased risk for secondary cancers for 2 to 3 decades is possible, and early identification can help with prompt diagnosis. Partner with other healthcare providers to provide instructions to families as the child transitions from oncology treatment back to the pediatrician so they understand the importance of telling all healthcare providers about the cancer and treatment. Establish oncology clinics to track and examine survivors. As children grow into teen and young adult years, help them take over this important task in their care.

Families Want to Know

Care of the Child With a Soft-Tissue Tumor

- Teach the family about the chemotherapeutic drugs and their side effects.
- Teach about the care of surgically placed venous access devices.
- Provide written and illustrated information about the chemotherapy protocol(s).
- Provide the family with radiation and surgery education specific to the tumor treatment.
- Refer the family to nutrition resources such as dietitians for ways to promote the child's adequate intake of food and fluid.

Some recommended annual examinations include the following:

- CBC
- Physical examination with special attention to skin, abdomen, and thyroid
- Monitoring for signs of hypothyroidism and hyperthyroidism
- Neurologic and developmental examinations; monitoring of school performance
- First mammogram at 25 years in those with chest radiation
- Pap and pelvic examinations for teen and young adult women
- Mental status assessment

Evaluation

The following expected outcomes of nursing care for the child with a soft-tissue tumor are examples that illustrate the varied tumor presentations:

- Side effects of treatment are successfully managed.
- The surgical site heals with no signs of infection.
- The child adapts successfully to sensory loss resulting from cancer or treatment.
- The child adapts to an altered self-image.
- The child achieves growth and development to maximum potential.
- In cases of terminal disease, parents receive adequate support for the process of anticipatory grieving.

Chapter Highlights

- Cancer is a leading cause of illness and death among children.
- Cancer may be influenced by chromosomal or genetic messages, environmental carcinogens, or infectious process; often a combination of factors is present.
- Cancer treatments include surgery, chemotherapy, radiation, biotherapy, and alternative therapies. Palliative care is needed when disease has relapsed and cure is no longer possible.
- Oncologic emergencies are life-threatening conditions caused by cancer or its treatment; the main types of emergencies are metabolic, hematologic, or space occupying.
- Key signs of childhood cancer are pain, cachexia, anemia, infection, bruising, petechiae, and neurologic symptoms.
- A protocol is a plan of action for chemotherapy that is based on the type of cancer, its stage, and the particular cell type.
- Nursing assessment for children with cancer involves detailed physical data, as well as psychologic factors, developmental achievements, and family social status.
- Common physical nursing interventions for children with cancer involve nutrition, medication administration, hydration, infection prevention, pain management, and measures to decrease side effects of treatment. Families require ongoing psychosocial support, information, and referral to diverse resources when caring for the child with cancer.
- While the numbers of children who are long-term survivors continue to grow, some of these children experience lasting effects such as cognitive or behavioral problems, recurrent or secondary cancers, or discrimination.
- Nursing care after cancer treatment is completed includes monitoring for any long-term physiologic or psychosocial sequelae.
- Common brain tumors in children include medulloblastoma, astrocytoma, ependyoma, and glioma; neuroblastoma is a tumor that is located along the sympathetic nervous system chain.
- Headache, vomiting, ataxia, seizures, increased intracranial pressure, hydrocephalus, and sensory disturbances are the major clinical manifestations of brain tumors.
- Nephroblastoma (Wilms tumor) is an intrarenal tumor; when suspected, the abdomen should not be palpated.
- Common bone tumors in childhood are osteosarcoma and Ewing sarcoma; both are most common among adolescents.
- Leukemia is a common childhood malignancy, with the major types being acute lymphoblastic leukemia (ALL) and acute myelogenous leukemia (AML).
- A variety of soft tissue tumors are seen in children and adolescents; they include Hodgkin disease, non-Hodgkin lymphoma, rhabdomyosarcoma, and retinoblastoma.
- Nurses are in a key position to assist families during the cancer diagnosis, treatment during adjustment to school and other life tasks, and in providing palliative care for children who do not survive.

Clinical Reasoning in Action

Seven-year-old Christina is brought to the hospital with an unusual rash, lethargy, and fever. Blood work is drawn, and the results are abnormal. The hematologist confirms that Christina has acute lymphoblastic leukemia (ALL), the most common childhood cancer. Her parents are in shock and disbelief about the news; she seems too young. Christina is immediately admitted to the hospital and put on an IV with orders for more blood work.

Christina's blood work demonstrates the following: hemoglobin 9 g/dL, leukocytes 20,000/mm^3, and platelets 90,000/mm^3. Chemotherapy was initiated and precautions were taken to avoid infections. Recommendations for Christina include rest times daily, generous amounts of water, intake of healthy foods, and avoidance of sun exposure. The parents are happy when Christina comes home during the chemotherapy. The hematologist advises them it is not uncommon to return to the hospital because of a chemotherapeutic complication. The parents are encouraged to remember to take care of themselves. This will help them deal with Christina's therapy more effectively.

1. What are some of the common side effects of chemotherapy?
2. Why is it important to check Christina's daily weights?
3. What symptoms should Christina's parents report to the doctor while she is on chemotherapy?
4. What are some developmentally appropriate techniques you can encourage that will assist Christina to deal with her illness?

Chapter 25
Alterations in Gastrointestinal Function

Monkey 3000/Fotolia

I was so worried when Jerome was born. He had no anal opening and his esophagus did not lead to his stomach. Now that he's had several surgeries, he is growing and doing pretty well, and I'm so happy to see him starting to smile. I can't wait until his final surgery is completed and he no longer has the colostomy.

—Mother of Jerome, 6 months old

Learning Outcomes

25.1 Describe the general function of the gastrointestinal system.

25.2 Discuss the pathophysiologic processes associated with specific gastrointestinal disorders in the pediatric population.

25.3 Identify signs and symptoms that may indicate a disorder of the gastrointestinal system.

25.4 Contrast nursing management and plan care for disorders of the gastrointestinal system for the child needing abdominal surgery versus the child needing nonoperative management.

25.5 Analyze developmentally appropriate approaches for nursing management of gastrointestinal disorders in the pediatric population.

25.6 Plan nursing care for the child with an injury to the gastrointestinal system.

What causes structural defects of the gastrointestinal tract such as the esophageal atresia and imperforate anus experienced by Jerome? What special care do children with gastrointestinal abnormalities need to promote growth and development during treatment for those anomalies? This chapter discusses the care of infants who have structural defects and those with other common disorders of gastrointestinal functioning.

Structural Defects

Structural defects can involve one or more areas of the gastrointestinal tract. These defects occur when growth and development of fetal structures are interrupted during the first trimester. This can leave the structure incomplete, resulting in *atresia* (absence or closure of a normal body orifice), malposition, nonclosure, or other abnormalities.

Cleft Lip and Cleft Palate

Cleft lip and cleft palate are two distinct facial defects that can occur singly or in combination (Figure 25–2). Cleft lip with or without cleft palate occurs in 1 out of every 750 to 1000 live births. The incidence is higher in Asian (1 in 500) than in White children (1 in 750). The defect is less common in African Americans, with an incidence of 1 of every 2000 live births. Cleft lip

FOCUS ON:
The Gastrointestinal System

Anatomy and Physiology

The gastrointestinal (GI) tract includes the esophagus, stomach, pancreas, small intestine, and large intestine (Figure 25–1). Through the GI tract, a child ingests and absorbs the foods and fluids necessary to sustain life and promote growth. Elimination of waste products is another role of the GI tract. Other organs located in the abdominal region include the gallbladder, liver, and spleen. The abdomen is generally divided into four quadrants for purposes of assessment. (Refer to Figure 5–25 for the abdominal organs and structures in each quadrant.)

Esophagus and Stomach

The esophagus is a continuous tube that allows food to pass to the stomach. Food enters the esophagus through the mouth, where it is chewed. Initial enzyme secretion then occurs to begin food digestion. (See Chapter 19 for more information related to the mouth and pharynx.) The stomach is located in the left upper quadrant (LUQ) of the abdomen. The role of the stomach is to store food and to secrete enzymes and digestive juices that aid in the digestion of the food. Hydrochloric acid stimulates the stomach's pepsinogens to become pepsins, which break down proteins and are active in acidic levels (pH of 3 or less). The stomach propels food that is partially digested into the duodenum (a part of the small intestine).

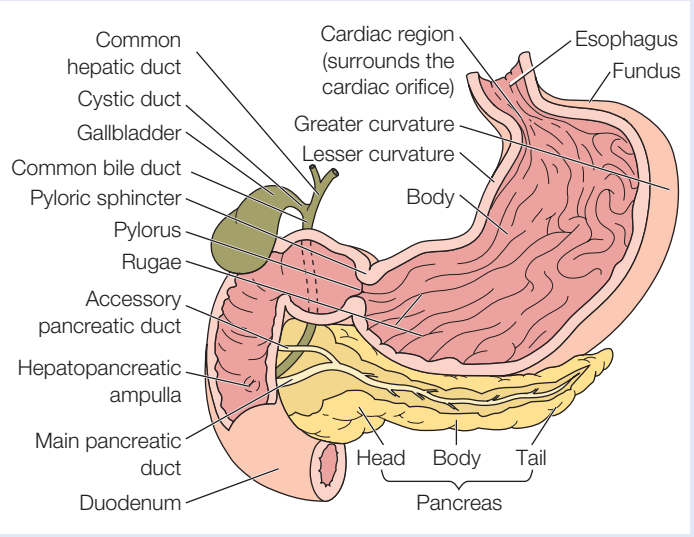

Figure 25–1 The internal anatomic structures of the stomach, including the pancreatic, cystic, and hepatic ducts; the pancreas; and the gallbladder.

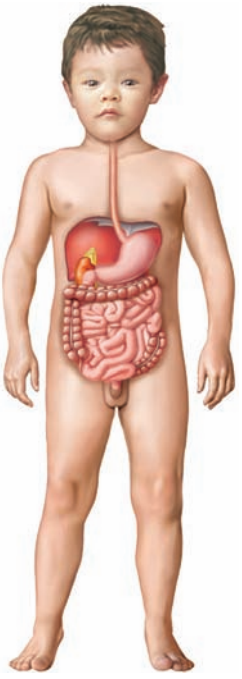
As Children Grow: **Stomach Capacity**

The young infant has a smaller stomach capacity than that of an older child or adolescent. A newborn has a stomach capacity of approximately 20 mL (Bergman, 2013). As infants grow, their stomach capacity increases, decreasing the frequency with which they need to be fed (American Academy of Pediatrics [AAP], 2014). Stomach capacity increases to approximately 90 mL in a 30-day-old term infant and to 360 mL around 1 year of age. An adult stomach holds 2 to 3 L (Collopy & Friese, 2010).



Source: Data from American Academy of Pediatrics. (2014). *Amount and schedule of formula feedings*. Retrieved from healthychildren.org/English/ages-stages/baby/feeding-nutrition/Pages/Amount-and-Schedule-of-Formula-Feedings.aspx; Bergman, N. J. (2013). Neonatal stomach volume and physiology suggest feeding at 1-h intervals. *Acta Paediatrica, 102*, 773–777; Collopy, K., & Friese, G. (2010). Pediatric drug administration. *Emergency Medical Services Magazine, 39*(6), 52–57.

Pancreas

The pancreas is located behind the stomach and has several functions. The pancreas secretes enzymes, electrolytes, and bicarbonate that aid in the digestion and absorption of fats, proteins, and carbohydrates (Werlin & Wilschanski, 2016). Another key function of the pancreas is to regulate blood glucose metabolism through production of insulin, glucagon, and gastrin.

Liver and Gallbladder

The liver, the largest organ in the abdomen, is located in the right upper quadrant (RUQ). Its primary functions include production of blood clotting factors, fibrinogen and prothrombin; secretion of bile and bilirubin (yellow pigment produced from the breakdown of red blood cells); metabolism of fat, protein, and carbohydrates; detoxification of hormones, drugs, and other substances; and storage of vitamins A, D, E, and K and glycogen. The gallbladder is a small organ located behind the liver. The gallbladder stores and concentrates the bile that is produced in the liver. It then releases stored bile as needed into the duodenum. Bile includes a variety of substances such as water, salts, bilirubin, and cholesterol. A major role of bile is to emulsify fats so that fatty acids become soluble and absorbable (Huppert & Balistreri, 2016).

Spleen

The spleen is located in the LUQ of the abdomen and is a highly vascular organ. The spleen contains about 30% of the circulating platelets and is a site for red blood cell production as well. Defense against infection is another key role of the spleen (Brandow & Camitta, 2016).

Small and Large Intestine

The small intestine consists of the duodenum, the jejunum, and the ileum. Each part of the small intestine plays a vital role in the digestion and absorption of carbohydrates, amino acids, and fats. The intestinal wall is covered with small villi, the brush border, through which absorption occurs. Absorption occurs both through diffusion (commonly monosaccharides, amino acids, fatty acids, and glycerol) and active transport (commonly disaccharides, dipeptides, and tripeptides). A complex system of innervation and secretions maintains a basic pH that facilitates metabolism and absorption. The large intestine includes the cecum, the appendix, the colon (consisting of ascending, transverse, descending, and sigmoid portions), and the rectum, which passes to the exterior through the anus. The primary function of the large intestine is reabsorption of fluid and electrolytes from the GI tract and excretion of wastes (Liacouras, 2016). Bacteria in the large intestine synthesize vitamin K and facilitate some vitamin B absorption.

Pediatric Differences

Although the fetus makes sucking and swallowing movements in utero and ingests amniotic fluid, the GI system is immature at birth. The processes of absorption and excretion do not begin until after birth, because the placenta provides nutrients and removes waste. Sucking is a primitive reflex that occurs whenever the lips or cheeks are stroked. The infant does not have voluntary control over swallowing until about 6 weeks of age.

The stomach capacity of the newborn is quite small, and intestinal motility (**peristalsis**) is greater than in older children (see *As Children Grow: Stomach Capacity*). These characteristics explain the newborn's need for small, frequent feedings and the increased frequency and liquid consistency of bowel movements. Because of the relaxed cardiac sphincter, infants frequently regurgitate small amounts of feedings.

Digestion takes place in the duodenum. Infants have a deficiency of several enzymes: amylase (which digests carbohydrates), lipase (which enhances fat absorption), and trypsin (which catabolizes protein into polypeptides and some amino acids). Enzymes are usually not present in sufficient quantities to aid digestion until 4 to 6 months of age. Thus abdominal distention from gas is common.

Liver function is also immature. After the first few weeks of life the liver is able to conjugate bilirubin and excrete bile. The processes of **gluconeogenesis** (formation of glycogen from noncarbohydrates), plasma protein and ketone formation, vitamin storage, and **deamination** (removal of amino group from amino compound) remain immature during the first year of life.

By the second year of life, digestive processes are fairly complete. Stomach capacity increases to accommodate a three-meals-per-day feeding schedule. Around 18 months of age, the child becomes aware of a full rectum and is physically able to have some control over excretory functions (Goldson & Reynolds, 2012).

Use *Assessment Guide: The Child With a Gastrointestinal Condition* to perform a nursing assessment of the gastrointestinal system. A list of diagnostic and laboratory tests used to evaluate gastrointestinal conditions is provided in Table 25–1. See Appendices D and E for further information about lab values and test procedures for the gastrointestinal system.

TABLE 25–1 Diagnostic Tests and Laboratory Procedures for the Gastrointestinal System

DIAGNOSTIC PROCEDURES	LABORATORY TESTS
Abdominal ultrasound	Complete blood count
Barium or contrast enema	Bilirubin
CT of the abdomen	Electrolytes
Endoscopy	Liver enzymes
GI series	Stool for occult blood
Intraesophageal pH probe monitoring	Stool for ova and parasites
Abdominal radiographs	

Note: See Appendices D and E for information about these diagnostic procedures and tests.

(*continued*)

ASSESSMENT GUIDE | The Child With a Gastrointestinal Condition

Assessment Focus	Assessment Guidelines
Abdomen—inspection	• Observe the shape of the abdomen. • Note any abdominal distention. Measure abdominal girth. • Observe the umbilicus for protrusion. • Observe for peristaltic waves (visible rhythmic contractions of the intestinal wall smooth muscle). • Observe for jaundice, bruising, and increased bleeding.
Abdomen—auscultation	• Auscultate for bowel sounds in all four quadrants prior to palpation.
Abdomen—palpation	• Palpate the abdomen and note if it is soft or firm. • Palpate the size of the umbilical ring. • Does the child complain of pain or tenderness during palpation? Does the infant cry? • Describe any masses palpated by location, shape, size, and consistency. • Palpate the liver for size and tenderness. • Palpate the spleen for size and tenderness.
Mouth and esophagus	• Note the presence of increased oral secretions. • Note the presence of cleft lip or palate.
Nutrition	• Note tolerance of feedings, spitting up, emesis, and recurrent respiratory infections. • Observe amount, color, and frequency of emesis. • Note if emesis is associated with feeding and whether or not it is projectile. • Note amount of intake, frequency of feedings, and growth.
Stool	• Observe color, consistency, and size of stool. Note any changes in stool patterns.
Family history	• Ask about history of gastrointestinal illness with genetic influences such as celiac disease and inflammatory bowel disease.

Figure 25–2 **Unilateral cleft lip.**

SOURCE: Dr. P. Marazzi/Science Source.

and palate occur together in approximately 45% of cases, while cleft palate occurs alone approximately 35% of the time, and cleft lip occurs alone approximately 20% of the time (Patel, Cohen, Ramaswamy, et al., 2014).

ETIOLOGY AND PATHOPHYSIOLOGY

Cleft lip with or without cleft palate results when the maxillary processes fail to fuse with the elevations on the frontal prominence during the sixth week of gestation. Normally, union of the upper lip is complete by the seventh week. Fusion of the secondary palate occurs between 5 and 12 weeks of gestation. Failure of the tongue to move downward at the correct time prevents the palatine processes from fusing.

The intrauterine development of the hard and soft palates is completed in the first trimester. It is during this time that other major organ systems develop. Approximately 30% of children with cleft and/or palate will have another congenital anomaly (Setó-Salvia & Stanier, 2014). There is an increased incidence in families with a prior history of cleft lip or palate. The cause is believed to be multifactorial, involving a combination of environmental and genetic influences. Etiologic factors include smoking during pregnancy, maternal use of alcohol, and use of medications such as anticonvulsants and steroids during pregnancy (Setó-Salvia & Stanier, 2014). Additional studies have suggested that folate intake during pregnancy may reduce the incidence of cleft lip and palate (Blanton et al., 2011; Kelly, O'Dowd, & Reulbach, 2012).

CLINICAL MANIFESTATIONS

A cleft that involves the lip is readily apparent at birth. It may be a simple dimple in the vermilion border of the lip or a complete separation extending to the floor of the nose. The defect may be unilateral or bilateral and may occur alone or in combination with a cleft palate defect. Varying degrees of nasal deformity may also be present.

Cleft palate defects are less obvious when they occur without a cleft lip and may not be detected at birth. Clefts of the hard palate form a continuous opening between the mouth and nasal cavity and may be unilateral or bilateral, involving just the soft palate or both the soft and hard palates.

CLINICAL THERAPY

A multidisciplinary team is involved in cleft lip and palate management since these children have an increased risk for impairment in speech, hearing, and dentition. The team should include the pediatric primary healthcare provider and specialists in plastic and oral surgery, audiology, speech/language pathology, otolaryngology, dentistry, genetics, social work, and psychology (Crockett & Goudy, 2014).

Cleft lip and palate are usually diagnosed at birth or during the newborn assessment, but may be diagnosed in utero. Successful imaging of the face via transabdominal ultrasound can be performed as early as 13 to 14 weeks' gestation. Use of three-dimensional ultrasound or magnetic resonance imaging, if available, allows for a clearer picture of the defect and enhances the ability to detect isolated cleft palate prenatally (Wilkins-Haug, 2014). After the child is born, cleft lip and cleft palate are diagnosed by characteristic physical findings. The upper lip, alveolar arches, nostrils, and primary and secondary palates should be inspected and palpated (Crockett & Goudy, 2014).

The timing of cleft lip repair varies among surgeons. Repair generally occurs between 3 and 5 months of age, but may occur earlier or later depending on surgeon preference (Figure 25–3). If the defect is severe, the child may need more than one operation to achieve total repair. After surgery, soft elbow immobilizers (also known as restraints) are used for 2 weeks to protect the incision. (See the *Clinical Skills Manual* SKILLS.) The child should receive distraction and pain medication as needed because prolonged crying may disrupt the suture line. Antibiotics may also be prescribed (Crockett & Goudy, 2014).

Figure 25–3 **Repaired unilateral cleft lip.**

SOURCE: jorgecachoh/Fotolia.

Early closure of the lip enables the infant to form a better seal around the nipple for feeding. The sucking motion strengthens the muscles necessary for speech. Special feeding devices such as longer nipples with enlarged holes are available to help meet the infant's nutritional needs before surgical correction. A lactation consultant can assist with breastfeeding techniques.

Timing of the cleft palate repair varies among surgeons and depends on the size and severity of the cleft. The palate should be closed by 12 months of age (Wiet, Biavati, & Rocha-Worley, 2013). This protects the formation of tooth buds and allows the infant to develop more normal speech patterns.

Infants with cleft lip and cleft palate are prone to recurrent otitis media, which can lead to hearing problems. (Refer to Chapter 19 for care of the child with chronic otitis media.) The child who has had a cleft palate repair requires orthodontic care. Early visits permit assessment of tooth eruption and the need for future orthodontic work.

Nursing Management

For the Child With Cleft Lip and Cleft Palate

Nursing Assessment and Diagnosis

PHYSIOLOGIC ASSESSMENT

A cleft lip defect is observable at birth. A cleft palate defect is usually noted during the newborn assessment by palpation of the primary and secondary palate (Crockett & Goudy, 2014). A description of the location and extent of the defect helps the nurse determine the correct method of feeding. Thorough and complete physical assessment is required since additional defects are sometimes present.

Developing Cultural Competence **Corrective Surgery for Cleft Lip and Palate**

In many developing countries, infants do not have access to surgery for correction of cleft lip and palate. They may grow into childhood and adulthood with these abnormalities. Medical teams from the United States, Canada, and other countries sometimes travel to developing nations for short medical missions, performing surgery on the children and teaching local doctors surgical techniques. Are there medical missions teams from your area that perform these surgeries? What planning is required for such trips to perform surgery safely and care for the children? What is the impact on the communities served?

PSYCHOSOCIAL ASSESSMENT

Assessment of the family's reactions is an integral part of the overall nursing assessment. Physical deformities, especially of the face, can be devastating to parents. A poorly corrected defect can lead to the development of low self-esteem in the older child. Assess the child's developmental level and social interactions with peers.

The accompanying *Nursing Care Plan* lists common nursing diagnoses for the infant with a cleft lip and/or palate. Other diagnoses that might be appropriate include the following (NANDA-I © 2014):

- ***Anxiety (Parent)*** related to situational crisis and threat to self-concept

- ***Attachment, Risk for Impaired (Parent and Infant),*** related to newborn's structural defect
- ***Pain, Acute,*** related to surgical repair of defect
- ***Development: Delayed, Risk for,*** related to structural defect and altered nutritional intake

Planning and Implementation

Nursing care involves providing emotional support, performing postsurgical care, educating parents on feeding techniques, helping parents coordinate care and maintain a healthy home environment, and making appropriate referrals. See *Nursing Care Plan: The Infant With a Cleft Lip or Palate* for a summary of nursing care.

Nursing Care Plan: The Infant With a Cleft Lip or Palate

Preoperative Care

1. Nursing Diagnosis: *Aspiration, Risk for,* related to anatomic defect (NANDA-I © 2014)

GOAL: The infant will have no episodes of gagging or aspiration.

INTERVENTION	RATIONALE
• Assess respiratory status and monitor vital signs at least every 2 hr.	• Allows for early identification of problems.
• Keep suction equipment and bulb syringe at bedside.	• Suctioning may be necessary to remove milk or mucus.
• Position upright for feedings.	• Minimizes passage of feedings through cleft.
• Feed slowly and use adaptive equipment as needed.	• Facilitates intake while minimizing risk of aspiration.
• Hold upright for 30 minutes after feeding.	• Prevents aspiration of feedings.
• Burp frequently (after every 15–30 mL of fluid).	• Helps to prevent regurgitation and aspiration.

EXPECTED OUTCOME: Infant will exhibit no signs of respiratory distress.

2. Nursing Diagnosis: *Coping: Family, Compromised,* related to birth of a child with a defect (NANDA-I © 2014)

GOAL: Parents will begin bonding process with the infant. The family's coping ability will be maximized. Parents will verbalize the nature and sequelae of the defect.

INTERVENTION	RATIONALE
• Help parents hold the infant and facilitate feeding process.	• Contact is essential for bonding.
• Point out positive attributes of infant (e.g., hair, eyes, alertness.).	• Helps parents see the child as a whole, rather than concentrating on the defect.
• Explain surgical procedure and expected outcome. Show pictures of other children's cleft lip repair.	• Eliminating unknown factors helps to decrease anxiety.
• Assess parents' knowledge of the defect, their degree of anxiety and level of discomfort, and the interpersonal relationships among family members.	• Helps determine the appropriate timing and amount of information to be given regarding the child's defect.
• Provide information about the etiology of cleft lip and palate defects and the special needs of these infants. Encourage questions.	• Concrete information allows parents time to understand the defect and reduces guilt.
• Explore the reactions of extended family members.	• Extended family is an important source of support for most parents of a newborn. Family members can often help promote acceptance and compliance with the treatment plan.
• Support rooming in.	• Rooming in allows parents to continue the bonding process.
• Encourage parents to participate in caretaking activities (holding, diapering, feeding).	• Participation in infant care decreases anxiety and provides parents with a sense of purpose.
• Refer to parent support groups.	• Support groups allow parents to express their feelings and concerns, to find people with concerns similar to their own, and to seek additional information.

EXPECTED OUTCOME: Parents will hold, comfort, and show concern for the infant. Family will demonstrate ability to cope with and manage the infant's care. Parents receive necessary support to care for their infant.

3. Nursing Diagnosis: *Nutrition, Imbalanced: Less than Body Requirements,* related to the infant's inability to ingest nutrients (NANDA-I © 2014)

GOAL: The infant will gain weight steadily.

INTERVENTION	RATIONALE
• Assess fluid and calorie intake daily. Assess weight daily (same scale, same time, with infant completely undressed). Teach parents signs of adequate fluid intake such as frequency of wet diapers.	• Provides an objective measurement of whether the infant is receiving sufficient caloric intake to promote growth. Using the same scale and procedure when weighing the infant provides for comparability between daily weights.
• Observe for any respiratory impairment.	• Any symptoms of respiratory compromise will interfere with the infant's ability to suck. Feedings should be initiated only if there are no signs of respiratory distress.
• Provide weight-appropriate calories and fluid amounts. If the infant needs an increased number of calories to grow, referral to a nutritionist should be made. Higher calorie concentration formulas are available.	• Provides optimal calories and fluids for growth and hydration.
• Facilitate breastfeeding.	• Breast milk is recommended as the best food for an infant. The process of breastfeeding helps to promote bonding between mother and infant.
• Hold the infant in an upright position.	• Facilitates swallowing and minimizes the amount of fluid return from the nose.
• Give the mother information on breastfeeding the infant with a cleft lip or palate such as plugging the cleft lip and eliciting a letdown reflex before nursing.	• Information and specific suggestions may encourage the mother to persist with breastfeeding.
• Contact the La Leche League for the name of a support person.	• The La Leche League promotes breastfeeding for all infants. It can provide support people with experience who will aid the mother.
• If the mother is unable to breastfeed (or prefers not to), initiate bottle-feeding:	• Facilitates swallowing and minimizes the amount of fluid return from the nose.
• Place nipple against the inside cheek toward the back of the tongue. If needed, use a premature nipple (slightly longer and softer than regular nipple with a larger opening) or special cleft feeder.	• Use of longer, softer nipples makes it easier for the infant to suck. Special cleft feeders decrease the amount of pressure in the bottle and make the formula flow more easily.
• Initiate nasogastric feedings if the infant is unable to ingest sufficient calories by mouth.	• Adequate nutrition must be maintained. Use of a feeding tube allows the infant who has difficulty with oral feeding to receive adequate nutrition for growth.

EXPECTED OUTCOME: Infant will maintain adequate nutritional intake and gain weight appropriately. Successful breastfeeding will be achieved if desired. Feeding will provide necessary nutrients and will be a positive experience for parents and infant.

Postoperative Care

1. Nursing Diagnosis: *Breathing Pattern, Ineffective,* related to surgical correction of defect (NANDA-I © 2014)

GOAL: The infant will maintain an effective breathing pattern.

(*continued*)

Nursing Care Plan: The Infant With a Cleft Lip or Palate (*continued*)

INTERVENTION	RATIONALE
• Assess respiratory status and monitor vital signs at least every 2 hr.	• Frequent assessment allows for early identification of problems.
• Apply a cardiorespiratory monitor.	• The monitor enables early detection of abnormal respirations, facilitating prompt intervention.
• Keep suction equipment and bulb syringe at the bedside. Gently suction oropharynx and nasopharynx as needed; avoid suture areas.	• Gentle suctioning will keep the airway clear. Suctioning that is too vigorous can irritate the mucosa.
• Provide cool mist for first 24 hr postoperatively if ordered.	• A mist moisturizes secretions to reduce pooling in the lungs. It also moisturizes the oral cavity.
• Reposition every 2 hr.	• Repositioning ensures expansion of all lung fields.

EXPECTED OUTCOME: Infant will show no signs of respiratory infection or compromise.

2. Nursing Diagnosis: *Tissue Integrity, Impaired,* related to mechanical factors (NANDA-I © 2014)

GOAL: The infant's lip and/or palate will heal with minimal scarring or disruption.

INTERVENTION	RATIONALE
• Position the infant with cleft lip repair on back.	• Prone positioning would allow the infant to rub the suture line.
• Use soft elbow immobilizers. Remove every 2 hr and replace. Do not leave the infant unattended when immobilizers are removed.	• Immobilizers prevent the infant's hands from rubbing surgical site. Regular removal allows for skin and neurovascular checks.
• Maintain suture line or Steri-Strips placed over cleft lip repair.	• Maintaining suture line will minimize scarring.
• Avoid metal utensils or straws after cleft palate repair.	• These devices may disrupt suture line.
• Do not allow pacifiers.	• Sucking can disrupt suture line.
• Keep the infant well medicated for pain in initial postoperative period. Have parents hold and comfort the infant.	• Good pain management minimizes crying, which can cause stress on the suture line. Increases bonding and soothes the child to decrease crying.
• Provide developmentally appropriate activities (i.e., mobiles, music).	• Appropriate activities soothe and keep the infant calm.

EXPECTED OUTCOME: Lip/palate will heal without complications.

3. Nursing Diagnosis: *Nutrition, Imbalanced: Less than Body Requirements,* related to inability to ingest nutrients (NANDA-I © 2014)

GOAL: The infant will receive adequate nutritional intake.

INTERVENTION	RATIONALE
• Maintain intravenous infusion as ordered.	• The IV provides fluid when the child is NPO (nothing by mouth).
• Begin with clear liquids, then give half-strength formula or breast milk as ordered.	• Ensures adequate fluids and nutrients.
• Use syringe or dropper inside of mouth.	• Avoids suture line and resultant accumulation of formula in that area.
• Give high-calorie soft foods after cleft palate repair.	• Rough foods, utensils, and straws could disrupt the surgical site.

EXPECTED OUTCOME: Infant will receive adequate nutritional intake. The infant resumes usual feeding patterns and gains weight appropriately.

PROVIDE EMOTIONAL SUPPORT

When a child is born with a cleft lip/cleft palate, parents may grieve the loss of the ideal child that they expected. Parents may need assistance to view their infant as a whole person, rather than focusing solely on the physical defect. Promote parent–infant bonding by explaining the nature of the structural defect and the procedure for correction. Interact and speak to the infant in the parents' presence and point out positive attributes such as alertness, soft skin, or active movements. Self-blame is common among parents. Parents can also be referred to the American Cleft Palate Association for information about the disorder. Pictures of children who have had repair are available at this website. Seeing pictures of children who have had a successful repair offers reassurance to parents.

Parental anxiety is a typical response when children undergo surgery, and it is heightened when the surgery involves an infant. To minimize anxiety, give clear, concise explanations to parents. Allow sufficient time for parents to ask questions. Encourage parents to hold and cuddle the infant before surgery (see Chapter 11).

PROVIDE POSTOPERATIVE CARE

Provide general postoperative care for the infant. (See *Nursing Care Plan: The Infant With a Cleft Lip or Palate* here and *Nursing Care Plan: The Child Undergoing Surgery* in Chapter 11.) Additional postoperative nursing diagnoses may include (NANDA-I © 2014):

- ***Infection, Risk for,*** related to location of surgical procedure
- ***Knowledge, Deficient (Parent),*** related to lack of exposure and unfamiliarity with resources

Assess vital signs frequently and maintain the infant's airway. Measure intake and output. When oral fluids with clear liquids are started, they are usually given through a dropper, syringe, or special feeder. Position the infant in a sitting position for the feedings to avoid aspiration. Frequently burp the infant during feedings. The infant then progresses to half-strength formula or breast milk. After each feeding, cleanse the suture line with water or normal saline to avoid accumulation of feedings. In addition, the following specific interventions are necessary to ensure healing of the suture line:

- Prevent the infant from rubbing the suture line on the bedding by positioning the infant in a supine position.
- Maintain soft elbow immobilizers.
- Maintain the suture line or Steri-Strips placed over the incision. Place antibiotic body ointment on the incision site as ordered.
- Medicate the infant as prescribed to control pain and to minimize crying and stress on the suture line.
- After cleft palate surgery, avoid the use of metal utensils or straws, which may disrupt the surgical site.

COMMUNITY-BASED NURSING CARE

Identify and address home care needs well in advance of discharge. Discuss all aspects of the infant's care with the parents throughout hospitalization and after surgery. Involve parents in the infant's care to increase their comfort level before discharge and to promote bonding. Teach feeding techniques, how to recognize signs of infection, how to position the infant, and how to care for the suture line. Breastfeeding is usually possible with some assistance from a lactation specialist, even if the mother pumps her breasts and milk is fed by a special nurser. For infants requiring assistance to feed, several wide-based nipples, squeezable bottles, and other special bottles are available. Management involves many different healthcare professionals. In addition to hospital, clinic, and home health nurses, members of the healthcare team often include specialists such as a plastic surgeon, orthodontist, dentist, social worker, audiologist, speech pathologist, and pediatrician. The parents are the best coordinators of the child's care. Encourage them to keep a diary listing the professionals with whom they talk and the content of the discussions.

Teach parents how to care for the child after discharge. Teach them how to feed the infant, identify signs of complications (fever, vomiting, respiratory distress), administer any medications as prescribed, and care for the surgical site. Emphasize the importance of soft elbow immobilizers as prescribed.

Discuss with the parents the financial implications of long-term care. Private insurance does not always cover all the costs of care necessary for the child. Refer parents to programs and financial aid for which the parents and child may be eligible. Relief from financial worries enables parents to concentrate on caring for the child. Determine whether additional family supports are necessary.

Growth and Development

An infant who has had a cleft lip repair needs stimulation to provide distraction. This approach will minimize crying, which can damage the suture line. Soft, colorful toys, mobiles, and other visual objects are helpful. Music also can be used to soothe the infant. Parental presence is comforting and reassuring.

Referral to a home healthcare agency for support may be helpful. Encourage follow-up visits with healthcare professionals (see *Health Promotion: The Child With Cleft Lip or Cleft Palate*). The child may need further evaluation of speech development, ear infections, or a recommendation for plastic surgery.

Evaluation

Expected outcomes of nursing care are provided in the accompanying *Nursing Care Plan*.

Esophageal Atresia and Tracheoesophageal Fistula

Esophageal atresia is a malformation that results from failure of the esophagus to develop as a continuous tube during the fourth and fifth weeks of gestation. The defect affects occurs in approximately 1 in 4500 neonates (Liszewski, Bairdain, Buonomo, et al., 2014). At least 90% of those affected also have a tracheoesophageal fistula (Khan & Orenstein, 2016a).

ETIOLOGY AND PATHOPHYSIOLOGY

In esophageal atresia, the foregut fails to lengthen, separate, and fuse into two parallel tubes (the esophagus and trachea) during fetal development. Instead the esophagus may end in a blind pouch or develop as a pouch connected to the trachea by a fistula (tracheoesophageal fistula) (see *Pathophysiology Illustrated: Esophageal Atresia and Tracheoesophageal Fistula*). Esophageal atresia is often associated with a maternal history of polyhydramnios (Khan & Orenstein, 2016a; Saxena, Blair, & Konkin, 2014). Other congenital anomalies occur in greater than 50% of children with esophageal atresia (Barman, Mandal, Shukla, et al., 2014). Jerome, the child described in the quotation at the beginning of the chapter, had esophageal atresia as well as an imperforate anus.

Health Promotion The Child With Cleft Lip or Cleft Palate

The child with cleft lip or cleft palate requires close monitoring and intervention to foster growth and development. The nurse can assist the child and family to achieve healthy outcomes.

Growth and Development Surveillance

- Monitor the child's growth and developmental patterns.
- Monitor for developmental delays.
- Explain to parents that regression following surgery in the toddler or older child is normal.

Nutrition

- Refer the family to sources for nipples, nursers, and other special feeding devices.
- Assist the mother with learning how to express breast milk and facilitate breastfeeding.
- Teach parents to avoid giving foods that can pose a choking hazard to the child.
- Teach parents to feed the infant in an upright position and to burp the child frequently during feedings.

Physical Activity

- Activity for the child having surgical procedures to correct cleft palate is generally restricted for approximately 2 to 3 weeks postsurgery to allow for healing.
- After healing has occurred, encourage the parents to promote the child's activities as they would any child without cleft lip or cleft palate.

Oral Health

- The child should be routinely screened for dental caries. Ask the family about dental visits.
- Teach the parents to provide good dental hygiene to the child.
- Routine dental/orthodontic evaluation is necessary for the child with cleft palate.

Mental and Spiritual Health

- For uncorrected or poorly corrected cleft lip or palate, the child may experience poor self-esteem related to body image.
- Encourage the family to adhere to treatment and surgical correction plan, including staged surgical corrections, dental care, and speech pathology assistance.
- Ask the family about financial ability regarding speech therapy, dental care, and other services that may be required. Financial constraints can impede compliance with recommended therapies.
- Be alert for the child who has had experiences with teasing associated with articulation or physical appearance.
- Refer parents to websites such as Project Smile and other resources.
- Refer the child for counseling if indicated.

Relationships

- Evaluate the parents for parent–infant bonding.
- Promote bonding by encouraging the parents to participate in the infant's care, to hold the infant, and to recognize the infant's positive attributes.

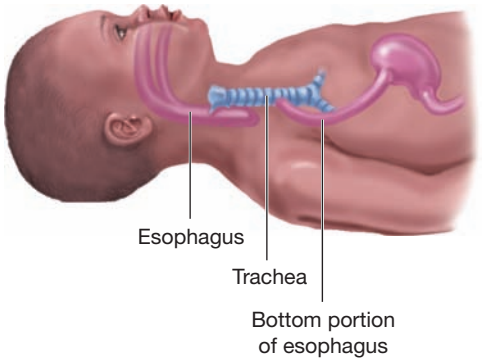
Disease Prevention Strategies

- Teach the family to recognize signs and symptoms of ear or other infections and to seek immediate evaluation. Treatment of acute otitis media is necessary to prevent long-term effects of repeated infections.
- Emphasize to the parents the importance of audiology screening for children with cleft lip and palate to evaluate conductive hearing loss.

Injury Prevention Strategies (Safety)

- Assist parents in properly applying elbow immobilizers to protect the suture line in the postoperative period.
- Ask the parents about eating utensils the child uses.
- Teach parents to avoid straws, metal spoons, and other sharp utensils that may damage the palate.

Pathophysiology Illustrated: Esophageal Atresia and Tracheoesophageal Fistula



In the most common type of esophageal atresia and tracheoesophageal fistula, the upper segment of the esophagus ends in a blind pouch connected to the trachea; a fistula connects the lower segment to the trachea.

CLINICAL MANIFESTATIONS

Symptoms in the newborn include excessive salivation and drooling, often accompanied by three classic signs for this defect: cyanosis, choking, and coughing. Sneezing may also be noted. During feeding, fluid returns through the infant's nose and mouth. Aspiration places the infant at risk for pneumonia. Depending on the type of defect, the infant's abdomen may be distended because of air trapping.

CLINICAL THERAPY

Esophageal atresia is suspected based on the presence of polyhydramnios and a small or absent fetal gastric bubble noted on prenatal ultrasound (Garabedian et al., 2014; Nowicki, 2013). After the child is born, passage of a radiopaque tube through the esophagus may be attempted. If the tube meets resistance, a chest and abdominal radiograph can confirm the presence of esophageal atresia. Radiologic examination may also reveal associated anomalies (Nowicki, 2013). Early diagnosis is essential to prevent aspiration of secretions, which can lead to pneumonia (Khan & Orenstein, 2016a).

Primary repair is preferred when possible and involves connecting the two ends of the esophagus and ligating the fistula if present (Nowicki, 2013). If primary repair of the esophageal atresia is not possible in the neonatal period, a gastrostomy tube is placed for feedings and the fistula is ligated (Nowicki, 2013; Saxena et al., 2014). Several procedures have been developed that allow for stretching of the esophagus over a period of time. Once the length of the esophagus is adequate, the two ends are reconnected in a delayed primary repair. The child will generally remain in the hospital setting until the repair. Potential postoperative complications include gastroesophageal reflux, aspiration, stricture formation, leak at the area of anatamosis, and tracheomalacia (Nowicki, 2013).The prognosis is usually good with surgery; however, some conditions are complicated, requiring repeated surgeries and long-term management. In the event that the two ends of the esophagus cannot be reconnected, colonic, jejunal, or gastric segments may be used to lengthen the esophagus (Khan & Orenstein, 2016a).

Nursing Management

The nurse may recognize the signs and symptoms in the immediate newborn period. Assess the infant for difficulty feeding and excessive drooling and the classic signs of choking, coughing, and cyanosis. Assess for respiratory distress and assess the lung sounds carefully.

Esophageal atresia is a surgical emergency. Preoperatively the infant requires close observation and intervention to maintain a patent airway. Specific interventions include:

- Have suction readily available to remove any secretions that accumulate in the nasopharyngeal airway.
- Place the infant with the head of the bed slightly elevated to minimize aspiration of secretions into the trachea.
- Use continuous or low intermittent suction to remove secretions from the blind pouch.
- Withhold oral fluids, and provide maintenance intravenous fluids.
- Constantly monitor the infant's vital signs and overall condition.

After surgery administer intravenous fluids and antibiotics. Monitor strict intake and output. Total parenteral nutrition may be needed until gastrostomy or oral feedings are tolerated. Monitoring and assessment of feeding tolerance are ongoing. Feedings are introduced slowly and in small amounts. Assess for respiratory difficulty during reintroduction of feedings. Monitor weight, growth, and developmental achievements.

The parents require emotional support throughout the infant's hospitalization. Clearly explain all procedures. Encourage parents to bond with the infant by stroking and talking to the infant. Eliciting questions and allowing parents to participate in the infant's care, especially feeding (when permitted), can facilitate bonding and help to prepare parents for care of the infant after discharge.

The specific details of discharge teaching depend on the types of procedures the child has had. Teach the parents about gastrostomy tube care and feedings if applicable, signs of infection, and how to prevent postoperative complications.

The outcomes of nursing care will depend on the extent of the defect and correction. Examples include the following:

- The child does not experience respiratory distress and maintains normal respirations.
- The child achieves and maintains a normal weight.
- Positive parent–infant bonding is established.
- The parent has knowledge of the defect, its corrections, and the child's needs.

Pyloric Stenosis

Pyloric stenosis is a hypertrophic obstruction of the circular muscle of the pyloric canal. Pyloric stenosis occurs in approximately 2 of every 1000 births (Lin et al., 2014). There is an increased incidence in firstborn males (Hunter & Liacouras, 2016; Taylor, Cass, & Holland, 2013). Pyloric stenosis is more common in the White population (Hunter & Liacouras, 2016; McAteer, Ledbetter, & Goldin, 2013)

ETIOLOGY AND PATHOPHYSIOLOGY

The exact cause of pyloric stenosis is unknown, although frequently there is a family history of the disorder. *Hypergastrinemia* (too much gastrin in the blood) is thought to play a role in the development of pyloric stenosis. Studies have indicated a higher incidence of the disorder in infants who received oral erythromycin before 2 weeks of age (Lozada, Royall, Nylund, et al., 2013).

Hypertrophy of the circular pylorus muscle results in stenosis of the passage between the stomach and the duodenum, partially obstructing the lumen of the stomach (see *Pathophysiology Illustrated: Pyloric Stenosis*). The lumen becomes inflamed and edematous, which narrows the opening until the obstruction becomes complete. At this time, vomiting becomes more forceful. As the obstruction progresses, the infant becomes dehydrated and electrolytes are depleted, resulting in metabolic imbalances.

CLINICAL MANIFESTATIONS

Symptoms usually become evident 2 to 8 weeks after birth, although onset may vary (Taylor et al., 2013). Initially, the infant appears well or regurgitates slightly after feedings. The parents may describe the infant as a "good eater" who vomits occasionally. As the obstruction progresses, the vomiting becomes projectile. In **projectile vomiting**, the contents of the stomach may be ejected up to 3 feet from the infant. The vomitus is nonbilious and may become blood tinged because of repeated irritation to the esophagus. The infant generally appears hungry, especially after emesis; irritable; fails to gain weight; and has

Families Want to Know

Teaching the Family About Gastrostomy Tube Feedings

The infant or child who has difficulty swallowing, consuming oral feedings, or gaining weight may be a candidate for a gastrostomy tube. Indications for a gastrostomy tube placement may include neurologic deficit; avoidant/restrictive food intake disorder (failure to thrive); severe gastroesophageal reflux; feeding aversions; short bowel syndrome; defects of the mouth, esophagus, or stomach; and cerebral palsy (Hannah & John, 2013). Depending on the condition, the child may need the gastrostomy tube for all feedings or supplementary feedings. Research indicates that the use of a standardized education protocol is beneficial. Patient outcomes were improved and caregiver confidence and knowledge increased (Schweitzer et al., 2014). See Chapter 11 for general guidelines related to teaching plans. See also the *Clinical Skills Manual* SKILLS.

General Principles

Preoperatively

- Assess what the family knows about a gastrostomy tube and gastrostomy tube placement.
- Assess what methods will be most effective in teaching care of the gastrostomy tube and enteral feedings.
- Show the family pictures or dolls with gastrostomy tubes and explain what the child's abdomen will look like in the immediate postoperative period.
- Provide the family with a booklet about gastrostomy tubes and enteral feedings.

Postoperatively

- Show the family the child's gastrostomy tube and reassess their understanding of the tube.
- When feedings are ordered, demonstrate the first feeding to the parents while explaining each step.
- Actively involve a family member in the second feeding. With subsequent feedings, have a family member feed the child with the nurse watching.
- Teach the family about:
  - Feeding administration
  - Medication administration
  - Daily care of the tube and the site surrounding the tube
  - How to handle common complications such as blockage, leaking, dislodgement, presence of hypergranulation tissue, and site irritation or infection
  - Phone numbers to call if needed
  - When to seek medical care related to the gastrostomy tube
- All family members who are involved in care of the child should practice feeding the child and administering medications to the child prior to discharge. This allows the nurse to assess for understanding of the procedure and gives the family confidence in their ability to care for the child. Some children will need bolus feedings, others may have continuous feedings via a feeding pump, and yet others may have bolus feedings during the day and continuous feedings at night.

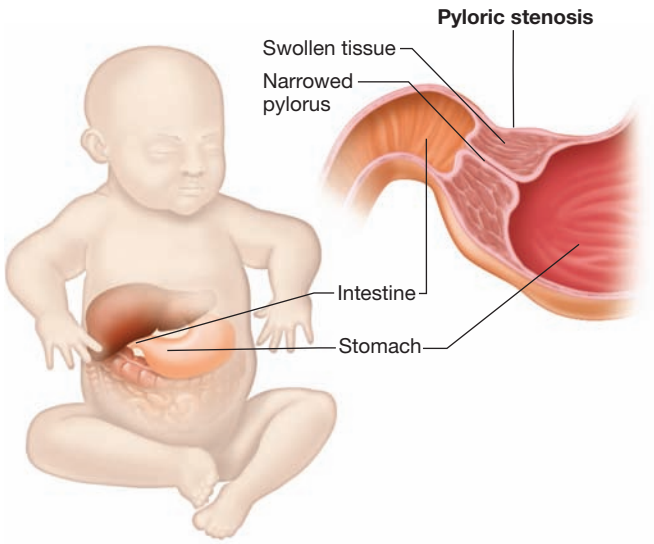
fewer and smaller stools. The child may present with dehydration and metabolic alkalosis depending on how long the child has been vomiting (Tigges & Bigham, 2012). On physical examination, peristaltic waves may be observed across the abdomen as the stomach attempts to move contents past the narrowed pyloric canal (Lin et al., 2014). An olive-sized mass in the right upper quadrant may be evident (Lisonkova & Joseph, 2013; Markowitz, 2014).

CLINICAL THERAPY

An abdominal ultrasound to determine the diameter and length of the pyloric muscle is the preferred method performed to confirm the diagnosis (Castellani, Peschaut, Schippinger, et al., 2014; Markowitz, 2014). Blood tests will determine if the child is dehydrated or has an electrolyte or acid–base imbalance (see Chapter 18). Infants with pyloric stenosis are at risk for hypochloremia, hypokalemia, and metabolic alkalosis; however, recent studies show that normal laboratory values are found most often. This could be attributed to earlier diagnosis and the increased use of ultrasound to confirm the diagnosis (Taylor et al., 2013; Tutay, Capraro, Spirko, et al., 2013).

Surgery is performed as soon as possible after the infant's fluid and electrolyte balance is restored. Laparoscopic pyloromyotomy is the preferred surgical method to correct pyloric stenosis (Castellani et al., 2014). In a pyloromyotomy, the pyloric muscle is split to allow the passage of food and fluid. The prognosis is good. The infant is usually taking fluids within a few hours following surgery and discharged on full-strength formula within 24 hours after surgery.

Pathophysiology Illustrated: **Pyloric Stenosis**



In pyloric stenosis, the hypertrophied pyloric muscle causes symptoms of projectile vomiting and visible peristalsis.

Nursing Management

For the Child With Pyloric Stenosis

Nursing Assessment and Diagnosis

Observe the infant's abdomen for the presence of peristaltic waves. Bowel sounds are hyperactive on auscultation. Auscultate before palpating the abdomen since palpation can cause a change in bowel patterns (see Chapter 5). Palpation reveals an olive-shaped mass in the right upper quadrant of the abdomen.

Assess the infant's history of vomiting, vital signs, weight, and nutritional status. Assess skin turgor, anterior fontanelle, urinary output (weigh diapers), urine specific gravity, and mucous membranes for signs of dehydration. Describe vomiting episodes and estimate emesis amount. Be alert for signs of an electrolyte and/or acid–base imbalance. (See Chapter 18 for a discussion of electrolyte and acid–base imbalances.) Assess parental anxiety related to the child's condition. The child usually appears hungry. Crying and general discomfort are frequently observed.

Nursing diagnoses that might be appropriate for the child with pyloric stenosis include (NANDA-I © 2014):

- ***Fluid Volume: Deficient,*** related to vomiting
- ***Nutrition, Imbalanced: Less than Body Requirements,*** related to vomiting and inability to ingest nutrients
- ***Sleep Pattern, Disturbed,*** related to discomfort and hunger
- ***Anxiety (Parents)*** related to surgery
- ***Pain, Acute,*** related to surgical incision

Planning and Implementation

Nursing care focuses on meeting the infant's fluid and electrolyte needs, minimizing weight loss, promoting rest and comfort, preventing infection, and providing supportive care for parents.

MEET FLUID AND ELECTROLYTE NEEDS

Withhold oral feedings preoperatively because projectile vomiting will continue until the obstruction is relieved. Emphasize to the parents the importance of maintaining an NPO status preoperatively. Intravenous therapy is administered to correct fluid and electrolyte imbalances as needed and to maintain adequate hydration. Maintain nasogastric tube to suction if one is present and measure output from the tube. Inform parents that all diapers will be weighed to measure the infant's output of urine and stool.

MINIMIZE WEIGHT LOSS

The infant loses weight because of frequent vomiting. Monitor weight daily both preoperatively and postoperatively. Begin feedings postoperatively according to the healthcare provider's orders. Some surgeons prefer an NPO period following pyloromyotomy, with slow, incremental increases in volume and strength of feedings once feeding has resumed. Others will implement an earlier postoperative feeding approach.

PROMOTE REST AND COMFORT

During the preoperative period, the infant is hungry and cries often. The infant is swaddled to maintain warmth and provide comfort. Encourage the parents to hold and cuddle the infant. Provide a pacifier to meet the infant's need to suck.

Postoperatively, the infant is uncomfortable because of the surgical incision. Analgesics can be administered to relieve discomfort as ordered. (See Chapter 15 for a discussion of pain management.) Instruct parents to avoid pressure on the incision. When diapering the infant, slide the diaper gently under the buttocks rather than lifting the legs. Swaddling, rocking, and use of a pacifier provide comfort to the infant.

PREVENT INFECTION

Postoperatively, the incision is covered with collodion or Steri-Strips and should be kept clean and dry. Inspect the incision site for redness, swelling, or discharge. Monitor the infant's temperature every 4 hours. Auscultate the lungs to assess for any adventitious sounds.

PROVIDE SUPPORTIVE CARE

The need for hospitalization and surgery creates anxiety for parents. Encourage them to participate in the infant's care and to discuss their fears and concerns. Provide simple and clear explanations about the infant's condition and care. Advise parents that occasional vomiting after surgery may occur.

DISCHARGE PLANNING AND HOME CARE TEACHING

Instruct parents to observe the incision for redness, swelling, or discharge and to notify the healthcare provider immediately if these occur or if the infant develops a fever. To reduce the possibility of infection, advise parents to fold the infant's diaper so that it does not touch the incision. Provide instructions about feeding to ensure the infant's intake.

Evaluation

Expected outcomes of care include pain control, intake of recommended fluid and food with absence of vomiting, and manifestation of normal growth patterns.

Gastroesophageal Reflux

Gastroesophageal reflux (GER), the return of gastric contents into the esophagus, is the result of relaxation of the lower esophageal sphincter (Khan & Orenstein, 2016b; Marcdante & Kliegman, 2015). GER is the most common esophageal disorder in children (Khan & Orenstein, 2016b). Approximately 50% of infants have some degree of reflux (Lightdale & Gremse, 2013). Factors that increase the incidence of GER in the pediatric population include a short narrow esophagus, small stomach, large volume feedings, an immature lower esophageal sphincter, a liquid diet, and frequent horizontal position (Marcdante & Kliegman, 2015). Additional factors that increase the incidence of GER include prematurity, neurologic impairment, obesity, chronic respiratory disorders, and a history of repaired esophageal atresia (Lightdale & Gremse, 2013).

The primary symptoms of GER are regurgitation, spitting up, or vomiting (Lightdale & Gremse, 2013). Children with GER are frequently hungry and irritable. They eat often but still lose weight. Infants with reflux are at risk for aspiration and apnea.

Gastroesophageal reflux disease (GERD) is a more serious manifestation of GER. Symptoms of GERD in infants include vomiting or regurgitation associated with irritability, refusal of feedings, poor weight gain, sleep disturbance, respiratory symptoms including coughing, choking and wheezing and arching of the back during feedings (Lightdale & Gremse, 2013; Randel, 2014). Symptoms of GERD in older children include dysphagia, heartburn, and chest pain (Lightdale & Gremse, 2013).

Diagnosis is confirmed by a thorough history of the child's feeding patterns and by diagnostic evaluation. An upper GI series is helpful in assessing anatomy and possibly detecting an alteration in motility. Esophageal pH monitoring and intraluminal esophageal impedance are the preferred diagnostic tools for GER. Upper endoscopy with esophageal biopsy is the method used to determine the amount of damage to the esophagus in the presence of GERD and to rule out other conditions (Lightdale & Gremse, 2013; Randel, 2014).

Treatment depends on the severity of the condition. Generally, feeding modification, thickened feeds, and positioning are effective management for milder cases. A smaller feeding volume and increased frequency of feedings is recommended (Lightdale & Gremse, 2013). The healthcare provider may decide that rice cereal needs to be added to the infant's bottle to thicken feedings (Schwarz & Hebra, 2014). A special nipple may need to be used. Prethickened formulas are commercially available. For example, Enfamil AR contains added rice, is nutritionally balanced, and may be beneficial to young infants who are formula-fed (Schwarz & Hebra, 2014). Children may benefit from smaller, more frequent meals. Greasy and spicy foods, chocolate, peppermint, citrus, and caffeine should be avoided (Schwarz & Hebra, 2014). See *Professionalism in Practice: Guidelines for Management of Gastroesophageal Reflux*.

Professionalism in Practice **Guidelines for Management of Gastroesophageal Reflux**

The American Academy of Pediatrics has established guidelines related to the management of complicated GER and GERD. Included in these guidelines are recommendations related to infant feeding and positioning. Formula-fed infants may need a different formula and maternal diet may need to be modified in breastfed infants. Smaller, more frequent feedings and thickened feedings may decrease symptoms. Upright positioning is recommended. Semisupine positioning in a car seat or infant carrier should be avoided after feedings, as this may exacerbate symptoms (Lightdale & Gremse, 2013). Pediatric nurses care for infants with GER and GERD in both inpatient and outpatient settings. They have the opportunity to help families reduce the symptoms of reflux in the infant by educating parents about strategies related to feeding and positioning.

Use of medications to treat GERD in children varies among healthcare providers. See *Medications Used to Treat: Gastroesophageal Reflux Disease* for examples of medications that may be used.

Treatment for severe cases of GERD may include surgery that involves wrapping the greater curvature of the stomach (fundus) around the distal esophagus (fundoplication) (Khan & Orenstein, 2016b; Lightdale & Gremse, 2013; Randel, 2014). A gastrostomy tube may be inserted during surgery to serve as an access for venting and as a means for feeding if needed (Khan & Orenstein, 2016b).

Nursing Management

Nursing management focuses on supporting the infant's or child's nutritional intake, promoting interventions to reduce associated complications, and supporting the family.

Monitor the infant's weight daily and plot on a growth chart to note progress. Observe for any signs of respiratory distress, and keep the infant's nose and mouth clear of emesis.

Adequate nutrition must be maintained for the child to achieve normal growth and development. Infants receiving oral feedings should be given small, frequent feedings. Elevate the head of the bed to prevent aspiration if vomiting should occur. If the child has a gastrostomy tube, it is important to maintain skin integrity around the stoma site.

Medications Used to Treat: Gastroesophageal Reflux Disease

MEDICATION AND ACTION	NURSING IMPLICATIONS
Histamine H_2 Receptor Antagonists Zantac (ranitidine) Pepcid (famotidine) Inhibit the histamine H_2 receptor on the gastric parietal cell, thus blocking gastric acid secretion.	May be administered with or without food. Teach parents to avoid OTC medications without checking with healthcare provider. Monitor for side effects: Bradycardia, Fatigue, Rash Constipation, Headache, Confusion Nausea, Irritability, Thrombocytopenia Dizziness, Diarrhea
Proton Pump Inhibitors Prevacid (lansoprazole) Prilosec (omeprazole) These powerful inhibitors of gastric acid secretion alleviate symptoms and help to heal esophagitis. Block the final common pathway of acid production by inhibiting activated proton pumps in the gastric parietal cell canaliculus.	Administer in the morning on an empty stomach. Monitor for side effects: Abdominal pain, Fatigue, Nausea Diarrhea, Headache, Proteinuria Dizziness, Hematuria, Rash Constipation, Anorexia Teach family to inform primary healthcare provider if severe diarrhea occurs. Teach family to inform primary healthcare provider if changes in urinary elimination, such as pain or discomfort associated with urination, occur.

(2015). *Pearson nurse's drug guide 2015*. Hoboken, NJ: Pearson Education.

Clinical Tip

Parents are encouraged to hold their infant in an upright position for 20 to 30 minutes following feedings. Minimize seated positioning such as in an infant car seat because this increases intra-abdominal pressure and promotes reflux.

Clinical Tip

In older children, a pattern of chronic vomiting (low-grade, nearly daily emesis) or cyclic vomiting (repeated severe vomiting of an episodic nature) can occur. These patterns differ from vomiting seen in colic or gastroesophageal reflux. **Chronic vomiting** is often associated with upper gastrointestinal tract diseases such as gastritis and esophagitis, whereas **cyclic vomiting** (also called *cyclic vomiting syndrome*) is a functional disorder characterized by recurrent episodes of severe nausea and vomiting that last several hours to days. The affected children have symptom-free periods between episodes, in which they are able to participate in normal activities (Tarbell & Li, 2013). Continuous vomiting of any nature should be evaluated.

Discharge planning focuses on instructing parents in how to feed and position the infant, as well as providing comfort and emotional support. Encourage parents to hold and cuddle the infant during all feedings. Providing the infant with a pacifier helps to meet nonnutritive sucking needs. Teach parents how to suction the nose and mouth if vomiting occurs.

Omphalocele and Gastroschisis

Omphaloceles are congenital malformations in which intra-abdominal contents herniate through the umbilical cord (Figure 25–4). An omphalocele results when the intestines fail to return to the abdominal cavity during the 10th to 12th week of gestation (Ledbetter, 2012). The size of the sac varies depending on the extent of the protrusion. Large defects may contain intestines, stomach, liver, and the spleen (Hood & Zimmerman, 2013). The abdominal contents are contained in a sac that is composed of peritoneum, Wharton jelly, and amniotic membrane (Glasser, 2014). Rupture of the sac results in evisceration of the abdominal contents. Omphalocele with herniation of intestines into the umbilical cord occurs in 1 in 5000 births, while omphalocele with herniation of liver and intestines occurs in 1 in 10,000 births (Carlo & Ambalavanan, 2016). Fifty to seventy percent of infants with omphalocele will have an associated anomaly such as bladder exstrophy, cardiac defects, and Meckel diverticulum (Razmus, 2011).

Gastroschisis is a congenital defect of the abdominal wall, characterized by protrusion of bowel through a defect in the abdominal wall to the side (most often to the right) of the umbilicus. Unlike the omphalocele, no membrane covers the organs

Figure 25–4 **In omphalocele, the size of the sack depends on the extent of the protrusion of abdominal contents through the umbilical cord.**

SOURCE: Courtesy of Carol Harrigan, RNC, MSN, NNP.

(Corey et al., 2014; Hood & Zimmerman, 2013; Ruano et al., 2011) (Figure 25–5). Gastroschisis occurs in 4 to 5 per 10,000 births (Benjamin & Wilson, 2014). Approximately 20% of infants with gastroschisis have an associated anomaly, most often atresia or intestinal stenosis (Razmus, 2011).

Care of the child with gastroschisis or omphalocele centers on protecting the protruding abdominal organs, correcting the defect, and preventing complications such as hypothermia, infection, and injury to involved organs.

Both gastroschisis and omphalocele are associated with elevation of maternal serum alpha-fetoprotein (MSAFP) (Glasser, 2014). Routine prenatal ultrasonography and determination of MSAFP levels lead to early diagnosis, education of the family, and coordination of the team of specialists needed to manage these congenital anomalies (Razmus, 2011).

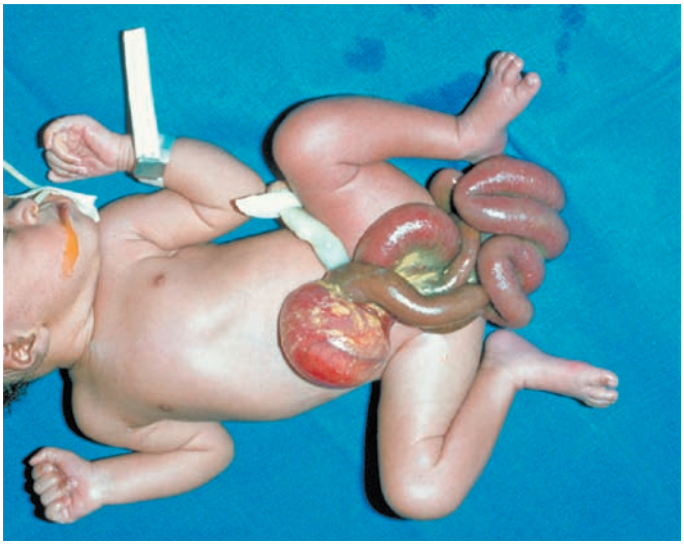


Figure 25–5 **The newborn with gastroschisis has abdominal contents located outside the abdominal wall.**

SOURCE: Ansary/Custom Medical Stock Photo/Newscom.

The immediate action upon birth is to protect the sac (in omphalocele) or exposed abdominal contents (in gastroschisis) from injury by placing the infant feet first into a bowel bag (large sterile clear bag) that extends to the nipple line and is secured with ties. The bag is filled with warm saline to decrease heat loss, to keep organs moist, and to allow for visualization of the defect (Razmus, 2011). The child will often be transferred to a neonatal intensive care unit (NICU) with surgical capability for this defect.

One surgery may be all that is needed to repair a small defect. For larger defects, the first stage of repair may involve nonoperative placement of the abdominal contents or sac into a Silastic silo. Once the abdominal cavity can accommodate the intestinal contents, the child will have surgery to close the abdominal wall (Razmus, 2011).

Nursing Management

Be alert for signs of associated congenital anomalies. (Refer to the discussion of tracheoesophageal fistula earlier in this chapter, of genitourinary anomalies in Chapter 26, and of congenital heart defects in Chapter 21.)

Immediately after birth, follow healthcare provider protocol for maintaining the omphalocele sac or for the exposed abdominal contents in gastroschisis as discussed previously. Monitor vital signs at least hourly, paying close attention to temperature, as the infant can lose heat through the sac. The child should be in a warmer or isolette for maintenance of temperature control. Inspect the area for signs of infection.

Because the infant is NPO preoperatively, maintain fluid and electrolyte balance with intravenous fluids. Postoperative care includes measures to control pain, prevent infection, maintain fluid and electrolyte balance, and ensure adequate nutritional intake. Attainment of bowel motility and function varies and is often delayed for weeks after surgery. Total parenteral nutrition for the infant is used until full bowel function has returned (Hood & Zimmerman, 2013).

Throughout the infant's hospitalization, parents need clear, accurate explanations about the infant's condition. To help the parents deal with the crisis of an acutely ill newborn, provide emotional support and encourage parents to express their feelings. When the child has multiple anomalies, parents need ongoing support for the lengthy treatment, numerous hospitalizations, and management of nutritional intake.

Expected outcomes of nursing care depend on the severity of the defect and its correction, but may include:

- Fluid volume balance is maintained.
- The incision heals without signs of infection.
- Stable thermoregulatory function is maintained.
- Effective pain management is achieved.
- Parent–infant bonding and attachment are demonstrated.

Intussusception

Intussusception occurs when one portion of the intestine prolapses and then invaginates or telescopes into another. It is one of the most frequent causes of intestinal obstruction during infancy and occurs at a rate of 1 in 2000 infants and children. Intussusception is more common in male babies. An estimated 65% of cases occur in children prior to 1 year of age (Deloach & Farber, 2013).

ETIOLOGY AND PATHOPHYSIOLOGY

Ninety percent of intussusception cases in children are idiopathic because a direct cause is not generally identified. Although the exact cause is unknown, there is frequently a current or recent enteritis or upper respiratory infection (Pepper, Stanfill, & Pearl, 2012).

The most common site of intussusception is the ileocecal valve (Cochran, Higgins, & Strout, 2011). Telescoping of the intestine obstructs the passage of stool. The walls of the intestine rub together, causing inflammation, edema, and decreased blood flow. This can lead to bowel wall edema, necrosis, and perforation (Territo, Wrotniak, Qiao, et al., 2014) (Figure 25–6).

CLINICAL MANIFESTATIONS

The onset of intussusception is usually abrupt. A previously healthy infant or child suddenly experiences acute abdominal pain with vomiting and passage of brown stool. There may be periods of comfort between acute episodes of pain. As the condition worsens, painful episodes increase. The child may have bilious emesis and a palpable abdominal mass. The stools become red and resemble currant jelly because of the mix of blood and mucus (Cochran et al., 2011; Deloach & Farber, 2013).

CLINICAL THERAPY

Diagnosis is made on the basis of the history and confirmed by radiographs and ultrasound of the abdomen. A contrast enema using air or barium can be both diagnostic and therapeutic. An air (or pneumatic) enema reduces the intussusception in approximately 90% of cases and is considered safer than a barium enema because of the decreased risk of perforation (Pepper et al., 2012).

A nasogastric tube is inserted for gastric decompression. If reduction of the intussusception does not occur during the contrast enema, surgical intervention to reduce the invaginated bowel and remove any necrotic tissue is necessary. Surgery is generally successful in correcting the problem; however, intussusception can recur after hydrostatic reduction or surgical correction.

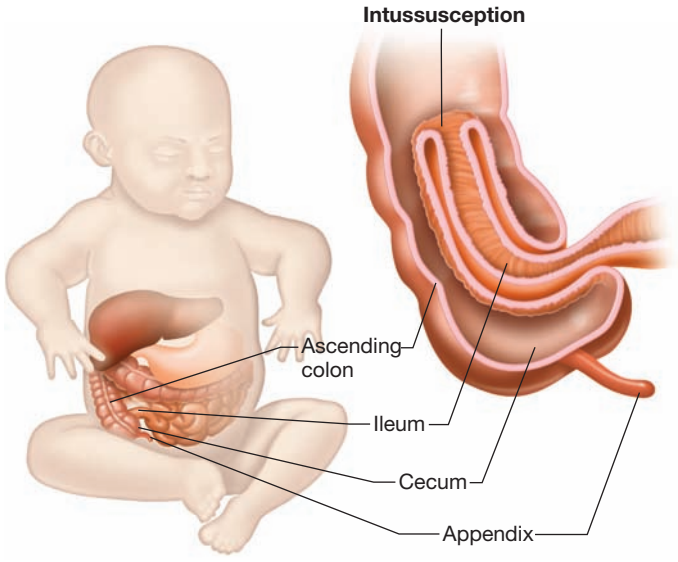

Figure 25–6 **In infants, intussusception is commonly associated with viral illnesses and gastroenteritis.**

Nursing Management

Nursing management focuses on maintaining or restoring fluid and electrolyte balance. Intravenous fluids are started immediately. Serum electrolyte monitoring is essential to correct imbalances.

Postoperative care focuses on monitoring for early signs of infection, managing the child's pain, and maintaining nasogastric tube patency. Assess vital signs, check for abdominal distention, and assess for return of bowel function. Feeding protocols vary among practitioners. Generally, after normal bowel function returns, clear liquid feeding or breastfeeding can resume. Feedings are then advanced as the infant or child tolerates them.

Discharge usually occurs shortly after the infant or child begins taking full feedings. Instruct parents to watch for infection and to call the healthcare provider if symptoms recur, a fever develops, or appetite decreases.

Clinical Tip

The passage of a normal brown stool may indicate that an intussusception has been reduced. Report this finding to the primary healthcare provider immediately, as the course of treatment may be altered, especially in the case of a planned surgical reduction.

Volvulus

During the 7th to 12th week of gestation the small intestine undergoes rapid growth. In normal development, the intestine rotates counterclockwise as it settles into its permanent position inside the abdominal cavity. Malrotation of the intestine occurs in approximately 1 of every 500 live births (Shalaby, Kuti, & Walker, 2013). When malrotation of the intestine occurs, the child is at risk for *volvulus*, a twisting of the intestine. Volvulus disrupts blood flow in the intestines and can lead to necrosis of the bowel, short bowel syndrome, and death. Volvulus is considered a surgical emergency. Early diagnosis and treatment is necessary to preserve the bowel and to save the child's life (Hebra & Cuffari, 2012; Shalaby et al., 2013).

Symptoms of volvulus in the infant include bilious vomiting, firm abdomen with distention, irritability secondary to pain, and passage of bloody stools. The diagnosis is confirmed through radiologic studies. Intravenous fluids are given to rehydrate the infant and to correct any electrolyte imbalance. Emergency exploratory surgery to untwist the bowel is essential (Zerpa & Shapiro, 2013). If a portion of the bowel is necrotic, that portion of the bowel is removed. An ostomy may need to be created, depending on the amount of bowel removed. See the section on ostomies later in this chapter. The child is at risk for developing short bowel syndrome if a significant amount of bowel is removed (see discussion later in this chapter).

Nursing Management

The infant or child who presents to the emergency department with bilious vomiting and a firm and distended abdomen should be assessed quickly to determine the cause of the symptoms. Once volvulus has been diagnosed, nursing management focuses on keeping the child NPO, administering intravenous fluids, assessing vital signs, and reporting symptoms of a worsening condition. The child who has had surgery to correct uncomplicated volvulus will need care similar to that described for the child with intussusception. If a necrotic bowel was removed, the child may have an ostomy for a period of time.

Hirschsprung Disease

Hirschsprung disease, also known as *congenital aganglionic megacolon*, is a congenital anomaly in which inadequate motility causes mechanical obstruction of the intestine. The disease occurs in approximately 1 in 5000 live births, and is more common in males than females (Burkhardt, Graham, Short, et al., 2014). Hirschsprung disease can occur as a single anomaly or in combination with other anomalies such as congenital heart defects, Down syndrome, and urinary tract anomalies (Burkhardt et al., 2014; Langer, 2013).

ETIOLOGY AND PATHOPHYSIOLOGY

Hirschsprung disease is the congenital absence of ganglion cells (nerve cells) in the wall of a variable segment of rectum and colon. The absence of autonomic parasympathetic ganglion cells in the colon prevents peristalsis at that portion of the intestine, resulting in the accumulation of intestinal contents and abdominal distention. In most cases, the area lacking ganglion cells is limited to the rectosigmoid region of the colon (Fiorino & Liacouras, 2016).

CLINICAL MANIFESTATIONS

Clinical manifestations of Hirschsprung disease vary depending on the child's age at onset. Symptoms in newborns generally include abdominal distention, feeding intolerance, bilious vomiting, and failure to pass meconium within the first 24 to 48 hours after birth (Holder & Jackson, 2013; Langer, 2013; Nelville, 2014). *Enterocolitis* (inflammation of the intestines) is a complication of Hirschsprung disease that can be fatal if not recognized and treated early. Symptoms of enterocolitis include fever, foul smelling and/or bloody **diarrhea** (frequent, watery stools), abdominal pain, and vomiting (Nelville, 2014).

The older infant or child may have a history of failure to gain weight, malnutrition, and chronic severe **constipation** (difficult and infrequent defecation with passage of hard, dry stool), (Langer, 2013; Nelville, 2014).

CLINICAL THERAPY

Diagnosis is made on the basis of the history, bowel patterns, radiographic contrast studies, and rectal biopsy for presence or absence of ganglion cells. The rectum is small in size on palpation and does not contain stool. Abdominal radiographs generally show a distended bowel with dilated bowel loops throughout the abdomen. Water-soluble contrast studies reveal a transition zone between the normal and aganglionic bowel (Burkhardt et al., 2014; Langer, 2013). Rectal biopsy revealing the absence of ganglionic cells and the presence of hypertrophic nerve bundles has proven to be the most reliable test for confirmation of the diagnosis (Burkhardt et al., 2014; Fiorino & Liacouras, 2016; Langer, 2013).

The primary repair of Hirschsprung disease is to remove the aganglionic portion of the bowel using a pull-through procedure. A primary repair may not be possible in the presence of extensive dilated proximal bowel, enterocolitis, or bowel perforation. In that case, a temporary colostomy is created and is closed when the definitive surgery takes place (Langer, 2013).

The return of normal bowel function depends on the amount of bowel involved. Some fecal incontinence and constipation may persist following surgery. Enterocolitis is a serious complication that can occur before or after surgery, resulting in ischemia and ulceration of the bowel wall. Treatment for enterocolitis associated with Hirschsprung disease includes rectal irrigations and antibiotics (Holder & Jackson, 2013).

Nursing Management

Nursing assessment in the newborn period includes careful observation for the passage of meconium. Because newborns are often discharged within 24 hours of birth, tell parents to notify the healthcare provider if no stool is passed or the abdomen becomes distended. When the disease is diagnosed later in infancy or in childhood, obtain a thorough history of weight gain, nutritional intake, and bowel elimination habits.

When Hirschsprung disease is diagnosed, nursing care includes monitoring for infection, managing pain, maintaining hydration, measuring abdominal circumference to detect any distention, and providing support to the child and family. Preoperative oral intake varies depending on the surgeon; however, intake is generally restricted to clear fluids the day before surgery. Rectal irrigations may be performed to evacuate the bowel prior to surgery.

Initial postoperative nursing care is the same as for any other infant or child having abdominal surgery: Maintain intravenous fluids and nasogastric tube. Monitor intake and output. Administer pain medications as prescribed and assess at least every hour for evidence of pain utilizing a pain scale and documenting assessment. If a colostomy was performed, the stoma should be assessed frequently as well as the return of bowel function. See the section on ostomies later in this chapter.

Children occasionally develop constipation and parents may need guidance to adapt the diet and fluid intake to manage this complication. Because some children develop malabsorption, be alert for signs of poor growth or malnutrition.

Expected outcomes of nursing care include:

- Fluid and electrolyte balance is maintained.
- Adequate nutritional intake to promote growth and development is evident.
- Adequate bowel function is demonstrated.
- The child's pain is managed effectively.
- The parents demonstrate effective coping with stress of the child's condition.

Anorectal Malformations

Anorectal malformations refer to anomalies of the rectum and distal anus, the urinary tract, and the genital tract. They have an incidence of approximately 1 in 5000 live births worldwide (Guardino & Pieper, 2013). Anorectal malformations are frequently associated with other anomalies. Some babies have VACTERL conditions. VACTERL refers to the presence of three or more of the following anomalies: **v**ertebral anomalies, **a**nal atresia, **c**ongenital heart disease, **t**racheo**e**sophageal fistula, **r**enal anomalies, and **l**imb defects (Akay & Klein, 2016).

ETIOLOGY AND PATHOPHYSIOLOGY

The term *imperforate anus* (absence of the anal opening) is frequently used to refer to anorectal malformations and is classified according to the specific defect. Boys with an imperforate anus frequently have a rectourethral fistula and girls generally have a rectovestibular fistula (Orr, 2011). Anal stenosis (narrowing of the anus) is a mild form of imperforate anus (Guardino & Pieper, 2013; Akay & Klein, 2016).

CLINICAL MANIFESTATIONS

Imperforate anus affects boys and girls equally. Perineal inspection at birth reveals the absent anal opening. Failure to pass meconium within the first 24 hours of birth may be indicative of imperforate anus. Stool in the urine usually indicates the

presence of a fistula between the colon and urinary tract. Cloacal malformations in girls, in which the urinary tract, vagina, and rectum fuse together, forming a common channel, may occur. The child with a cloacal malformation has one opening in the perineum (Guardino & Pieper, 2013).

Diagnosis of anorectal malformation is usually made at birth or during the newborn assessment of anorectal structures and rectal patency. Ultrasound and lower gastrointestinal radiographic studies are used to confirm the diagnosis and demonstrate the extent of the anomaly.

CLINICAL THERAPY

Management depends on the extent of the malformation and presence of associated conditions. Anal stenosis may be treated with dilation alone. A single operation, anoplasty, may be used to repair rectoperineal defects (previously known as low defects). Higher defects require a three-stage procedure. A temporary colostomy in the newborn period provides for bowel decompression and for protection of the surgical site when the anomaly is repaired. Reconstructive surgery is accomplished via a posterior sagittal anorectoplasty (PSARP). This surgery generally occurs between 3 to 6 months of age, although timing varies among surgeons. When the operative site has healed, approximately 2 weeks after surgery, anal dilations are begun. When the desired size of the anal opening has been achieved, the colostomy is closed (Orr, 2011).

Nursing Management

During the initial newborn assessment, the perineal area is inspected for a poorly developed anal dimple or sacral anomalies. Observe and record passage of meconium.

Once the diagnosis has been made, intravenous fluids are initiated and a nasogastric tube is inserted to decompress the stomach. Monitor the child's intake and output (I&O) and cardiorespiratory functioning. Provide emotional support to the parents and give them information about the upcoming surgery.

Postoperative care specific to the child who has had a PSARP procedure centers on protection of the surgical site. A Foley catheter will be in place for 5 days to protect the new anal opening from urine. The colostomy that is still in place protects the surgical site from stool. The child should have nothing placed in the rectum. Provide adequate pain management for the child. Maintain intravenous fluids until the child is able to take liquids by mouth.

Nursing care for the child who has had colostomy closure is more complex because the bowel has been manipulated during surgery. It is essential to maintain the nasogastric tube to low wall suction until bowel function returns. Provide intravenous fluids or total parenteral nutrition through peripheral or central venous access until the child can tolerate fluids by mouth. Monitor intake and output. The child will frequently have a Foley catheter in place for accurate measurement of urine output.

Care of the operative site may include dressing changes in addition to assessment for signs of infection. As the child begins to pass stool through the anal opening for the first time, skin breakdown is likely. Protect the perineal area with a barrier cream or paste.

Provide intravenous pain medication on a regular basis. The nurse is also responsible for administering prescribed antibiotics that protect the child from infection.

The child with associated abnormalities may need several surgeries and interventions to treat all of the conditions present. Partnering with families and a group of healthcare providers will assist in case management that facilitates the child's health and development. Health promotion and health maintenance that include support of family members, ensuring immunizations, and monitoring developmental status are important.

DISCHARGE PLANNING AND HOME CARE TEACHING

Infants are increasingly discharged shortly after birth, so parents need clear instructions about normal newborn stools and what abnormalities to report. The nurse should:

- Teach parents how to care for the ostomy site if a colostomy is performed in the newborn period (see discussion of ostomies later in this chapter).
- Reassure parents that the colostomy will be closed in the future, and help them plan for that hospitalization.
- Refer parents to ostomy support groups in the community or online.
- Discuss follow-up care and long-term management.
- Arrange follow-up visits and home care visits to evaluate the child's ostomy site and monitor growth.

Clinical Tip

Following colostomy closure in the child who has had a colostomy for several months, the perineal area is not accustomed to contact with stool. Without meticulous skin care, breakdown is very likely. Teach parents to change diapers frequently, clean the perineal area carefully, and apply a protective barrier ointment or cream at each diaper change.

After surgery to create the anal opening, teach parents how to take the infant's temperature using the axillary route (see the *Clinical Skills Manual* SKILLS). Once anal dilations have begun, the family will be taught how to perform them at home. After the final surgical procedure, discuss feeding regimens and bowel habits necessary to maintain adequate nutrition for growth and development. Advise parents that children with anorectal malformations may have difficulty achieving bowel control. Patience in toilet training is important. When the child reaches an age appropriate for toilet training, encourage the family to speak with a healthcare provider to discuss the child's progress.

Clinical Reasoning **Imperforate Anus and Esophageal Atresia**

Six-month-old Jerome was born with both imperforate anus and esophageal atresia. He had a colostomy created shortly after birth. His esophageal atresia has been repaired. He has just had surgery to create a new anal opening and will have the colostomy closed in approximately 6 weeks. What are the priorities of nursing care after an anorectoplasty? How can the surgical site be protected to ensure healing? What are essential components or preoperative and postoperative teaching related to the colostomy closure? What information related to toilet training should be given to Jerome's parents in the future?

Expected outcomes of nursing care include:

- The child's pain is effectively managed.
- Incisions heal without signs of infection.
- Fluid and electrolyte balance is maintained.
- Adequate bowel function is demonstrated.
- The parents demonstrate an understanding of ostomy care and other treatment protocols.

Hernias

A **hernia** is the protrusion or projection of an organ or a part of an organ through the muscle wall of the cavity that normally contains it. This protrusion may result from the failure of normal openings to close during fetal development or from weakness in the supporting musculature. When intra-abdominal pressure increases (as when the infant cries or strains to pass stool), the weakened area separates, causing a protrusion of underlying organs. Inguinal hernias are the most common type of hernia occurring in children (see Chapter 26). Other hernias that occur frequently in children are diaphragmatic and umbilical.

CONGENITAL DIAPHRAGMATIC HERNIA

In a diaphragmatic hernia, abdominal contents protrude into the thoracic cavity through an opening in the diaphragm. Sites of herniation include the substernal space, the posterolateral region, and the esophageal hiatus. The cause is a delay or failure in closure of the pleuroperitoneal musculature, which forms the diaphragm (Lee, Jun, & Lee, 2014). Intestines and other abdominal structures enter the thoracic cavity through the opening in the diaphragm. The overall incidence of diaphragmatic hernia is 1 in 2200 births (Rollins, 2012). Associated anomalies are present in 40% to 60% of infants born live with diaphragmatic hernia (Sfakianaki, 2012).

A diaphragmatic hernia is a life-threatening condition with an overall mortality rate of 20% to 35% in infants born alive with this condition (Rollins, 2012). Severe respiratory distress secondary to pulmonary hypoplasia occurs shortly after birth. As the infant cries, abdominal organs extend into the thorax, decreasing the size of the thoracic cavity. The infant becomes dyspneic and cyanotic. Characteristic findings include a barrel-shaped chest and sunken abdomen.

Congenital diaphragmatic hernia is diagnosed in utero by ultrasound in approximately two thirds of patients. Prenatal diagnosis improves survival rates, as it allows for early identification of infants who will require complex care after birth (Rollins, 2012).

Immediate respiratory support is essential in a neonatal intensive care unit (NICU). Ventilator support is necessary to manage respiratory compromise. Conventional mechanical ventilation, high-frequency oxygen ventilation, nitric oxide, and extracorporeal membrane oxygenation (ECMO) are the main methods used to treat respiratory failure in these children (Rollins, 2012; Sfakianaki, 2012; Sluiter, van de Ven, Wijnen, et al., 2011).

The infant is positioned with the head and thorax higher than the abdomen to facilitate downward movement of abdominal organs. A nasogastric tube is inserted to decompress the stomach. Intravenous fluids are administered through an umbilical artery catheter.

Once the infant's condition is stabilized, the defect is corrected surgically. The chance for a successful repair and survival is affected by the size of the defect. Children who survive will generally continue to have health concerns and should have continued evaluation of pulmonary, gastrointestinal, nutritional, and neurodevelopmental related problems (Rollins, 2012).

Nursing Management

The infant with a diaphragmatic hernia is admitted to the NICU and requires continuous monitoring. Preoperative management centers on providing supportive care to the infant and parents and includes the following:

- Note the infant's vital signs every 30 minutes on the cardiorespiratory monitor.
- Observe for worsening of respiratory compromise.
- Maintain intravenous fluid administration.
- Promote decreased stimulation to keep the infant calm and thus maintain low abdominal pressure.
- Keep parents informed about the infant's condition, and provide emotional support both before and after surgery.

Postoperative care includes the following:

- Position the infant on the affected side to facilitate expansion of the lung on the unaffected side.
- Observe closely for signs of infection.
- Maintain respiratory support.
- Manage pain.
- Carefully monitor fluid and electrolyte balance.

Before discharge, instruct parents in wound care, prevention of infection, and feeding techniques.

UMBILICAL HERNIA

An umbilical hernia results from a weak or imperfectly closed umbilical ring. Umbilical hernia is a common condition in childhood and occurs more frequently in Black children and low–birth-weight infants (Carlo & Ambalavanan, 2016).

An umbilical hernia appears as a soft swelling covered by skin. Omentum and small intestine herniate or protrude through the opening with coughing, crying, or straining during a bowel movement. It is easily reduced by pushing the bowel back through the fibrous ring. Most defects that appear prior to 6 months of age will resolve spontaneously by 1 year of age. Surgery is indicated in cases of *strangulation* (closure of the muscular ring around a portion of the bowel, preventing it from moving back into the abdomen). Surgery is also recommended if the defect does not resolve by 4 to 5 years of age or if the defect becomes larger after 1 to 2 years of age (Carlo & Ambalavanan, 2016).

Nursing Management

Nursing management is generally supportive. Instruct parents not to apply tape, straps, or coins to reduce the hernia as these methods have not been proven to be effective. If surgery is required, it is usually performed in a short-stay unit. Postoperatively, teach parents how to care for the surgical site, to watch for bleeding, and to recognize signs of infection. Reinforce the importance of returning for follow-up evaluation.

Ostomies

An intestinal **ostomy** is an opening, or **stoma**, into the small or large intestine that diverts fecal matter, providing an outlet when a distal surgical anastomosis, obstruction, or nonfunctioning structure prevents normal elimination (Figure 25–7).

Figure 25–7 **This infant has several gastrointestinal problems and requires ostomies for gastric feedings and for drainage of fecal material. Note the appearance of the healthy stoma.**

Depending on the integrity and function of anatomic structures, the ostomy may be temporary or permanent. Infants and small children with imperforate anus, necrotizing enterocolitis, Hirschsprung disease, or volvulus may require a temporary or permanent colostomy or ileostomy. Ostomies may also be indicated for children with inflammatory bowel disease, intestinal tumors, or abdominal trauma.

An ostomy may be elective or considered a surgical emergency. In all cases, it affects a child's lifestyle, alters body image, causes anxiety, and increases the risk for alterations in physiologic processes (electrolyte imbalance, increased nutritional requirements). For adolescents, it may also result in dependence at a time when autonomy is a major developmental need.

When assessing the family and child approaching ostomy surgery, it is important to determine their ability to understand and accept the physical changes that will occur. Parents may feel guilt and anger about the need for an ostomy when the child has a genetically transmitted disease, is injured, or has developed an obstruction from necrosis of the bowel. Encourage the parents and child to express their feelings, and correct any misunderstandings. Parents and older children may be referred for counseling and to support groups to help them deal with their feelings. Adolescents often benefit from a visit with an adolescent ostomate (someone who has an ostomy) who can answer questions about living with an ostomy.

PREOPERATIVE CARE

Preoperative education focuses on educating the child and family and preparing them for postoperative management.

Growth and Development

The preschooler has some manual dexterity and can help with some parts of the procedure for changing an ostomy appliance and cleaning the stoma. Teach the child using a doll or stuffed animal. Many school-age children are able to care for their ostomy independently. Teach them how to avoid leakage around the bag, which could be embarrassing. Adolescents are generally totally independent in their self-care of ostomies. However, they may need support to deal with the fact that they are different from their peers.

Discuss how the appliance or ostomy pouch will look, and explain the purpose of the appliance in developmentally appropriate terms. Encourage the parents and child to touch and manipulate all equipment. Show a younger child how to place a pouch on a doll. Older children can practice placing a pouch on their skin. These measures help relieve anxiety by providing information and increasing familiarity with the appliance.

In addition to discussion of the appliance, preoperative education should include discussion of pain control and measures that will be used to prevent postoperative complications (turning, coughing, and breathing deeply). Gear the instructions to the child's developmental level. Encourage parental participation to promote compliance.

POSTOPERATIVE CARE

Postoperative care of a child with an ostomy is similar to that of any child who undergoes abdominal surgery. (See the discussion of nursing management for appendicitis later in this chapter and *Nursing Care Plan: The Child Undergoing Surgery* in Chapter 11.) Management of the stoma may be done by an "ostomy nurse" or other nurses. Major interventions involve ensuring proper function of the stoma, identifying complications, and instituting daily stoma care. Complications include skin breakdown, mucotaneous separation, necrosis, stenosis, prolapse, hernia, retraction, laceration, and leakage (Coha, 2013; Lindholm et al., 2013). Assess the stoma, quality and amount of fecal matter, skin condition, and adherence of the pouch. Evaluate the understanding and ability of the family to care for the ostomy.

Identify and address home care needs well in advance of discharge. Instructions include skin care, care of the stoma, appliance removal and application, and frequency of appliance changes (see the *Clinical Skills Manual* SKILLS). Begin teaching immediately after surgery with responsibility for care transferred gradually to the parents and child as they are ready. Discuss diet, activity level, hygiene, clothing, equipment, and financial considerations. Arrange for home visits to check periodically on the home management program.

Parents and children can be referred to the United Ostomy Association or a local ostomy group for information and support. Make referrals to social service, counseling, and a home health agency, if appropriate.

Expected outcomes of nursing care include successful adjustment to the ostomy, thorough evacuation of the bowel, absence of infection and other complications, intact skin, and formation of a positive self-image in the child.

Clinical Tip

Avoid adhesive enhancers on the skin of newborns and premature infants. Their skin layers are so thin that removal of the appliance can strip off the skin. Remember also that adhesive contains latex and its frequent use is not advised because of the risk of latex allergy development (see Chapter 22).

Inflammatory Disorders

Inflammatory disorders are reactions of specific tissues of the GI tract to trauma caused by injuries, foreign bodies, chemicals, microorganisms, or surgery. These disorders may be acute or chronic and may involve various segments of the GI tract.

Appendicitis

Appendicitis is an inflammation of the vermiform appendix, the small sac near the end of the cecum, and is the most common cause of emergency surgery in children (Hung, Lin, & Chen, 2012; Singh, Kadian, Rattan, et al., 2014). The condition occurs most often in children and adolescents ages 10 to 19 years. While the overall rate of perforated appendix is 20% to 35%, the rate in children less than 3 years of age is 80% to 100% as compared to 10% to 20% in children 10 to 17 years of age (Minkes & Alder, 2014). Other factors may affect the rate of appendiceal perforation. See *Evidence-Based Practice: Perforated Appendix.*

EVIDENCE-BASED PRACTICE | Perforated Appendix

Clinical Question

Early diagnosis and treatment is essential for positive outcomes for the child with appendicitis. Increased morbidity and mortality is associated with a perforated appendix. Young children have a higher rate of perforated appendix than older children. What are other factors that increase the rate of perforated appendix in children?

The Evidence

Ladd et al. (2013) conducted a retrospective study of 667 children who underwent appendectomies to determine if racial and socioeconomic factors were associated with an increased risk of perforated appendix. They also examined whether these factors were associated with symptom duration of greater than 48 hours. Results revealed that symptom duration and age had the strongest effect on the risk of perforated appendix, regardless of the race or ethnicity of the child. Children ages 0 to 4 and those presenting after 2 days of symptoms had significantly higher rates of perforation. Black and Hispanic children had significantly higher rates of perforated appendix than White children. Black children were more likely to have symptom duration of greater than 48 hours, leading the investigators to conclude that the increased incidence of perforated appendix in this population is related to delay in presentation to the hospital for treatment; however, they were not able to conclude that it was related to socioeconomic factors. The investigators found that the incidence of perforated appendix is higher in Hispanics regardless of other factors, leading them to conclude that being of Hispanic origin was a risk factor alone, and that perhaps there might be other cultural or economic factors not examined in this study that might contribute to the higher incidence in this group.

Levas et al. (2014) conducted a multicenter study to determine if there was an association between Hispanic ethnicity and limited English proficiency (LEP) and the rate of perforated appendix and the use of computed tomography (CT) and ultrasound in children presenting with abdominal pain. The sample was comprised of 2590 children ages 3 to 18 presenting with abdominal pain that was concerning for a diagnosis of appendicitis. A diagnosis of appendicitis was made in 1001 of these children. Perforated appendix was diagnosed in 25% of English-speaking non-Hispanics, 31% of English-speaking Hispanics, and 34% of Hispanics with LEP ($p < .01$) English-speaking non-Hispanics had a trend toward a higher incidence of perforated appendix, but it was not statistically significant. Twenty percent of Hispanics with LEP presented with a duration of pain greater than 72 hours, compared with 9.8% of English-speaking non-Hispanics. Hispanics with LEP were less likely to undergo CT or ultrasound. Those with mid-range Pediatric Appendicitis Scores (PAS) were significantly less likely to have these imaging studies, compared with English-speaking non-Hispanics. There was no significant difference in the timing between imaging studies and surgery based on English proficiency or ethnicity.

Lee, Yaghoubian, Stark, et al. (2012) examined whether being treated at a county hospital versus a private hospital affected the rate of perforated appendix, rate of laparoscopic appendectomy, and outcomes in children with appendicitis. For the study, 7902 cases of children treated for appendicitis between 1998 and 2007 were reviewed. Of these, 682 were treated at the county hospital and 7220 were treated at 1 of 11 private medical centers that are part of a larger system. The county hospital in this study was also referred to as a Safety Net hospital, which treats the highest number of uninsured patients and provides care to anyone regardless of financial, immigration, or insurance status. Results of the study showed that patients treated at the county hospital had a lower income, a higher rate of perforated appendix, and longer hospital stays. These patients also had a higher rate of laparoscopic appendectomy and a lower postoperative abscess drainage rate. The study showed that patients treated at the county hospital did not have poorer outcomes than those treated at private hospitals. They did have higher rates of perforated appendix, which the investigators attributed to delayed access to care. These patients had longer hospital stays, even though there was a higher rate of laparoscopic appendectomy, and a lower rate of postoperative abscess drainage. The delay in discharge could be related to fewer resources available, including transportation for discharge or insufficient care available at home for these children because parents are at work. Outcomes within the county hospital were similar regardless of income level or ethnic group. The investigators concluded that the differences in patients at the two hospitals might be related to differences in access to health care and other underlying ethnic and socioeconomic disparities as opposed to hospital type.

Best Practice

Young children have a higher incidence of perforated appendix. This is related to their inability to understand the concept of pain and verbalize this to their parents. Parents must be educated about the importance of recognizing cues in their children that could be indicative of pain. A longer duration of symptoms or delay in seeking health care was also identified as a risk factor for perforated appendix. This could be related to lack of knowledge related to symptoms requiring medical attention or lack of access to health care. Ongoing education for parents related to signs of illness in children is essential. Nurses play a key role in this education, especially in the outpatient clinic setting. Access to health care and resources continues to be a concern and demonstrates the need for improvement in access to all patients regardless of ethnic background, language proficiency, or socioeconomic status. Nurses play an important role in advocating for these patients.

Clinical Reasoning

Give specific examples of how nurses can work with children and families to decrease the incidence of perforated appendix. What are some factors that might attribute to the higher incidence of perforated appendix in Hispanics?

ETIOLOGY AND PATHOPHYSIOLOGY

Appendicitis almost always results from an obstruction in the appendiceal lumen. It can be caused by a fecalith (hard fecal mass), parasitic infestations, stenosis, hyperplasia of lymphoid tissue, or a tumor.

Continued secretion of mucus following acute obstruction of the lumen increases pressure, causing ischemia, cellular death, and ulceration. The appendix may perforate or rupture, resulting in fecal and bacterial contamination of the peritoneum. Peritonitis spreads quickly and if untreated can result in small bowel obstruction, electrolyte imbalances, septicemia, and hypovolemic shock.

CLINICAL MANIFESTATIONS

At onset, symptoms include periumbilical cramps, abdominal tenderness, anorexia, nausea, and fever. In adolescent and young adult females, symptoms must be differentiated from those associated with ruptured ectopic pregnancy, endometriosis, ovarian cysts, and pelvic inflammatory disease (Minkes & Alder, 2014).

As the inflammation progresses, pain in the right lower abdomen becomes constant. Pain is often most intense at the McBurney point, halfway between the anterior superior iliac crest and the umbilicus (see *Pathophysiology Illustrated: Appendicitis*). Symptoms progress to include guarding, rigidity, nausea, vomiting, onset of pain before vomiting, anorexia, and rebound tenderness following palpation over the right lower quadrant (Bishop & Carter, 2013; Minkes & Alder, 2014).

As appendicitis progresses, the child remains motionless, usually in a side-lying position with knees flexed. Sudden relief of pain usually means that the appendix has perforated.

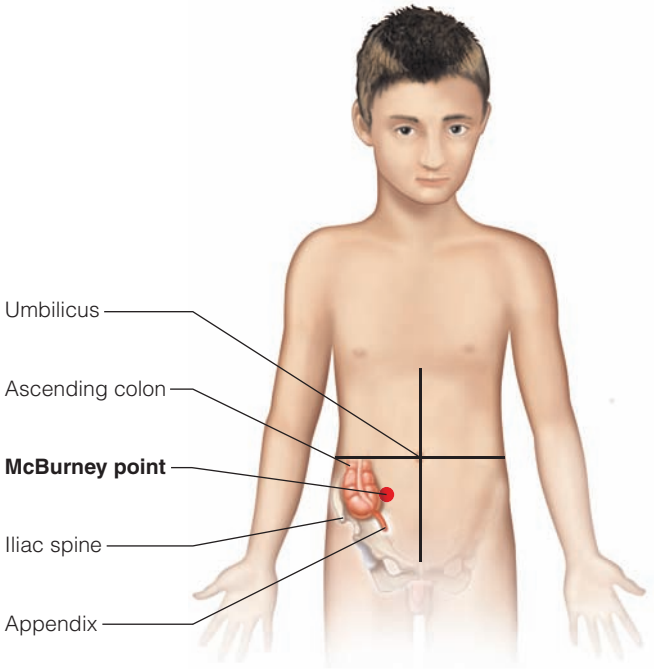
CLINICAL THERAPY

Diagnosis of appendicitis in young children can be difficult because their pain may be less localized and their symptoms more diffuse than in the older child. Continuing evaluations over several hours are often needed to establish the diagnosis. The presence of an elevated white blood cell count (above 10,000/mm^3), increased neutrophil ratio, and an elevated C-reactive protein combined with the symptoms supports a diagnosis of appendicitis (Bishop & Carter, 2013). A white blood cell count greater than 15,000/mm^3 in a patient with appendicitis is a strong indicator that the appendix has perforated (Minkes & Alder, 2014). Abdominal ultrasound is preferred by some healthcare providers as the initial screening tool in the diagnosis of appendicitis; however, CT scans are more sensitive and may be used, especially when the appendix cannot be seen well on ultrasound or the results are inconclusive (Bishop & Carter, 2013; Minkes & Alder, 2014).

Treatment of uncomplicated appendicitis involves immediate surgical removal (appendectomy), generally through a laparoscopic appendectomy (Groves et al., 2013). Preoperatively, the child is kept NPO. Intravenous fluids and electrolytes, and antibiotics are administered (Minkes & Alder, 2014). Postoperatively, the child has an abdominal incision with a dressing covering the incision. Antibiotics may be administered. The child is generally discharged within 24 to 36 hours as long as they have adequate oral intake, are afebrile, and receive effective pain relief with oral pain medication (Bishop & Carter, 2013).

With perforated appendix, laparoscopic appendectomy is generally performed. While open appendectomy has been the treatment of choice in the past, recent studies have indicated that laparoscopic appendectomy is an effective approach for the treatment of perforated appendix as well. With laparascopic appendectomy the abdominal cavity can be explored and lavaged (Groves et al., 2013). Postoperatively, the child with a perforated appendix may have a nasogastric tube to decompress the abdomen and will remain NPO until signs of bowel function return. Bowel function is best indicated by the passage of

Pathophysiology Illustrated: **Appendicitis**



The McBurney point is the common location of pain in children and adolescents with appendicitis.

flatus or stool. The child will also have a peripheral or temporary central line for administration of intravenous fluids and medications. After surgery for a perforated appendix, the child will receive antibiotics for several days. Morphine is generally given for pain.

In some cases, where an abscess is formed secondary to rupture of the appendix, the surgeon may choose to place a percutaneous drain, begin broad-spectrum antibiotics, and remove the appendix at a later time. This process is referred to as an interval appendectomy (Santacroce & Ochoa, 2013).

Nursing Management

For the Child With Appendicitis

Nursing Assessment and Diagnosis

PHYSIOLOGIC ASSESSMENT

A detailed assessment of the child's pain is necessary to differentiate appendicitis from other illnesses (see Chapter 15). Ask the child to point to the painful area and describe the pain. Recognize that localizing the pain may be difficult for young children. Note onset, location, and intensity of pain; precipitating factors; and relief measures tried. Remember to inspect, auscultate, and then palpate gently to identify distention and areas of pain. Rebound tenderness can also be assessed. Deep palpation of the left side of the abdomen followed by removing the hand quickly can lead to pain in the area of the appendix (rebound tenderness). However, once appendicitis is suspected or verified, avoid abdominal palpation in order to minimize pain to the child. Assess vital signs to determine baseline values, and monitor every 4 hours thereafter.

PSYCHOSOCIAL ASSESSMENT

Because appendicitis usually occurs in school-age children and adolescents, assessment of the child's coping skills is important. Adolescents, because of their preoccupation with body image, may be concerned about the surgical scar. Assess the parents' and child's anxiety about the sudden hospitalization and need for emergency surgery.

Among the nursing diagnoses that might be appropriate for the child with appendicitis are the following (NANDA-I © 2014):

- ***Pain, Acute,*** related to inflammation and surgery
- ***Fluid Volume: Deficient, Risk for,*** related to fluid volume loss and inadequate fluid volume intake
- ***Anxiety*** related to physical condition
- ***Infection, Risk for,*** related to bowel trauma
- ***Airway Clearance, Ineffective,*** related to retained secretions

Planning and Implementation

Nursing management focuses on promoting comfort, maintaining hydration, providing emotional support, supporting respiratory function, providing care of the surgical site, and monitoring for symptoms of infection.

PROMOTE COMFORT

Preoperatively, a right side-lying position with knees bent is usually the most comfortable. If the appendix has perforated, lying on the right side helps the peritoneal cavity drain. Administer analgesics as ordered, and note relief from pain. Postoperatively, the child should be placed in a semi-Fowler or side-lying position on the right side. The child with a perforated appendix will require intravenous pain medication on a regular basis. The child who has an appendectomy for uncomplicated appendicitis will need oral or intravenous pain management for postoperative pain control.

MAINTAIN HYDRATION

An intravenous infusion is initiated preoperatively and continued until bowel function returns after surgery. Once bowel function returns and after the nasogastric tube has been removed, offer water in small amounts and then other clear fluids. The child should be monitored closely for nausea after beginning to take oral fluids.

PROVIDE EMOTIONAL SUPPORT

For many children, appendicitis may be their first hospitalization and their first experience with healthcare personnel other than their primary healthcare provider. The nurse must elicit a history, perform a physical examination, coordinate diagnostic tests, and prepare the child for surgery in a short period of time. Emotional support is essential for both child and parents. Good preoperative education can reduce anxiety. Answer any questions the child or parents may have.

SUPPORT RESPIRATORY FUNCTION

General anesthesia during surgery compromises respiratory function. It is important for the child to turn, cough, and breathe deeply to prevent atelectasis. Provide adequate analgesia and encourage the child to splint the incision area with a pillow during coughing to decrease pain. Incentive spirometry is frequently ordered for the child. Young children may be resistant to this procedure or may be too young to understand the procedure. An effective alternative approach is to give the child bubbles or a pinwheel to blow.

RECOGNIZE SYMPTOMS OF INFECTION

Assess vital signs and observe the abdominal incision every 4 hours for redness, edema, or drainage. If a drain is present, assess drainage for color, consistency, and amount. The amount of drainage from the wound should decrease gradually as the wound heals. If the appendix perforated, the child is hospitalized for several days of intravenous antibiotics.

DISCHARGE PLANNING AND HOME CARE TEACHING

Children with uncomplicated appendicitis are discharged once bowel function returns and they have a bowel movement. Children with perforated appendix will have a longer hospitalization since they require several days of intravenous antibiotics. When the child is ready for discharge, give parents instructions for home care. Teach parents to recognize the signs and symptoms of infection and to seek early treatment.

Normal activities can be resumed fairly quickly, but the child should avoid strenuous activities and contact sports in the immediate postoperative period. Parents should check with the child's healthcare provider before allowing the child to resume sports activities. Home tutoring may be needed for a short time so the child can keep up with schoolwork.

Evaluation

Expected outcomes of nursing care include the following:

- The child's pain is effectively managed.
- The child demonstrates effective airway clearance.
- The wound heals without the development of a secondary infection.
- Adequate hydration is achieved and maintained.

Necrotizing Enterocolitis

Necrotizing enterocolitis (NEC) is a potentially life-threatening inflammatory disease of the intestinal tract that occurs primarily in premature infants. The overall incidence is 1 in 1000 live births. The disease affects up to 7% of infants of very low–birthweight infants (weighing less than 1500 g). NEC is associated with a mortality rate of 5% to 24% (Huda, Chaudhery, Ibrahim, et al., 2014). The disease occurs most often in the ileum (Berman & Moss, 2011; Huda et al., 2014).

The etiology of NEC is multifactorial. Intestinal ischemia and inflammation, bacterial or viral infection (a result of the premature infant's decreased immune response and greater risk for infection), enteral feeding, and immaturity of the gastrointestinal mucosa may all be contributing factors (Gregory, DeForge, Natale, et al., 2011; Morgan, Young, & McGuire, 2011).

Manifestations generally occur during the second week of life after enteral feedings are started; however, NEC can develop before feedings are started, after several weeks of life, and long after feedings are started. The infant may initially show signs of feeding intolerance (increased gastric residuals, vomiting, irritability, and abdominal distention). Bloody diarrhea may be present because of the hemorrhagic bowel. The condition progresses to lethargy, periods of apnea and bradycardia, and temperature instability (Berman & Moss, 2011).

Diagnosis is made on the basis of characteristic clinical findings and the presence of free peritoneal gas, dilated bowel loops, bowel distention, and bowel wall thickening on abdominal radiographs. Stools and emesis are monitored for occult blood. Laboratory data reveal anemia, leukopenia, leukocytosis, thrombocytopenia, electrolyte imbalance, and metabolic or respiratory acidosis. Blood cultures are positive for the organism present.

Necrotizing enterocolitis requires prompt intervention to decrease the morbidity and mortality associated with this illness. Treatment includes bowel rest (NPO status), gastric decompression with nasogastric suction, and antibiotic therapy (Gregory et al., 2011; Rapoport & Nishii, 2013; Wright & Miller, 2012). The infant will need central venous access to provide nutrition (Rapoport & Nishii, 2013). Serial radiographs of the abdomen should be performed to detect worsening or resolution of the disease process (Wright & Miller, 2012). Perforation or necrosis of the bowel necessitates surgical resection of the bowel. An ileostomy or colostomy may be performed.

All cases of necrotizing enterocolitis are treated with strict enteric precautions to prevent the spread of infection to other premature infants on the unit.

Long-term complications of necrotizing enterocolitis include short bowel syndrome, strictures, cholestasis, impaired nutrition and growth, and delayed developmental performance.

Nursing Management

Nursing care centers on prevention and early detection of necrotizing enterocolitis to minimize bowel loss, and providing postoperative care. Observe for feeding intolerance by aspirating gastric residual (if the infant is receiving enteral feedings). Measure abdominal circumference and assess bowel sounds in the premature or high-risk infant every 4 to 8 hours. Even minimal changes in circumference can indicate necrotizing enterocolitis and should be reported to the primary care provider.

SAFETY ALERT!

The infant with NEC is at risk to develop sepsis. Signs of sepsis in the newborn or premature infant include:

- Hypothermia or hyperthermia
- Jaundice
- Respiratory distress
- Hepatomegaly
- Abdominal distention
- Poor feeding
- Vomiting
- Lethargy

Report these symptoms to the primary healthcare provider immediately.

Maintaining fluid and electrolyte balance is essential. Provide comfort by holding and cuddling an infant who is NPO, and offer a pacifier to meet nonnutritive sucking needs. Careful assessment for infection and maintenance of skin integrity are essential. Feedings are gradually reestablished once bowel function returns. Because the symptoms of necrotizing enterocolitis may not appear until several days after feedings begin, parents may not be prepared for the infant's decline. Recovery is slow and can be complicated. Give clear explanations and encourage parents to ask questions and express their fears and concerns. If the infant's condition worsens, offer the parents support (see Chapter 13).

After the child is discharged, frequent follow-up is needed. Parents need specific education related to feedings, medications, and any other treatments prescribed. The infant requires regular and thorough physical assessments to check weight gain, assess development, and identify signs of complications. If the child had to have an ostomy created, the family must be taught ostomy care.

The infant requires regular and thorough physical assessments to identify any complications. Growth of the child is monitored and compared with previous findings. Developmental progress is assessed by regular administration of a developmental test such as the Denver II.

Clinical Tip

Cholestasis is a disruption of bile flow and the most common problem in survivors of necrotizing enterocolitis. It is a complication of total parenteral nutrition (TPN) and commonly occurs 2 weeks after TPN therapy has been initiated. It is characterized by hyperbilirubinemia, hepatomegaly, and elevated serum aminotransferase levels (Vitola & Balistreri, 2016).

Expected outcomes of nursing care for the child with necrotizing enterocolitis include:

- The child is free of signs and symptoms of infection.
- Fluid and electrolyte balance is achieved and maintained.
- Tissue perfusion is maintained following surgical removal of necrotic bowel.
- The child consumes adequate nutrition to support growth and development needs.

If surgery is performed, complete healing without infection or other complication is desired. If the infant is not successfully treated, support and comfort for the parents are necessary. When the child survives, desired long-term outcomes include normal developmental progression and nutrition to support growth.

Meckel Diverticulum

Meckel diverticulum results when the omphalomesenteric duct, which connects the midgut to the yolk sac during embryonic development, fails to atrophy. Instead, an outpouching of the ileum remains, usually located near the ileocecal valve. The pouch contains gastric or pancreatic tissue, which secretes acid, causing irritation and ulceration. Meckel diverticulum is the most common GI malformation and occurs in 1% to 4 % of the population (Pepper et al., 2012).

Clinical manifestations usually appear by age 2. Meckel diverticulum most commonly presents as GI bleeding or obstruction. The child generally presents with bloody stool, irritability, fatigue, abdominal pain and distention, nausea, and vomiting (Pepper et al., 2012).

Diagnostic testing for Meckel diverticulum depends on the presentation and includes laboratory analysis to evaluate for the presence of anemia and dehydration (Pepper et al., 2012). Imaging studies are also used to assist in the diagnosis and include radiographs, ultrasound, CT scan, and radionuclide scanning (Kotecha, Bellah, Pena, et al., 2012). Technetium-99*m* pertechnetate nuclear medicine (also called a *Meckel scan*) is the current imaging test of choice for a bleeding diverticulum (Pepper et al., 2012).

Treatment is surgical excision of the diverticulum and removal of any involved bowel. The prognosis is good following surgical excision.

Nursing Management

Preoperatively, an intravenous infusion is initiated to correct fluid and electrolyte imbalances. Monitor intake and output. Observe for rectal bleeding, and test stools for **occult blood** (blood that is present in small quantities and is measurable only by laboratory testing). Keep the child on bed rest. Assess vital signs every 2 hours, and monitor for signs of shock. Postoperative care is similar to that for an infant or child undergoing abdominal surgery. (See the earlier discussion of postsurgical nursing management of appendicitis and *Nursing Care Plan: The Child Undergoing Surgery* in Chapter 11.)

At discharge, parents need instructions on caring for the surgical site, preventing infection, providing an adequate diet, and administering prescribed medications.

Inflammatory Bowel Disease

CROHN DISEASE AND ULCERATIVE COLITIS

Inflammatory bowel disease encompasses two distinct chronic disorders, Crohn disease and ulcerative colitis, that have similar symptoms and treatment. Inflammatory bowel disease differs from irritable bowel syndrome.

Crohn disease is a chronic, inflammatory process. The disorder can occur randomly throughout the GI tract with the ileum, colon, and rectum as the most common sites. A distinct feature of Crohn disease is the development of enteric fistulas between loops of bowel or nearby organs. Mucosal ulcers begin in small locations, and then grow in size and depth into the mucosal wall. Submucosal inflammation can be severe. The etiology is unknown. There is strong evidence to support a genetic association. Crohn disease is more common in Whites than African Americans. It is rare in Asian and Hispanic populations (Grossman & Mamula, 2014). It most often develops in adolescents and young adults. Crohn disease has an incidence of approximately 4.56 per 100,000 (Grossman & Baldassano, 2016). The onset of Crohn disease is subtle. Crampy abdominal pain is usually reported first, followed by diarrhea. Other symptoms include fever, anorexia, growth failure or weight loss, general malaise, and joint pain. Diagnosis is based on laboratory evaluation, diffuse abdominal tenderness, and radiologic and biopsy examinations. Anemia, an elevated erythrocyte sedimentation rate, hypoalbuminemia, and thrombocytosis are other possible findings. Stools are positive for occult blood (Glick & Carvalho, 2011).

Clinical Tip

Irritable bowel syndrome (IBS) refers to a functional disorder of the gastrointestinal tract that is characterized as chronic and episodic. There is no structural cause, but it seems to be triggered by events such as gastroenteritis, major life events or stressors, or dietary intolerance. Other causative factors may include stress, diet, drugs, and alcohol. IBS is characterized by episodes of abdominal cramping and pain, diarrhea or constipation, and bloating (Mason, 2014). Management generally focuses on the symptoms. A change in lifestyle and diet might be effective in decreasing the frequency of symptoms. Medications such as antispasmodics, antimotility agents, and laxatives may also be used (Mason, 2014).

Ulcerative colitis is a chronic recurrent disease of the large intestine and rectal mucosa of unknown etiology. Inflammation is limited to the mucosa, as opposed to Crohn disease, which extends deep into the bowel wall. Ulcerative colitis can involve the entire length of the bowel with varying degrees of inflammation, ulceration, hemorrhage, and edema. Emotional and other psychosocial factors may influence the presentation and course of the disease. It is more prevalent among persons of Jewish heritage. The disease develops before 20 years of age with peak onset at about 12 years. The incidence of pediatric ulcerative colitis in North America is approximately 2 per 100,000 (Grossman & Baldassano, 2016). See Table 25–2 for a comparison of the two diseases.

The first symptom of ulcerative colitis is usually diarrhea. Lower abdominal pain and cramping are present before and during a bowel movement and are relieved by the passage of stool and flatus. The stool is often mixed with blood and mucus. Weight loss or delayed growth, nutritional deficiencies, and arthralgias often occur as effects of the disease.

Diagnosis centers on evaluating the cause and identifying the extent of involved bowel and differentiating an infectious process from ulcerative colitis. Upper endoscopy and colonoscopy are helpful to determine the extent and severity of the inflammatory process. Laboratory studies generally indicate an elevated erythrocyte sedimentation rate, elevated C-reactive protein, hypoalbuminemia, antineutrophil cytoplasmic antibodies (ANCA), and anti–*Saccharomyces cerevisiae* antibodies (ASCA) (Kelsen & Mamula, 2013).

Crohn disease and ulcerative colitis have periods of remission and exacerbation. Treatment for both diseases includes pharmacologic interventions, nutrition therapy, and, in severe cases, surgery. First-line pharmacologic treatment of Crohn disease involves aminosalicylates. Sulfasalazine inhibits prostaglandin synthesis, thereby decreasing inflammation. Corticosteroids and immunosuppressants are used in children with more severe disease. Biologic therapies such as infliximab

TABLE 25–2 Clinical Manifestations of Ulcerative Colitis and Crohn Disease

	ULCERATIVE COLITIS	CROHN DISEASE
Type of lesions	Continuous, superficial involvement	Segmental, transmural (through the wall) involvement
Clinical manifestations		
Anal or perianal lesions	Rare	Common
Anorexia	Mild to moderate	Can be severe
Diarrhea	Often severe	Moderate
Growth retardation	Mild	Significant
Pain	Present	Common
Rectal bleeding	Present	Absent
Weight loss	Moderate	Severe
Risk of cancer	Slightly increased	Greatly increased

(Remicade) have been effective in patients with Crohn disease and ulcerative colitis who fail to respond to other therapies (Glick & Carvalho, 2011).

A nutritionist is part of the team treating the child. The goal of nutrition therapy is to provide adequate caloric intake and nutrients necessary for growth. Vitamin, iron, zinc, and folic acid supplementation is frequently required. Total parenteral nutrition (TPN) is often given to treat nutritional deficiencies and malnutrition, which accompany inflammatory bowel disease (see the *Clinical Skills Manual* SKILLS). A high-protein, high-carbohydrate, low-fiber diet with normal amounts of fat is recommended.

Clinical Tip

The following drugs are used in the treatment of inflammatory bowel disease:

Aminosalicylates

- Sulfasalazine
- Mesalamine

Corticosteroids

- Prednisone
- Prednisolone
- Hydrocortisone
- Budesonide

Biologic Therapies

- Infliximab (Remicade)
- Adalimumab (Humira)
- Certolizumab (Cimzia)

Immunosuppressants

- 6-Mercaptopurine (6-MP)
- Azathioprine
- Cyclosporine
- Methotrexate

Antibiotics

- Metronidazole
- Ciprofloxacin

Source: Data from Glick, S. R., & Carvalho, R. S. (2011). Inflammatory bowel disease. *Pediatrics in Review, 32*(1), 14–25; Peyrin-Biroulet, L. (2011). Why should we define and target early Crohn's disease? *Gastroenterology & Hepatology, 7*(5), 324–326; Triantafillidis, J. K., Merikas, E., & Georgopoulos, F. (2011). Current and emerging drugs for the treatment. *Drug Design, Development and Therapy, 5*, 185–210.

If other treatment measures fail to reduce inflammation, surgery is generally indicated. A temporary colostomy or ileostomy is performed to allow the bowel to rest. However, in Crohn disease, ulcerations tend to recur elsewhere in the GI tract. In ulcerative colitis, removal of the diseased bowel provides a permanent cure.

Nursing Management

Nursing management occurs mainly in the community and home and focuses on helping the child and family adjust to the emotional impact of a chronic disease, administering medications and diet therapy, monitoring nutritional status, and providing appropriate referrals. Provide emotional support and counseling to help the child adjust to feeling "different" from peers. Inability to compete with peers and frequent absences from school can affect the child's self-esteem. Have the parents contact the school district to arrange for tutoring in case extended absences from school become necessary. Encourage the child who is not attending school regularly to maintain contact with friends through telephone calls, cards, and visits.

Body image is a major concern for children and adolescents with inflammatory bowel disease. Corticosteroid therapy causes growth retardation and delayed sexual maturation. Encourage the child to discuss feelings about these side effects. If a permanent colostomy or ileostomy is required, help the child and family understand the need for surgical treatment. (See the discussion of ostomies earlier in this chapter.) Introduce the child and family to other children who have stomas.

If the child is unable to eat or the intake of calories is insufficient to meet basic nutritional and metabolic needs, total parenteral nutrition is ordered (see the *Clinical Skills Manual* SKILLS). If the child is able to eat, parents need instructions about dietary needs. Frequently measure growth and assess nutrition.

Teach parents about medication administration and diet therapy. Reinforce to both the parents and child the importance of adhering to a strict medication regimen. Emphasize that medications should be continued even when the child is asymptomatic. Discuss side effects of the drugs and what to do if any of these symptoms occur. Since immune status may be altered by steroid use, have families avoid contact with infectious diseases when the child is taking steroids. Immunization schedules may need to be altered.

Growth and Development

Providing adequate stress reduction may be helpful in control of inflammatory bowel disease. Teach young children relaxation techniques, such as deep breathing, progressive tensing and relaxing of muscles, and visualization of favorite places. Encourage busy school-age children and teens to have quiet and restful times each day in addition to physical activity periods. Meditation might be effective in older children and teens.

Families Want to Know

Diet Instructions for Inflammatory Bowel Disease

- Several small feedings are usually better tolerated than three meals daily.
- Limiting fiber intake can help decrease intestine motility and inflammation. Peel fruits and avoid large quantities of whole grains and nuts.
- If the child is not eating well, offer high-calorie meals. If lactose intolerance is not a problem for the particular child, cream soups, milkshakes, puddings, and custards can be offered.
- Liquid dietary supplements may be helpful to ensure protein and caloric requirements are met.
- Watch for foods that cause intestinal problems for the individual child, and avoid them in the future.
- Avoid having mealtime become a reason for family strife. Seek help of nurses and dietitians if needed.

Parents need instructions for TPN if this therapy is used, as well as information about care of a central venous catheter, including dressing changes, sterile and nonsterile techniques, signs of infection, how to handle infusion pumps and tubing, and how to measure the child's intake and output. Assist parents in obtaining equipment and supplies necessary for the child's care. Have parents demonstrate their mastery of care for the central venous catheter and their understanding of TPN techniques during home visits and appointments for health care.

Refer parents to social services, the visiting nurse association, and home healthcare agencies, if they are not receiving any of these services. For information about inflammatory bowel disease, refer families to the Crohn's and Colitis Foundation.

Expected outcomes of nursing care for the child with inflammatory bowel disease include the following:

- Normal growth and development are achieved.
- The child demonstrates the ability to cope with episodes of GI distress.
- The child adheres to the medication regimen.
- There is no evidence of central line infection.
- The child has a positive body image.
- The child is able to integrate stress-lowering practices into daily life.

Peptic Ulcer

A peptic ulcer is an erosion of the mucosal tissue in the lower end of the esophagus, in the stomach (usually along the lesser curvature), or in the duodenum. Peptic ulcers occur primarily in individuals receiving nonsteroidal anti-inflammatory drugs and those with *Helicobacter pylori* infection (Chason, Reisch, & Rockey, 2013).

Clinical manifestations vary according to the age of the child and location of the ulcer. The most common symptom is abdominal pain (burning) associated with an empty stomach, which may awaken the child at night. Vomiting and pain after meals, anemia, occult blood in stools, and abdominal distention may also be present.

Diagnosis is based on the history and radiologic studies. Bleeding from peptic ulcer disease is treated with acid-suppressant medications. These medications include histamine-2 receptor antagonists (H2RAs) such as rantidine and famotidine and proton pump inhibitors such as omeprazole, pantoprazole, and lansoprazole. *H. pylori* infection is generally treated with a proton pump inhibitor, amoxicillin, and clarithromycin for 7 to 14 days (Anand, 2015). Follow-up is important to ensure that the organism has been eradicated. The prognosis is usually good with early intervention.

Nursing Management

Assess the child for abdominal pain, vomiting, and abdominal distention. Assess for family history of *H. pylori* infection. Nursing care focuses on interventions to promote adequate nutritional intake, promote healing, and prevent recurrences. Provide a nutritionally sound, age-appropriate diet. Omit foods only if they exacerbate the disorder.

Medications must be given as scheduled. Emphasize the importance of continuing medication therapy as prescribed. The family needs encouragement to continue the medications as ordered and to return for follow-up visits. Children who attend school may prefer to take medications in the form of tablets, which are easier to carry than liquid preparations. The appropriate form must be completed in order for the child to receive medication at school.

Parents should discuss any additional medications with the primary healthcare provider before administering to the child. Caution parents to avoid ibuprofen, which irritates the gastric mucosa. If an antipyretic or pain medication is needed, acetaminophen should be given. Advise parents to read medication labels if they are unsure of product contents.

Because psychologic stress can contribute to peptic ulcer disease, the parents and child should be assisted in identifying sources of stress in the child's life. Assess coping mechanisms and provide referral for psychologic counseling, if appropriate. Teach relaxation techniques and recommend community classes on yoga or other stress reduction.

Disorders of Motility

Fluids are an important part of normal GI functioning. As food passes through the intestines, fluids are reabsorbed and moderately soft stool is formed and evacuated. In disorders such as diarrhea and constipation, fluid balance is altered, causing either more or less fluid to be reabsorbed. This can severely alter the characteristics of the stool. Reabsorption of too little water produces diarrhea and can lead to fluid and electrolyte alterations. Reabsorption of too much fluid can cause constipation, which if untreated can lead to bowel obstruction.

Gastroenteritis (Acute Diarrhea)

Gastroenteritis is an inflammation of the stomach and intestines that may be accompanied by vomiting and diarrhea.

Gastroenteritis can affect any part of the GI tract. It may be an acute problem, caused by viral, bacterial, or parasitic infections, or a chronic problem. Rotavirus is a leading cause of severe gastroenteritis in children less than 5 years of age worldwide. The rotavirus vaccine is recommended for infants in order to decrease the morbidity and mortality related to this organism (Agócs et al., 2014). Infants and small children with gastroenteritis or diarrhea can quickly become dehydrated and are at risk for hypovolemic shock if fluid and electrolyte losses are not replaced (see Chapter 18). A significant number of infants and young children are hospitalized each year for dehydration secondary to gastroenteritis.

ETIOLOGY AND PATHOPHYSIOLOGY

Diarrhea in children is related to many different causes (Table 25–3). The specific etiology is not always identified. The common mechanism is a decrease in the absorptive capacity of the bowel through inflammation, decrease in surface area for absorption, or alteration of parasympathetic innervation. Children in childcare centers and those living in substandard housing with improper sanitation are at increased risk.

Clinical Tip

Carbonated beverages and those containing high amounts of sugar should not be given when a child has diarrhea. Fermentation of sugar in the gastrointestinal tract causes increased gas, abdominal distention, and an increased frequency of diarrhea.

CLINICAL MANIFESTATIONS

Diarrhea may be mild, moderate, or severe. In mild diarrhea, stools are slightly increased in number and have a more liquid consistency. In moderate diarrhea, the child has several loose or watery stools. Other symptoms include irritability, anorexia, nausea, and vomiting. Moderate diarrhea is usually self-limiting, resolving without treatment within 1 or 2 days.

TABLE 25–3 Causes of Diarrhea in Children

ETIOLOGY	BOWEL MANIFESTATIONS
Emotional stress (anxiety, fatigue)	Increased motility
Intestinal infection (bacteria [*Escherichia coli, Salmonella, Shigella*], viral [human rotavirus, enteric adenovirus], fungal overgrowth)	Inflammation of mucosa; increased mucus secretion in colon
Food sensitivity (gluten, cow's milk)	Decreased digestion of food
Food intolerance (lactose, introduction of new foods, overfeeding)	Increased motility; increased mucus secretion in colon
Medications (iron, antibiotics)	Irritation and suprainfection
Colon disease (colitis, necrotizing enterocolitis, enterocolitis)	Inflammation and ulceration of intestinal walls; reduced absorption of fluid; increased intestinal motility
Surgical alterations (short bowel syndrome)	Reduced size of colon; decreased absorption surface

In severe diarrhea, watery stools are continuous. The child exhibits symptoms of fluid and electrolyte imbalance (see Chapter 18), has cramping, and is extremely irritable and difficult to console.

CLINICAL THERAPY

Diagnosis is based on the history, physical examination, and laboratory findings. Physical examination provides a guide to the severity of dehydration (see Chapter 18). The stool can be examined for the presence of ova, parasites, infectious organisms, viruses, fat, and undigested sugars. Laboratory evaluation of serum and urine helps identify electrolyte imbalances and other deficiencies.

Medical management depends on the severity of the diarrhea and fluid and electrolyte imbalances. The goal of treatment is to correct the fluid and electrolyte imbalances. For mild and moderate dehydration, oral rehydration therapy is the first intervention (see Chapter 18). This may be accomplished at home or in the short-stay observation unit in a hospital.

For severe dehydration, rehydration is accomplished by intravenous infusion with a solution chosen to correct the specific electrolyte imbalances. (See Chapter 18 for further information about solutions to correct dehydration.) As soon as possible, introduce clear liquids or breast milk and then encourage the child to progress to a regular diet. Foods generally are not withheld for more than 1 to 2 days.

If the diarrhea is caused by bacteria or parasites, antimicrobial therapy may be prescribed. Antiemetics and antidiarrheals are generally not used in young children since they can mask the signs and symptoms of more serious illness.

Nursing Management

For the Child With Gastroenteritis

Nursing Assessment and Diagnosis

The nurse may encounter the child and family in the emergency department, urgent care center, clinic, or office. The child may be cared for over several hours at a clinic or urgent care center so that dehydration is treated with intravenous infusion and/or oral rehydration, and then sent home with instructions for parents to care for the child. A thorough history may help in identifying the cause.

If the child is hospitalized, it is important to assess onset, frequency, color, amount, and consistency of stools. If the child is also vomiting, monitor the amount and type of vomitus. Initial and ongoing physical assessment of the child focuses on observing for signs and symptoms of dehydration, which reflect underlying fluid and electrolyte status. Evaluate urinary output and specific gravity. An accurate weight must be obtained on admission and daily thereafter. Monitor vital signs every 2 to 4 hours. A febrile child has increased water loss, contributing to the dehydration. Assess skin integrity, especially in the perineal and rectal areas, and note any breakdown or rashes.

The accompanying *Nursing Care Plan* lists common nursing diagnoses for a child with gastroenteritis. The following diagnoses may also be appropriate (NANDA-I © 2014):

- ***Anxiety (Child and Parent)*** related to change in health status
- ***Sleep Pattern, Disturbed,*** related to pain
- ***Nutrition, Imbalanced: Less than Body Requirements,*** related to inability to ingest sufficient nutrients

Nursing Care Plan: The Child Hospitalized With Gastroenteritis

1. Nursing Diagnosis: *Diarrhea* related to infectious process (NANDA-I © 2014)

GOAL: The child's bowel function will be restored to normal.

INTERVENTION	RATIONALE
• Obtain baseline vital signs and monitor every 2–4 hr.	• Fluid and electrolyte imbalances can alter vital body functions.
• Observe stools for amount, color, consistency, odor, and frequency.	• Aids in the diagnosis and in monitoring the child's status.
• Test stools for occult blood.	• Frequent defecation and some infectious organisms can cause bleeding.
• Monitor results of stool culture and sample for ova and parasites.	• Rapid notification of the healthcare provider will facilitate treatment.
• Wash hands well before and after contact with the child.	• Helps prevent transmission of microorganisms.
• Isolate the child until the cause of the diarrhea is determined.	• Prevents exposure of other patients and staff.
• Assist the child with toileting and hygiene.	• The child may be weak, incontinent, physically impaired, or anxious and require assistance to use the bathroom.
• Administer prescribed oral rehydration and intravenous solutions.	• Provides necessary fluids and nutrients.
• Notify the healthcare provider if diarrhea persists, stool characteristics change, or other symptoms of dehydration electrolyte imbalance occur.	• Ensures early intervention.

EXPECTED OUTCOME: Child's bowel function will return to normal.

2. Nursing Diagnosis: *Fluid Volume: Deficient* related to active fluid volume loss (NANDA-I © 2014)

GOAL: The child will remain hydrated and will begin to drink fluids within 24 hours of admission.

INTERVENTION	RATIONALE
• Monitor intake and output. Document time of each voiding. Weigh all diapers.	• Will determine if output exceeds input. Long periods of time without urine output can be an early indicator of poor renal function. A child should produce 1–2 mL of urine/kg/hr.
• Compare admission weight to preadmission weight. Assess weight daily.	• The degree of dehydration can be determined by the percentage of weight loss. Daily weights aid in determining progress toward rehydration.
• Assess level of consciousness, skin turgor, mucous membranes, skin color and temperature, capillary refill, eyes, and fontanelles every 4 hours.	• Will determine degree of hydration and adequacy of interventions.
• Assess for vomiting.	• Vomiting frequently accompanies diarrhea and contributes to the child's fluid loss.
• Provide oral fluid and electrolyte replacement solution if able to tolerate.	• Less invasive than IV fluids. Provides for replacement of essential fluids and electrolytes.
• Provide and maintain IV replacement therapy, as ordered.	• Use of IV replacement is based on the degree of dehydration, ongoing losses, insensible water losses, and electrolyte results.

EXPECTED OUTCOME: Child will have normal fluid and electrolyte balance as indicated by laboratory evaluation and physical examination.

3. Nursing Diagnosis: *Skin Integrity, Risk for Impaired,* related to altered fluid status (NANDA-I © 2014)

GOAL: The child will remain free of skin breakdown and rashes.

INTERVENTION	RATIONALE
• Assess skin of perineum and rectum for signs of skin breakdown or irritation.	• Early assessment and intervention can prevent worsening of the condition.
• Provide prevention or restorative care for infants as follows:	
Preventive Care:	
• Change diapers every 2 hr or as needed.	• Minimizes skin contact with chemical irritants from stool and urine.
• Wash diaper area after each soiling.	• Removes traces of stool if present.
• Apply A&D ointment, Aquaphor, or another barrier ointment with each diaper change.	• Provides a barrier and protects intact or reddened skin from becoming excoriated.
Restorative Care:	
• Leave the buttocks open to air for a few minutes several times daily, placing absorbent pads under the infant.	• Promotes air circulation to the area.
• Notify the healthcare provider if the skin is severely broken or peeling or if a rash is present.	• Additional measures such as the use of a barrier cream or paste may be needed to ensure skin healing.
• *For toddlers and older children:* Tub bathe at least daily (if condition allows) in tepid water. Pat the area dry.	• Helps loosen any fecal matter without scrubbing, which can cause additional irritation to the skin.
• Discourage the wearing of underwear if possible.	• Allows air to circulate and prevents accumulation of moisture.
• Apply barrier ointment with each diaper change or as instructed.	• Provides a barrier and protects intact or reddened skin from becoming excoriated.

EXPECTED OUTCOME: Child's perianal and rectal tissue will remain pink and intact.

Planning and Implementation

Nursing care focuses on providing emotional support, promoting rest and comfort, and ensuring adequate nutrition.

PROVIDE EMOTIONAL SUPPORT

The child may have been ill for several days or become suddenly ill a short time before seeking health care. The child and parents are usually anxious, so it is important to allow them to talk and ask questions. The child may require blood tests to help direct rehydration therapy. Most children are cared for at home, although care in a 24-hour monitoring unit may occur. Using therapeutic play techniques, such as allowing the child to manipulate equipment, can reduce anxiety (see Chapter 11).

PROMOTE REST AND COMFORT

Children with gastroenteritis may awaken frequently with periods of vomiting and diarrhea. Provide a quiet, restful environment and cluster nursing care to allow for periods of uninterrupted rest. To reduce the child's anxiety, encourage parents to room-in. Place the child's favorite toys and comfort objects within reach. Keep the child's mouth moistened with a wet washcloth, or an occasional ice chip. Provide skin care after each diarrheal episode to maintain skin integrity. Avoid using commercial baby wipes that contain alcohol as these irritate the skin and cause discomfort for the child.

ENSURE ADEQUATE NUTRITION

Liquids are offered throughout the illness, even if an intravenous infusion is in place. Follow guidelines for oral rehydration therapy in Chapter 18. Small amounts of normal diet for age are provided. Infants are breastfed or given formula. The child's diet progresses according to protocol or the child's tolerance for feedings.

Clinical Tip

Instruct parents in the importance of and techniques for hand hygiene, especially when caring for the child with gastroenteritis. Teach children in childcare centers and school how to wash their hands effectively to prevent spread of infectious diseases.

DISCHARGE PLANNING AND HOME CARE TEACHING

Discharge teaching begins on arrival at the healthcare facility. Teach the parents about the symptoms of dehydration and what actions to take if diarrhea recurs. Be sure that parents understand the recommended diet progression. Emphasize the necessity of good hygiene practices to prevent the spread of microorganisms that can cause gastroenteritis. If the child attends child care, have

the parent inform the care center about the infection so the staff can be alerted to watch for other cases and can take steps to prevent the spread of infection.

Evaluation

Expected outcomes of nursing care are provided on the accompanying *Nursing Care Plan*.

Constipation

Constipation is a common complaint in the pediatric population and accounts for 3% of all visits to the pediatric primary care provider (Nurko & Zimmerman, 2014). Up to 30% of the pediatric population experience constipation (Watson, 2014). Most children experience functional constipation. This refers to constipation that cannot be attributed to an underlying physiological or anatomic abnormality (Rogers, 2012).

Because stool patterns vary among children, identification of an abnormal pattern is sometimes difficult. Infants usually have several bowel movements a day. For a young child, one bowel movement a day may be normal. As the child grows, however, three to four bowel movements in a week may be a normal pattern. The diagnosis of constipation must take into account the child's normal stool patterns.

Constipation may be caused by an underlying disease, diet, or psychologic factor. It may result from defects in filling, or more commonly emptying, of the rectum. Pathologic causes of defective filling include ineffective colonic propulsive activity, caused by hypothyroidism or use of medication, and obstruction, caused by a structural anomaly (stricture or stenosis) or by an aganglionic segment (Hirschsprung disease). If the rectum fails to fill, stasis leads to increased water reabsorption and hard, dry stools. Emptying of the rectum depends on the defecation reflex. Lesions of the spinal cord, weakness of the abdominal muscles, and local lesions blocking sphincter relaxation all may impede attempts to defecate.

Constipation during infancy is rare and is most often caused by mismanagement of diet. The transition from formula to cow's milk may cause a transient constipation since the bowel must adjust to the increased protein content of cow's milk.

Constipation occurs most frequently in the toddler and preschool age groups. This increased incidence is often associated with learning to control body functions. Many children do not like the sensations of a bowel movement and may begin withholding stool, which accumulates in and dilates the rectum until the next urge to defecate. The increasingly hard and painful bowel movement reinforces the child's behavior, and a cycle begins (Rogers, 2012).

Constipation in the school-age child, older child, and adolescent is generally related to activity, diet, and toileting habits. The child may not be eating enough fiber and could be eating starchy foods that contribute to constipation. Constipation may occur because of limited time for toileting. The child may not take time during the day to have a bowel movement or may be hesitant to use an unfamiliar bathroom.

Diagnosis is based on a thorough history and physical examination. When constipation occurs along with growth failure, vomiting, or abdominal pain, further investigation is necessary to rule out other disorders. Tests may include thyroid function tests; measurements of calcium, glucose, and electrolytes; a complete blood count; and urinalysis.

CLINICAL THERAPY

Dietary management is the treatment of choice for constipation that has no underlying pathologic cause. Constipation in young infants can usually be corrected by increasing the amount of fluids or adding 2 oz of pear or apple juice to daily intake. Increasing physical activity and fluid intake may be effective for some children.

Removing constipating foods (e.g., bananas, rice, and cheese) from the child's diet often decreases constipation. Increasing the child's intake of high-fiber foods (e.g., whole-grain breads, raw fruits, and vegetables) and fluids also promotes bowel elimination. In older infants, increasing the intake of fluids, cereals, fruits, and vegetables in the diet should correct the problem. A single glycerin suppository or enema may be required to remove hard stool.

Encouragement from parents and relaxation of bathroom privileges at school promote regularity and return of usual bowel patterns within a short time for school-age children. Children may need to get up earlier to have breakfast to allow time for toileting before going to school.

Constipation may follow surgery, especially in children who are immobilized. Stool softeners and a diet high in fiber and fluids prevent and treat constipation. Pharmacologic management of severe constipation usually occurs in two stages. The first stage involves disimpaction, followed by maintenance therapy (Rogers, 2011).

Disimpaction is difficult for the child and those who are managing the child's constipation. Consider the most effective means to evacuate the stool while causing the least amount of stress and anxiety to the child. The oral route is less invasive, but if the child experiences nausea and vomiting, the rectal route might be used. Polyethylene glycol solution with electrolyte solution is recommended for disimpaction (Paul, Dewdney, & Lamb, 2012; Rogers, 2011, 2012). Once the stool has been evacuated, maintenance therapy that may include polyethylene glycol powder, docusate, lactulose, or other products is continued for several weeks after a regular bowel patterns are established (Rogers, 2012).

Behavior modification may prove beneficial to managing constipation and may include having the child sit on the toilet after meals. Providing rewards for toileting at routinely scheduled times is effective (Rogers, 2012).

Nursing Management

Nursing care focuses on teaching parents what constitutes normal bowel patterns in children and the importance of diet in maintaining normal bowel patterns. Assess the child's diet history and obtain a description of bowel patterns from parents. Ask what the family does to treat constipation. Assessment of the child's food likes and dislikes may provide a clue as to the cause of constipation. Regular bowel habits are encouraged by placing the child on the toilet 30 minutes after a meal or around the time defecation usually occurs. Providing positive reinforcement during toilet training helps prevent a withholding pattern.

Teach parents dietary measures to promote regularity of bowel movements. Children can be given a high-fiber diet that includes fruits and vegetables. Cut-up fresh fruits, dried fruits, and fruit juice can be offered as snacks. A glycerin suppository can be used periodically. This is a natural stimulant and lubricant of the bowel. Caution parents to avoid frequent use of laxatives, stool softeners, and enemas since overuse can cause bowel dependency. Herbal stimulant laxatives are discouraged for children younger than 12 years, whereas other intestinal motility aids are not generally harmful. Find out more about any herbs the family commonly uses.

Encopresis

Encopresis is an abnormal elimination pattern characterized by the recurrent soiling or passage of stool at inappropriate times by a child who should have achieved bowel continence. Encopresis is reported to occur in approximately 3% of children ages 3 to 12. Children with primary encopresis have never achieved bowel control. Children with secondary encopresis have been continent of stool for more than 6 months before developing encopresis (Coehlo, 2011).

Encopresis is usually associated with voluntary or involuntary retention of stool in the lower bowel and rectum, leading to constipation, dilation of the lower bowel, and incompetence of the inner sphincter. The retention of stool is usually a result of being "too busy"; the child puts off going to the bathroom because of the inconvenience of leaving an activity. The retention of stool leads to constipation that is untreated and chronic. Loose stool leaks around the hard feces, and the child becomes unaware of a need to eliminate. Soiling may occur during the day or night. Bowel movements are irregular, painful, small, and hard. The child may be ridiculed by peers because of offensive body odor. This rejection leads to withdrawal and behavioral problems, often resulting in altered school performance and attendance. The child continues to hold stool because the passage has become painful. Parents commonly seek health care, believing that the child has diarrhea or constipation.

The underlying constipation that leads to encopresis may be caused by the stress of environmental changes (e.g., birth of a sibling, moving to a new house, attending a new school), issues of anger and control related to bowel training, diet, a full schedule of activities, or a genetic predisposition.

A thorough history, physical examination, and diagnostic studies (possibly including barium or contrast enema) are necessary to rule out organic causes and anatomic abnormalities. Information about the child's toilet training habits and parents' attitudes concerning those habits is obtained. A dietary history, including eating habits and types of foods eaten, is often helpful. Physical examination sometimes reveals a nontender mass in the lower abdomen.

In addition to dietary management and treatment to evacuate the bowel if needed as discussed in the preceding section, bowel training, behavior management, and family support are important components in the management of encopresis. Bowel training involves having the child sit on the toilet for a specific amount of time after breakfast and after dinner. This allows the child to gain or regain control of their bowel and an awareness of a full rectum. Behavior management includes involving the child in their care and provides reward and positive reinforcement for successes. Treatment for encopresis may take 6 to 12 months. The family needs education and support during this process. Long-term management may include oral stool softeners (Coehlo, 2011).

Nursing Management

Prevention of encopresis is the nursing goal. Partner with parents to teach toilet training techniques, emphasizing the child's developmental readiness. Parents are encouraged to praise the child for successes and to avoid punishment and power struggles. Encourage high-fiber diets and regular times for elimination.

Nursing care centers on educating the child and parents about the disorder and its treatment and on providing emotional support. Explain the treatment plan, including dietary changes and use of laxatives or stool softeners. Reassure the child that he or she has a healthy body and, with treatment, will achieve normal functioning. The child is monitored during clinic visits for at least 6 months to be certain new patterns have been established.

Intestinal Parasitic Disorders

Intestinal parasitic disorders occur most frequently in tropical regions. Outbreaks take place where water is not treated, food is incorrectly prepared, or people live in crowded conditions with poor sanitation. In the United States, outbreaks of diseases caused by protozoa or helminths (worms) are increasing. Young children, especially those in day care, are most at risk of infection. Young children often lack good hygiene practices and are likely to put objects and their hands into their mouths. See Table 25–4 for common intestinal parasitic disorders.

Another common cause of young child infection is exposure to pets and wildlife. Pets should be checked regularly for parasites and treated for worms as needed. Sandboxes should be kept covered when not in use, and children should be taught good handwashing techniques after exposure to their pets (CDC, 2014b). Laboratory examination of stool specimens identifies the causative organism (protozoa, worms, larvae, or ova). Treatment usually involves an anthelmintic.

Nursing care centers on preventive teaching. Emphasize the importance of good hygiene practices, especially careful handwashing, after toileting and when handling food. Ensure the family understands proper medication administration. Instruct parents to administer prescribed medications as directed even if the child's condition seems to be improved.

Disorders of Malabsorption

Malabsorption occurs when a child cannot digest or absorb nutrients in the diet. Disorders of malabsorption include celiac disease, lactose intolerance, and short bowel syndrome. Celiac disease and lactose intolerance are discussed in Chapter 14. Cystic fibrosis, a common cause of malabsorption, is discussed in Chapter 20.

Short Bowel Syndrome

Short bowel syndrome is a decreased ability to absorb and digest a regular diet due to a shortened intestine. Loss of intestine may result from extensive bowel resection for treatment of necrotizing enterocolitis or inflammatory disorders or from a congenital bowel anomaly such as intestinal malrotation, gastroschisis, or atresia.

The extent and location of the involved bowel determine the severity of the disorder. Because specific types of absorption occur primarily in certain parts of the bowel, the section lost determines the particular vitamins and other nutrients that are inadequate.

During the first 3 months after bowel resection, watery diarrhea is common. In the transition period, the remaining bowel usually increases its absorptive surface area and partially compensates for the absent intestine. At first, the infant or young child requires nutritional support to provide sufficient nutrients for adequate growth and development. In the initial period, the child only receives total parenteral nutrition (TPN). Once the bowel begins to recover, in addition to TPN, start continuous enteral feedings. Continuous exposure to nutrients allows

TABLE 25–4 Common Intestinal Parasitic Disorders

PARASITIC INFECTION	TRANSMISSION, LIFE CYCLE, PATHOGENESIS	CLINICAL MANIFESTATIONS	CLINICAL THERAPY	COMMENTS
GIARDIASIS				
Organism: protozoan *Giardia lamblia*  Centers for Disease Control (CDC)	Transmission is through person-to-person contact, unfiltered water, improperly prepared infected food, and contact with animals. Cysts are ingested and passed into the duodenum and proximal jejunum, where they begin actively feeding. They are excreted in the stool.	May be asymptomatic. *Infants:* diarrhea, vomiting, anorexia, avoidant/restrictive food intake disorder (failure to thrive) *Older children:* abdominal cramps; intermittent loose, foul-smelling, watery, pale, and greasy stools	Medications used to treat giardiasis include metronidazole, tinidazole, and nitazoxanide (drugs of choice). Quinacrine, furazolidone, and paromomycin may be used.	Most common intestinal parasitic organism in the United States. Symptoms last 2–6 weeks. Medication may decrease this time frame. Parents or caregivers should wear gloves when handling diapers or stool of an infant or child infected with parasites.
ENTEROBIASIS (PINWORM)				
Organism: nematode *Enterobius vermicularis* B. G. Partin; Dr. Moore/CDC	Transmission is from discharged eggs inhaled or carried from hand to mouth. Eggs hatch in the upper intestine and mature in 1–2 months. Larvae then migrate to the colon and lay eggs. Movement of worms causes intense itching. Scratching deposits eggs on the hands and under the nails.	Intense perianal itching, irritability, restlessness, and short attention span; in females, can migrate to the vagina and urethra to cause infection. Itching intensifies at night when the female comes to the anal opening to lay eggs.	Medications used to treat enterobiasis include mebendazole, pyrantel pamoate, and albendazole. The child and all household members should be treated at the same time. Treatment may be repeated in 2 weeks.	Most common worm infection in the United States. Transmission is increased in crowded conditions such as housing developments, schools, and childcare centers.
ASCARIASIS (TYPE OF ROUNDWORM)				
Organism: nematode *Ascaris lumbricoides*  James Cavallini/BSIPSA/Alamy	Transmission is from discharged eggs carried from hand to mouth. The adult lays eggs in the small intestine. Eggs are excreted in stool. Swallowed eggs hatch in the small intestine. Larvae may penetrate intestinal villi, entering the portal vein and liver, then moving to the lung. Larvae that ascend to the upper respiratory tract are swallowed and proceed to the small intestine, where they repeat the cycle.	Mild infection may be asymptomatic. Severe infection may result in intestinal obstruction and impaired growth.	Medications used to treat ascariasis include ivermectin, mebendazole, and albendazole.	Most common in warm, moist climates. Associated with poor personal hygiene and poor sanitation.
HOOKWORM DISEASE				
Organism: nematode *Necator americanus* Centers for Disease Control (CDC)	Transmission is through direct contact with infected soil containing larvae. Worms live in the small intestine and feed on villi, causing bleeding. Eggs are deposited in the bowel and excreted in feces. Eggs hatch in damp, shaded soil. Larvae attach to and penetrate the skin, then enter the bloodstream, migrating to the lungs. Larvae then migrate to the upper respiratory passages and are swallowed.	In healthy individuals, mild infection seldom causes problems. Presence of larvae on the skin may cause itching and a rash. More severe infection may result in diarrhea, abdominal pain, anemia, weight loss, and fatigue.	Medications used to treat hookworm disease include mebendazole, albendazole, and pyrantel pamoate. Iron supplements may also be given.	Children should wear shoes when outdoors. Note, however, that other unprotected areas of the skin may still come in contact with larvae.

PARASITIC INFECTION	TRANSMISSION, LIFE CYCLE, PATHOGENESIS	CLINICAL MANIFESTATIONS	CLINICAL THERAPY	COMMENTS
STRONGYLOIDIASIS (TYPE OF ROUNDWORM)				
Organism: nematode *Strongyloides stercoralis*  Centers for Disease Control (CDC)	Transmission is from the ingestion of discharged larvae in the soil. Life cycle is similar to that of the hookworm, except this roundworm does not attach to the intestinal mucosa, and feeding larvae (rather than eggs) may be deposited in the soil.	Mild infection may be asymptomatic. Severe infection may result in abdominal pain and distention, nausea, vomiting, diarrhea, dry cough, throat irritation, and itchy rash.	Medications used to treat strongyloidiasis include ivermectin and albendazole. Treatment may need to be repeated if symptoms recur after treatment.	Most common in older children and adolescents.
TOXOCARIASIS (TYPE OF ROUNDWORM)				
Organism: nematode *Toxocara canis* or *T. cati*, commonly found in dogs and cats  Centers for Disease Control (CDC)	Transmission is through the ingestion of eggs in the soil. Ingested eggs hatch in the intestine. Mobile larvae then migrate to the liver and eventually to all major organs (including the brain). Once migration is complete, they encapsulate in dense fibrous tissue.	Most cases are asymptomatic. Severe symptoms include fever, coughing, pneumonia, and enlarged liver.	Medications used to treat toxocariasis include albendazole and mebendazole. Steroids may also be used.	Deworm household pets on a regular basis. Keep children away from areas contaminated with animal droppings.

Note: Some of the medications listed may not be available in the United States, and some of them may not be approved for use in all age groups.

the bowel to adapt (Cuffari, 2014). It is essential that the child receive the appropriate nutritional components regardless of the method in which nutrition is delivered.

SAFETY ALERT!

The child with short bowel syndrome will receive TPN via a central line. Aseptic technique in the care of the central line is essential to prevent a catheter-associated bloodstream infection and potential sepsis (Gutierrez, Kang, & Jaksic, 2011). Maintaining patency of the central line is also essential because this may be the child's only route for receiving nutrition. It is not uncommon for children with short bowel syndrome to require insertion of multiple central lines over time because of either infection or occlusion of the line, especially if they require long-term TPN. This not only places a stress on the child who must undergo yet another surgical procedure, but it is a stressor for the family as well.

Nursing Management

Nursing care focuses on meeting the child's nutritional and fluid needs and teaching parents how to care for the child at home. Establishing an adequate nutritional intake and bowel pattern is a lengthy process. TPN is provided initially until a feeding regimen can be established. Oral and enteral feedings are instituted gradually to allow the bowel time to compensate. Provide support to the family and child throughout this period. Teach parents how to prepare and administer total parenteral feedings and care for the central line (see the *Clinical Skills Manual* SKILLS). Once enteral or tube feedings have started, teach management of the feeding pump and care of the feeding tube. Ensure regular bowel function and maintain skin integrity. Arrange home visits to monitor the child's growth and development, care of the central line and tube-feeding site, and any side effects such as fluid and electrolyte imbalance and diarrhea.

Hepatic Disorders

The liver is one of the most vital organs in the body. Its primary functions include production of blood clotting factors, fibrinogen, and prothrombin; secretion of bile and *bilirubin* (yellow pigment produced from the breakdown of red blood cells); metabolism of fat, protein, and carbohydrates; detoxification of hormones, drugs, and other substances; and storage of vitamins A, D, E, and K and glycogen. Thus any inflammatory,

obstructive, or degenerative disorder that affects liver function can be life threatening. The following discussion focuses on four liver disorders in children: hyperbilirubinemia, biliary atresia, viral hepatitis, and cirrhosis.

Hyperbilirubinemia of the Newborn

Hyperbilirubinemia refers to an elevated serum bilirubin level and occurs in approximately 84% of term newborns (Muchowski, 2014). Jaundice manifests in newborns with total serum bilirubin (TSB) levels greater than 5 mg/dL (Schwartz, Haberman, & Ruddy, 2011).

ETIOLOGY AND PATHOPHYSIOLOGY

Physiologic or *neonatal jaundice* is a normal process that occurs during transition from intrauterine to extrauterine life and is caused by the newborn's shortened red blood cell life span (90 days compared with 120 days in the adult), slower uptake by the liver, lack of intestinal bacteria, and/or established hydration from initial breastfeeding.

CLINICAL MANIFESTATIONS

Jaundice in the newborn is first evident on the face and then progresses to the trunk and finally to the extremities. Jaundice may be difficult to see in babies with dark skin color (Lauer & Spector, 2011). In addition to jaundice, symptoms include lethargy, irritability, and poor feeding (Seagraves, Brulte, McNeely, et al., 2013).

DIAGNOSTIC TESTS

A blood test, performed by heelstick or venipuncture, measures total serum bilirubin (TSB) in the newborn. A transcutaneous bilirubin (TcB) measurement device is a noninvasive method for estimating serum bilirubin in newborns. This method for measuring bilirubin is a screening tool for use in determining if the TSB should be evaluated and is a good estimate of the TSB. A TSB should be obtained when treatment is being considered.

CLINICAL THERAPY

Phototherapy most effectively reduces serum bilirubin in newborns with physiologic jaundice (Wells, Ahmed, & Musser, 2013) Phototherapy is thought to reduce the amount of indirect, or unconjugated, bilirubin in the baby's bloodstream by promoting excretion via the intestines and kidneys. Phototherapy exposes the newborn's skin to blue light, which changes bilirubin into water-soluble forms that can be excreted (Lauer & Spector, 2011). Phototherapy can be provided by conventional banks of fluorescent tube phototherapy lights, by a fiber-optic blanket attached to a halogen light source around the trunk of the newborn, by a fiber-optic mattress placed under the baby, or by a combination of these delivery methods (Bhutani & Committee on Fetus and Newborn, 2011).

Clinical Tip

The newborn's eyes are covered during overhead phototherapy to prevent retinal damage (Hansen, 2014). The eye shields can be removed when the lights are off for feeding (Figure 25–8).

Many newborns with hyperbilirubinemia are also mildly dehydrated. When the newborn is breastfed, supplemental breast milk or formula may be given to improve hydration (Muchowski, 2014). If the newborn is unable to take adequate fluids and is dehydrated, intravenous fluid should be administered.

Figure 25–8 Infant receiving phototherapy. The phototherapy light is positioned over the incubator. Bilateral eye patches are always used during photo light therapy to protect the baby's eyes.

Nursing Management

For the Child With Hyperbilirubinemia

The nurse in the newborn nursery and in the outpatient setting plays a critical role in identifying the newborn at risk and providing parent education related to hyperbilirubinemia. Although the nurse in the newborn nursery may be providing care to a baby for a few days after birth, many newborns are discharged home within 24 hours. The newborn may be evaluated for jaundice in the outpatient setting and then admitted to the pediatric unit for treatment. Nurses working in acute care settings must familiarize themselves with the care of very young babies who require treatment for hyperbilirubinemia.

Nursing Assessment and Diagnosis

The newborn should be assessed for jaundice. If the nurse suspects the presence of jaundice, the newborn's primary care provider should be notified so that bilirubin levels can be measured.

FEEDING ASSESSMENT

The mother who is breastfeeding should nurse her newborn at least 8 to 12 times per day for the first several days (Muchowski, 2014; Seagraves et al., 2013). The nurse should be alert to mothers and newborns who are having difficulty and require lactation support during the hospital stay and following discharge. Adequate hydration is essential for adequate elimination of bilirubin from the body. Newborns who are not well hydrated are at increased risk for hyperbilirubinemia (Seagraves et al., 2013). Parents should be educated regarding the number of wet diapers and stools their newborn should have each day. Because many mothers and term newborns are discharged within 24 hours after birth, this is important information to teach parents prior to discharge.

NURSING ASSESSMENT

Nursing diagnoses that may apply to the newborn with hyperbilirubinemia may include the following (NANDA-I © 2014):

- ***Fluid Volume: Deficient*** related to decreased oral intake and ineffective breastfeeding
- ***Attachment, Risk for Impaired,*** related to disruption of parental/newborn interaction due to hospitalization and treatment

- ***Body Temperature: Imbalanced, Risk for,*** related to phototherapy
- ***Injury, Risk for,*** related to phototherapy

Planning and Implementation

The role of the nurse is to identify the newborn at risk for hyperbilirubinemia, educate parents about newborn jaundice, and care for the newborn and family undergoing treatment for this condition. For the baby undergoing phototherapy, the nurse should monitor the newborn frequently, ensuring that the newborn is receiving the phototherapy properly. Vital signs should be assessed every 4 to 8 hours, especially the newborn's temperature, which might indicate signs of infection or signs of hypothermia in a newborn whose clothing is removed for phototherapy. An accurate measurement of intake and output is essential to make sure the newborn is not dehydrated. Assist the family in breastfeeding or bottle-feeding as appropriate.

SAFETY ALERT!

In cases of severe and untreated hyperbilirubinemia, bilirubin encephalopathy can cause serious neurologic sequelae. The term *acute bilirubin encephalopathy* is used to describe the acute effects of bilirubin toxicity in the first few days to weeks of life. The term *kernicterus* is used when referring to chronic and irreversible effects of bilirubin toxicity (Schwartz, Haberman, & Ruddy, 2011).

DISCHARGE PLANNING AND HOME CARE TEACHING

Problems with breastfeeding in the first week of life can contribute to low caloric intake, dehydration, and subsequent risk of neonatal hyperbilirubinemia (Schwartz, Haberman, & Ruddy, 2011). The nurse assesses adequacy of breastfeeding prior to hospital discharge and coordinates with the newborn's healthcare provider in making appropriate referrals to lactation specialists and support groups in the community when necessary.

For term infants who develop uncomplicated hyperbilirubinemia, home phototherapy may be provided with the use of the fiber-optic pad, also known as a biliblanket. Serum bilirubin levels must be monitored regularly at the physician's office or neighborhood laboratory, or by the home healthcare worker. A visiting or home healthcare nurse often visits the family to establish the phototherapy and inform parents about the care needed. The nurse partners with other professionals such as staff from a medical supply company (to service equipment), a lactation specialist, and a pediatrician (to coordinate services).

Evaluation

Expected outcomes of nursing interventions include:

- The term or near-term newborn at risk for hyperbilirubinemia is identified prior to discharge and receives appropriate follow-up.
- The newborn's parents understand who and when to call if they suspect development of hyperbilirubinemia.
- The newborn receives appropriate intervention if hyperbilirubinemia occurs.
- The newborn's nutritional and fluid intakes are adequate to meet growth and development requirements.
- The newborn does not develop neurologic sequelae as a result of hyperbilirubinemia.

Biliary Atresia

Biliary atresia results when the extrahepatic bile ducts fail to develop or are closed. The disorder leads to cholestasis, cirrhosis, portal hypertension, end-stage liver disease, and death by 2 years of age if left untreated (Flanigan, 2013; Moreira, Cabral, Cowles, et al., 2012; Sira, Taha, & Sira, 2014). Biliary atresia is the leading indication for pediatric liver transplantation (Moreira et al., 2012).

CLINICAL MANIFESTATIONS

Initially, the newborn is asymptomatic. Jaundice may not be detected until 2 to 3 weeks after birth. At that point, bilirubin levels increase, accompanied by abdominal distention and hepatomegaly (see Appendix B for bilirubin levels and other liver function tests). As the disease progresses, splenomegaly occurs. The infant experiences easy bruising, prolonged bleeding time, and intense itching. Stools have putty-like consistency and are white or clay colored because of the absence of bile pigments. Excretion of bilirubin and bile salts results in tea-colored urine. Avoidant/restrictive food intake disorder (failure to thrive) and malnutrition occur as the destructive changes of the disease progress.

The cause of biliary atresia is unknown. Absence or blockage of the extrahepatic bile ducts results in blocked bile flow from the liver to the duodenum. This altered bile flow soon causes inflammation and fibrotic changes in the liver. In addition to blockage, the disease can also be caused by hepatocellular dysfunction. Lack of bile acids also interferes with digestion of fat and absorption of fat-soluble vitamins A, D, E, and K, resulting in steatorrhea and nutritional deficiencies. Without treatment the disease is fatal.

CLINICAL THERAPY

Diagnosis is based on the history, physical examination, and laboratory evaluation. Laboratory findings reveal elevated bilirubin and serum aminotransferase and alkaline phosphatase levels, prolonged prothrombin time, and increased ammonia levels (Schwarz, 2014). Percutaneous liver biopsy suggests biliary atresia, and an exploratory laparotomy and intraoperative cholangiography confirms the diagnosis (Robie, Overfelt, & Xie, 2014).

Treatment involves surgery to attempt correction of the obstruction (hepatoportoenterostomy) and supportive care. In a hepatoportoenterostomy (Kasai procedure), a segment of the intestine is anastomosed to the porta hepatis. The primary purpose of this procedure is to promote bile flow from the liver. Intravenous antibiotics are administered in the postoperative period to prevent cholangitis. Prophylaxis with oral antibiotics is continued for 1 to 2 years after surgery (Flanigan, 2013).

Additional treatment includes administration of intramuscular vitamin K prior to invasive procedures and surgery to decrease the risk of bleeding afterwards and vitamins A, D, E, and K to provide supplementation since absorption of these vitamins is impaired. The infant is breastfed or is given Pregestimil or Nutramigen, formulas that contain medium-chain triglycerides. As the liver disease worsens, the child may need cholestyramine and antihistamines to help decrease itching. Enteral feedings may be needed as well (Flanigan, 2013). Ursodeoxycholic acid (Actigall) may be given to the child to promote bile flow (Schwarz, 2014).

While bile flow is achieved with the Kasai procedure in many children with biliary atresia, approximately 70% to 80% of children having this surgery will eventually need a liver transplant (Mieli-Vergani & Tizzard, 2012). Advances in transplantation surgery now make it possible to perform partial liver transplants from living donor resections. This enables transplantation to be performed before the child develops end-stage liver disease (Flanigan, 2013).

Nursing Management

Nursing care in the initial stages of biliary atresia is the same as that for any healthy newborn. As symptoms develop, the focus of nursing care becomes long-term management and support.

Diagnosis of this potentially fatal disorder can be devastating to parents. Provide emotional support and offer frequent explanations of tests during the initial diagnostic evaluation. As the disease progresses, the infant becomes irritable because of intense itching and the accumulation of toxins. Tepid baths may help to relieve itching and provide comfort. Dry skin by patting rather than rubbing to avoid further skin irritation. Promote rest by grouping nursing activities while the infant is awake. Weigh the infant daily. Administer TPN, lipids, and fat-soluble vitamins A, D, E, and K as prescribed.

Care following a hepatoportoenterostomy is similar to that for a child undergoing abdominal surgery. (See the earlier discussion of postsurgical nursing management for appendicitis and *Nursing Care Plan: The Child Undergoing Surgery* in Chapter 11.) Posttransplant care includes immunosuppressant drugs and close monitoring for vascular complications. Discharge planning focuses on teaching parents how to care for the child's skin, provide for nutritional needs, administer medications, and monitor for increasing symptoms of liver disease. When the child has received a transplant, teach parents how to identify signs of rejection (nausea, vomiting, fever, and jaundice), as well as the administration and side effects of immunosuppressant medications. Refer parents to support groups, clergy, or social services if indicated. They will need ongoing visits from a home healthcare nurse to help them manage the child's complex care. Palliative care may need to be discussed with the family if it becomes evident the child will not survive (see Chapter 13). Expected outcomes for nursing care of the child with biliary atresia are as follows:

- The child consumes adequate nutrition in order to support growth and development.
- Parents cope effectively with stress of the child's condition.
- The child achieves growth and developmental milestones expected for age.

Viral Hepatitis

Hepatitis is an inflammation of the liver caused by a viral infection. Hepatitis may be an acute or chronic disease. Acute hepatitis is rapid in onset and, if untreated, may develop into chronic hepatitis. The most frequently diagnosed causative organisms are hepatitis A virus (HAV), hepatitis B virus (HBV), and hepatitis C virus (HCV). A lesser known type is hepatitis D virus (HDV). Hepatitis E (HEV) occurs primarily in developing countries and is rarely seen in the United States (CDC, 2012a). In 2012, the incidence of hepatitis A declined to 0.5 cases per 100,000 in the United States. The incidence of hepatitis B has also decreased remarkably during the past several years with an incidence of 0.9 cases per 100,000 in 2012 (CDC, 2014c). The decline in both of these illnesses is related to routine vaccine administration, especially in children.

ETIOLOGY AND PATHOPHYSIOLOGY

Hepatitis A is highly contagious and traditionally has been called *infectious hepatitis*. Infection occurs primarily through the fecal–oral route. Transmission is by direct person-to-person spread or through ingestion of contaminated water or food. Hepatitis A frequently occurs in children in childcare settings where hygiene practices are poor. Food handlers can spread hepatitis A if not aware of their infection; it is a common cause of foodborne illness. Because the virus is transmitted in the early stages of the disease when individuals are often asymptomatic or only mildly ill, large numbers of people may be exposed before the diagnosis is confirmed (Table 25–5). Most children recover from hepatitis A; however, in rare instances, acute liver failure may occur (Jensen & Balistreri, 2016).

Hepatitis B can result in acute or chronic infection and is transmitted by the parenteral route through the exchange of blood or any body secretion or fluids, sexual activity, and transmission from mother to fetus in utero (Peate & Jones, 2014). Adolescents who use intravenous drugs and have unprotected sexual intercourse are at risk for contracting hepatitis B. Major sources for the spread of HBV are healthy chronic carriers.

Hepatitis C is the most common chronic bloodborne infection in the United States. The hepatitis C virus is transmitted primarily through intravenous drug use, needlestick injury, and birth to a mother infected with hepatitis C. The virus can also be spread through blood transfusions, but the incidence of this route of transmission in the United States is rare because blood

TABLE 25–5 Comparison of Hepatitis Types

TYPE	IMMUNIZATION AVAILABLE	PROPHYLAXIS	PRIMARY TRANSMISSION	INCUBATION PERIOD
Hepatitis A	Yes	Immune globulin Hepatitis A vaccine	Fecal–oral	15–19 days
Hepatitis B	Yes	Hepatitis B immune globulin Hepatitis B vaccine	Needlesticks or sharps exposure Intravenous drug use During birth Sexual activity	60–180 days
Hepatitis C	No	None	Needlesticks or sharps exposure Intravenous drug use During birth	14–160 days
Hepatitis D	No	Hepatitis B vaccine	Needlesticks or sharps exposure Intravenous drug use During birth Sexual activity	21–42 days
Hepatitis E	No	None	Fecal–oral	21–63 days

Source: Data from Centers for Disease Control and Prevention (CDC). (2012a). *Hepatitis E information for health professionals*. Retrieved from http://www.cdc.gov/hepatitis/HEV/index.htm; CDC. (2012b). *Hepatitis B information for health professionals*. Retrieved from http://www.cdc.gov/hepatitis/HBV/index.htm; CDC. (2014d). *Hepatitis A information for health professionals*. Retrieved from http://www.cdc.gov/hepatitis/HAV/index.htm; CDC. (2014e). *Hepatitis C information for health professionals*. Retrieved from http://www.cdc.gov/hepatitis/HCV/index.htm; CDC. (2014f). *Hepatitis D information for health professionals*. Retrieved from http://www.cdc.gov/hepatitis/HDV/index.htm; Jensen, M. K., & Balistreri, W. F. (2016). Viral hepatitis. In R. M. Kliegman, B. F. Stanton, J. W. St. Geme III, & N. F. Schor (Eds.), *Nelson textbook of pediatrics* (20th ed., pp. 1942–1953). Philadelphia, PA: Elsevier Saunders.

is screened for this infection. Chronic infection occurs in 75% to 85% of those individuals infected with hepatitis C (CDC, 2014e).

Hepatitis D (delta virus) is a defective virus that can gain entry to a human only in connection with hepatitis B (CDC, 2014f). It can occur as a coinfection along with hepatitis B or as a superinfection in someone already infected with hepatitis B.

Hepatitis E infection is primarily transmitted through contaminated water and is most common in developing countries (Jensen & Balistreri, 2016).

The liver's response to injury by the viruses that cause hepatitis is similar (see *Pathophysiology Illustrated: Viral Hepatitis*). Initially, invasion of the parenchymal cells by the virus results in local degeneration and necrosis. Subsequent infiltration of the parenchyma by lymphocytes, macrophages, plasma cells, eosinophils, and neutrophils causes inflammation that heblocks biliary drainage into the intestine. Impaired bile excretion causes a buildup of bile in the blood, urine, and skin (jaundice). Structural changes in the parenchymal cells account for other altered liver functions.

CLINICAL MANIFESTATIONS

Symptoms of acute viral hepatitis infection include nausea, vomiting, fatigue, abdominal pain, joint pain, pruritus, and urticaria in the prodromal phase. In the icteric phase, the child develops jaundice, gray- or pale-colored bowel movements, gastrointestinal symptoms, right upper quadrant pain, and malaise. In the convalescent phase the jaundice resolves and laboratory values return to normal (Buggs, 2014; CDC, 2012c).

CLINICAL THERAPY

Diagnosis is often made on the basis of a thorough history and physical examination. A history of exposure to persons with the disease is significant. Physical examination reveals a tender, enlarged liver. Laboratory evaluation includes serologic testing (to detect the presence of antigens and antibodies to HAV, HBV, HCV, or HDV) liver function studies, serum bilirubin, and prothrombin time (Harris & Crawford, 2013; Jensen & Balistreri, 2016).

Early diagnosis is essential to follow the course of the illness and identify potential complications. Management includes bed rest, hydration, and adequate nutrition.

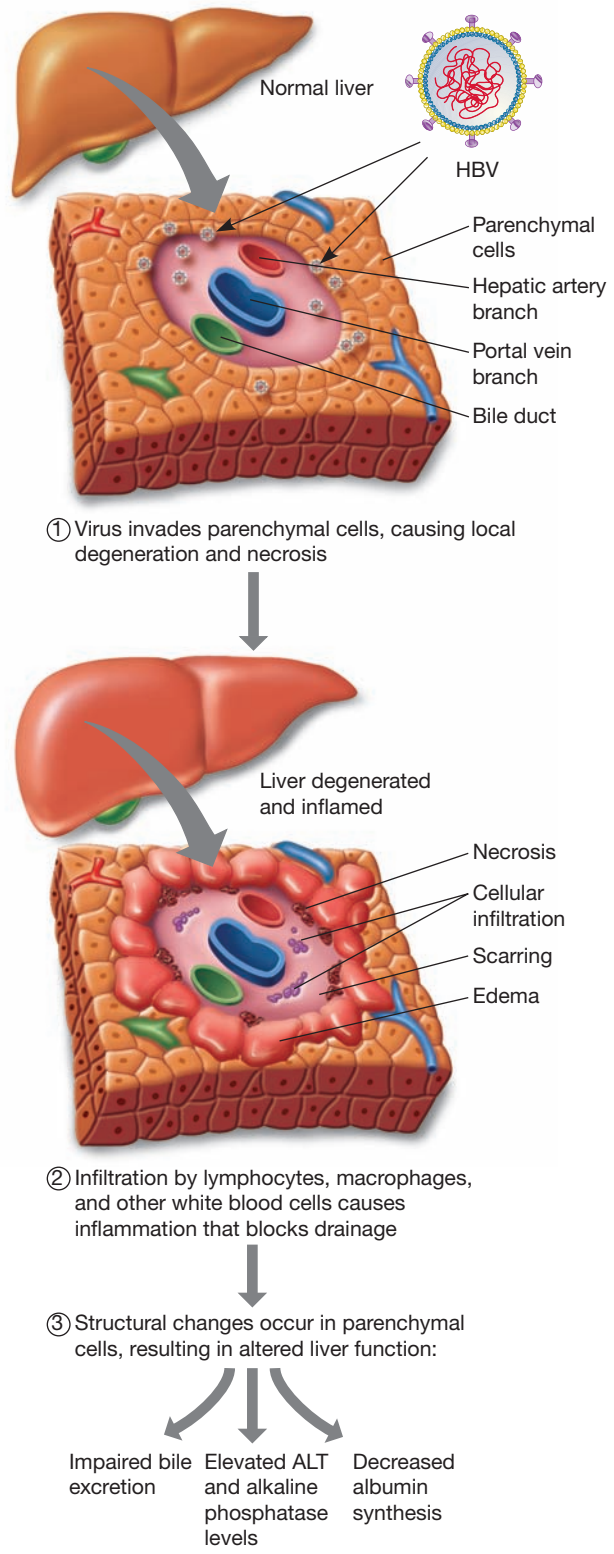
The spread of viral infections can be interrupted by elimination of the virus from the infected population, institution of proper hygiene, and passive or active immunization. To date, no antiviral agent has been developed to combat the hepatitis viruses. Prevention depends on breaking the cycle of infection.

Active immunization for hepatitis A, a two-dose series, is recommended for all people at increased risk of acquiring infection, for children, and for those who wish to acquire immunity to the illness. The CDC (2012c) recommends that all children receive the first hepatitis A vaccine at 1 year of age.

Hepatitis B immune globulin (HBIG) and the hepatitis B vaccine must be given to infants born to infected mothers within 12 hours of birth to provide protection against the virus. Administration of the first dose of the three-dose series of the hepatitis B vaccine shortly after birth to all infants further reduces the risk of perinatal infection in cases where the mother's status may be unknown or incorrectly documented (CDC, 2012b). (Chapter 16 provides specific information on immunization schedules.)

Individuals who have been exposed to hepatitis A and have not been previously immunized should receive immune globulin or the hepatitis A vaccine within 2 weeks of exposure. Healthy individuals, ages 12 months to 40 years of age, not previously immunized may receive the hepatitis A vaccine instead of immune globulin within 2 weeks of exposure (CDC, 2014d). Passive immunity to HBV can be achieved with hepatitis B immune globulin (HBIG). Used for one-time exposure and for infants of infected mothers, it is given within 12 hours after birth (CDC, 2012b).

Pathophysiology Illustrated: **Viral Hepatitis**



The hepatitis virus causes degeneration and necrosis of the liver, which results in abnormal liver function and illness.

Nursing Management

For the Child With Viral Hepatitis

Nursing Assessment and Diagnosis

The nurse usually encounters the child and family in an outpatient setting. In addition to observing the child for characteristic signs of hepatitis (jaundiced skin and sclera), assess for abdominal pain, anorexia, nausea and vomiting, malaise, and arthralgia. A history of the child's contacts in the past several weeks is also obtained. For an infant, the hepatitis history of the mother and other family members is important.

Common nursing diagnoses for the child with acute hepatitis might include the following (NANDA-I © 2014):

- ***Nutrition, Imbalanced: Less than Body Requirements,*** related to chronic illness
- ***Fatigue*** related to disease state
- ***Body Image, Disturbed (Older Child),*** related to jaundice
- ***Anxiety (Parent and Child)*** related to threat to health status

Planning and Implementation

Nursing care involves home and community considerations because children with hepatitis are seldom admitted to the hospital. The hospitalized child is placed in isolation. Prevention of the disease is integrated into all health care by discussion of immunization and standard precautions. Parents need additional detailed information about health precautions and infection control measures if hepatitis cases have occurred in the family or community. Teach parents the importance of checking with health professionals before administering any medications (even nonprescription medicines). Also teach them to maintain adequate nutrition, promote rest and comfort, and provide diversional activities.

PREVENT SPREAD OF INFECTION

Teach the parents and the child infection control measures to help prevent transmission of the virus. For parents, reinforce good hygiene practices, such as washing hands before and after toileting and proper disposal of soiled diapers. Vaccination for those exposed to hepatitis A or B should occur as discussed previously. All healthcare providers should receive the hepatitis B immunization series and use standard precautions at all times (see the *Clinical Skills Manual* SKILLS).

Clinical Tip

Nurses in childcare centers can provide assessment of the center's procedures and teaching to prevent hepatitis A transmission. Help the center to set standards about:

- Handwashing after each diaper change
- Proper disposal of diapers
- Cleaning diaper-changing surfaces after each diaper change
- Enforcing policy that food handlers never perform diaper changes
- Instructing parents to keep children at home for at least 2 weeks after a diagnosis of hepatitis A
- Informing parents of other children attending the childcare center when there is a case of hepatitis A and teaching them the symptoms of the condition

MAINTAIN ADEQUATE NUTRITION

Initially, the child is encouraged to eat favorite foods. Once the anorexia and nausea have resolved, a high-protein, high-carbohydrate, low-fat diet is recommended. Increased protein helps maintain protein stores and prevent muscle wasting. Increased carbohydrates ensure adequate caloric intake and prevent protein depletion. The use of low-fat foods lessens stomach distention. Offer the child small, frequent feedings.

PROMOTE REST AND COMFORT

Bed rest is necessary only if the child has severe fatigue and malaise. However, most children voluntarily limit their activities during the initial phase of the disease. Keep the child quiet and comfortable. Offer comfort items such as favorite toys, blankets, and pillows.

ADMINISTER MEDICATIONS

Drug metabolism is altered during hepatitis since the liver cannot detoxify medications readily. As with all liver disorders, medications need to be administered carefully, and the child's condition must be monitored for possible drug side effects, especially since so many drugs are metabolized by the liver. Caution parents to check with healthcare providers before giving any nonprescription medication. For example, acetaminophen is metabolized in the liver, and liver disease can interfere with its breakdown.

PROVIDE DIVERSIONAL ACTIVITIES

Hospitalized children with hepatitis are kept in isolation. Nonhospitalized children with hepatitis do not need to be isolated, but they should be kept at home for 2 weeks following the onset of symptoms. Parents who cannot take time off from work may need to arrange home sitters to stay with the child. Offer suggestions for diversional activities during this period. Young children can be given a new toy or favorite activities. Older children and adolescents can be given board games, puzzles, books or magazines, movies, or video games. Phone calls and short visits from friends help school-age children and adolescents maintain contact with peers.

Evaluation

Expected outcomes of nursing care for hepatitis include the following:

- The child demonstrates adequate nutritional intake to meet growth and development needs.
- The child participates in quiet, nonfatiguing activities and self-care.
- Positive body image is achieved.
- Parents demonstrate effective coping with the stress of the child's condition.
- Hepatitis is not spread to the child's contacts.

Cirrhosis

Cirrhosis is a degenerative disease process that results in fibrotic changes and fatty infiltration in the liver. It can occur in children of any age as the end stage of several disorders such as hepatitis and biliary atresia (Hassan & Balistreri, 2016; Squires & Balistreri, 2016). The diffuse destruction and regeneration of the hepatic parenchymal cells result in an increase in fibrous connective tissue and disorganization of the liver structure. Progressive scarring that occurs in cirrhosis leads to altered blood flow to the liver, which causes further deterioration of liver function (Squires & Balistreri, 2016).

Clinical manifestations of cirrhosis vary. Hepatomegaly may be evident on examination. Jaundice occurs as the disease progresses and is an indication of hyperbilirubinemia. Jaundice is sometimes the only sign of hepatic dysfunction, so its appearance must be investigated. Pruritus is common in children with cirrhosis, although it is not related to the degree of hyperbilirubinemia. Other clinical manifestations of cirrhosis in children include ascites, portal hypertension, encephalopathy, and variceal hemorrhage (Squires & Balistreri, 2016). Severe end-stage complications signaling hepatic failure can occur at any time and with little warning.

Diagnostic evaluation is based on the child's history of infection or disease with liver involvement. Physical examination may reveal jaundice, skin changes, ascites, and hemodynamic changes. Laboratory evaluation reveals abnormal liver function tests. A liver biopsy may help determine the extent of the parenchymal damage.

Medical management focuses on treating the child's symptoms and achieving optimal nutritional status and growth. Liver transplantation is the most common treatment for biliary atresia and metabolic disorders and is the only treatment for end-stage liver disease.

Nursing Management

Nursing care focuses on monitoring physiologic and psychosocial changes to identify early signs of end-stage hepatic failure. Monitor vital signs every 2 to 4 hours. Measure weight daily to assess for fluid retention. Close monitoring of electrolytes and liver function test results helps determine the need for fluid replacement therapy.

Careful administration of medications and monitoring for side effects are necessary because drug metabolism is altered in liver disorders. If ascites is present, provide a low-sodium, low-protein diet and restrict fluids. Remove all water pitchers, glasses, and straws to minimize the child's desire to drink.

Parents of a child with cirrhosis are coping with a life-threatening disorder, and their anxiety and stress are high. The child may be awaiting a liver transplantation that represents the only hope for recovery. Support parents and encourage them to talk about their fears and concerns (see Chapter 13). Encourage parents to participate in the child's care. Referral to a support group or counseling may be beneficial.

Injuries to the Gastrointestinal System

Refer to Chapter 17 for information related to injury to the GI system due to poisoning and ingestion of foreign objects.

Abdominal Trauma

Motor vehicle crashes, falls, and auto–pedestrian injury are the leading causes of blunt abdominal injury in children. Other causes include child abuse, all-terrain vehicle accidents, and bicycle accidents (Mendez, 2014). Although blunt trauma is most common, penetrating injury accounts for 10% to 20% of pediatric trauma admissions. Gunshot wounds are the most common cause of penetrating injury. Other causes include stabbing or impalement on an object (Daley, Raju, & Lee, 2013). Children are more likely than adults to sustain abdominal injuries because of their small pliable rib cage and less developed abdominal muscles, which provide little protection for major solid organs such as the spleen, liver, and kidneys. In addition, the solid organs in children are larger in proportion to their body size compared to adults, so less surface area of the organs is protected by the ribs, making them more exposed and vulnerable to injury (Daley et al., 2013; Mendez, 2014; Saxena, 2013).

The kind of injury determines the extent of organ damage. High-velocity blunt trauma, which may occur in motor vehicle crashes, usually involves multiple organs. Solid organs such as the liver and spleen can be bruised or lacerated. The sudden increase in abdominal pressure that occurs with a lap belt injury causes hollow organs such as the stomach, intestines, and bladder to burst. Sports-related abdominal trauma is often associated with a direct blow to the abdomen, and a single organ is usually injured. Bicycle accidents account for 5% to 14% of blunt abdominal trauma in children. Serious abdominal injury can result if the handlebars hit the child in the abdomen (Alkan et al., 2012; aCevek, Boleken, Sogut, et al., 2013).

Penetrating trauma is generally apparent upon inspection. Blunt trauma may not be as obvious. The abdomen should be inspected for abrasions, bruising, or markings (e.g., tire tracks or lap belt marks) that provide a clue to injury beneath the skin surface (Mendez, 2014). Abrasions, erythema, and ecchymosis in the lower abdominal area are classic visible signs of seat belt trauma (Borgialli et al., 2014). See Chapter 5 for abdominal assessment techniques. Additional clinical manifestations of abdominal injury include pain and tenderness, abdominal distention, and signs of hypovolemic shock such as pallor, altered mental status, hypotension, and tachycardia (Wesson, 2013).

Suspected abdominal trauma in a child necessitates a thorough history and physical examination. The description of the event should be compared with the child's signs and symptoms. Plain abdominal radiographs may reveal air in the abdomen. A focused abdominal ultrasound can reveal free fluid in the abdomen. An abdominal CT scan identifies a solid organ injury. Urinalysis that shows blood in the urine may be indicative of damage to the urinary tract or kidneys (McKenna & Pieper, 2013). Serial hemoglobin and hematocrit evaluation is essential to determine hemodynamic stability. Type and cross-match of blood is also necessary in case the child needs a blood transfusion. In addition, liver function tests and pancreatic enzymes are monitored in the case of injury to the liver and pancreas (Saxena, 2013).

SAFETY ALERT!

The child who is restrained in a motor vehicle with only a lap belt is at high risk for abdominal injury in a crash. As the car stops rapidly, the child's body is restrained and flexes around the lap belt. The sudden increase in abdominal pressure causes injury to hollow organs, and sometimes solid organs. Children no longer using car safety seats should sit in a booster seat so that a shoulder restraint is used in addition to the lap belt. A booster seat should be used until the child is 8 years of age or weighs at least 80 lb.

The spleen and the liver are the organs most commonly injured in blunt abdominal trauma. Nonsurgical management is preferred. The spleen plays a major role in immune function; therefore, the organ is salvaged whenever possible to decrease the risk of infection (Saxena, 2013). Liver lacerations are treated much like spleen lacerations as long as major vessels have not been injured. Exploratory laparotomy is performed to resect hollow organ injuries or to repair liver or spleen lacerations when bleeding is not controlled.

Treatment of an abdominal, liver, or spleen injury takes place in the pediatric intensive care unit (PICU) and focuses on preventing or managing hemorrhage and monitoring for signs of shock. An intravenous infusion is initiated for fluid maintenance and to provide access for blood products. The child is kept NPO. A nasogastric tube is inserted. Blood transfusions and pharmacologic management are used to treat blood loss.

The child is maintained on strict bed rest until bleeding is controlled and the hemoglobin and hematocrit are stable. The length of time the child is hospitalized ranges from 2 to 5 days depending on the severity of the injury. The length of time for activity restrictions after discharge ranges from 3 to 6 weeks and also depends on the severity of the injury (McKenna & Pieper, 2013).

Nursing Management

Nursing care includes initial and ongoing assessments of the child's condition. Assess the abdomen for bruising, pain, guarding, rebound tenderness, distention, and obvious signs of injury such as bruising. Monitor hematocrit and vital signs every hour as warranted to detect hypovolemia (see Chapter 21). Tachycardia and hypotension may indicate hypovolemia or internal bleeding. Strict monitoring of intake and output will provide information about the child's fluid status. Monitor the respiratory status because abdominal injuries may also have thoracic involvement. The child with associated thoracic injuries may not take deep breaths if it is painful.

The child and parents are usually fearful and anxious when the child is admitted to the hospital. If the injury was preventable, parents may have feelings of guilt or anger. Provide emotional support and avoid judgmental comments or statements that assign blame. Additional nursing care includes maintenance of the nasogastric tube, intravenous fluids, and blood, and monitoring of lab studies as appropriate. Any concerns should be reported to the healthcare provider immediately.

Once the child's condition is stabilized, the focus of nursing care shifts to preventive teaching. Parents should be taught safety measures to prevent future injuries. Discuss the use of car safety restraint devices for riding in an automobile (see Chapters 7, 8, and 9). If the child's injury was the result of a bicycle fall or crash, discuss the importance of the proper bicycle size and safety measures such as use of a helmet and proper use of hand signals.

Chapter Highlights

- A variety of structural defects caused by fetal development alterations can affect the gastrointestinal system of infants.
- Cleft lip and palate are structural defects that often involve care by a team of healthcare providers such as a plastic surgeon, pediatrician, nurse, audiologist, speech therapist, and orthodontist.
- A variety of defects of the esophagus and trachea can manifest as mild to life-threatening problems in the newborn period.
- Pyloric stenosis is a common cause of projectile vomiting in the newborn period.
- Gastroesophageal reflux is one of the most common gastrointestinal problems in infants and children.
- Abdominal wall defects and anorectal malformations are serious structural defects of infancy.
- Intussusception is one of the most common causes of intestinal obstruction in the pediatric population and primarily occurs in children less than 1 year of age.
- Hirschsprung disease, or aganglionic megacolon, leads to failure to pass normal stools and distention of the abdomen.
- Several of the intestinal problems of childhood necessitate temporary or permanent ostomy placement.
- Hernias can be present in the diaphragmatic area, umbilicus, or inguinal canal.
- The most common inflammatory disorder of the gastrointestinal tract is appendicitis.
- Necrotizing enterocolitis is a potentially life-threatening inflammatory disease of the intestines seen primarily in premature infants after enteral feedings are begun.
- Common inflammatory bowel diseases affecting primarily adolescent and young adult age groups are Crohn disease and ulcerative colitis.
- Peptic ulcers occur primarily in individuals receiving nonsteroidal anti-inflammatory drugs and those with *Helicobacter pylori* infection.
- Common disorders of motility include diarrhea, constipation, and encopresis.
- Gastroenteritis and parasitic disorders are common causes of gastrointestinal disturbance and distress in children, and may lead to fluid and electrolyte imbalance.
- Short bowel syndrome occurs when surgery is used to treat an intestinal disease and significant sections of the bowel are removed.
- Biliary atresia and hepatitis are the most common liver diseases in young children.
- Abdominal trauma most often occurs to children involved in motor vehicle crashes.

Clinical Reasoning in Action

Four-year-old Jenna has just been admitted to the pediatric unit following surgery for a perforated appendix. She complained of her stomach hurting last night, but this morning her condition was worse and she had a temperature of 102°F. Worried that this was not just a virus, Jenna's mother took her to the pediatrician. On the way to the doctor's office Jenna told her mother that her pain "just went away." While at the pediatrician's office she complained of feeling bad all over. On examination, her abdomen was rigid and no bowel sounds were heard. A complete blood count revealed a white blood count (WBC) of 22,000/mm^3. The pediatrician diagnosed that Jenna had appendicitis and most likely had a perforated appendix. He referred Jenna to the emergency department for assessment and surgical consultation. A CT scan confirmed a diagnosis of appendicitis. During surgery the appendix was found to have perforated.

Jenna had a laproscopic appendectomy. A dry dressing is in place. She has a peripherally inserted central catheter (PICC) line for fluids, pain medication, and intravenous antibiotics. She also has a nasogastric tube to suction and a Foley catheter.

Jenna's parents are anxious about the surgery. They feel guilty that Jenna became ill so quickly and wonder if they could have done something to prevent it. This is Jenna's first hospitalization. They are worried that she will have a lot of pain and wonder how she will cope with the hospitalization.

1. What is the priority of nursing care for Jenna in the immediate postoperative period?
2. What should the nurse include when teaching Jenna's parents about the postoperative course?
3. Jenna's parents ask why she needs all of the tubes. What information should the nurse include related to the purpose of the nasogastric tube, the Foley catheter, and the central line?
4. Create a concept map for Jenna based on postoperative management of a 4-year-old with a perforated appendix. Include nursing interventions related to fluid and electrolyte balance, pain management, prevention of pulmonary complications, treatment of infection, and developmental and psychosocial care.

Chapter 26
Alterations in Genitourinary Function

Amos Morgan/Getty Images

Planning Terrell's day can be a challenge, because his treatment often interferes with his activities. We all hope that Terrell receives a kidney transplant soon so his growth will improve and he will not have to miss school during treatment.

—Aunt of Terrell, 5 years old

Learning Outcomes

26.1 Describe the pathophysiologic processes associated with genitourinary disorders in the pediatric population.

26.2 Develop a nursing care plan for the child with a urinary tract infection.

26.3 Discuss the nursing management of a child with a structural defect of the genitourinary system.

26.4 Outline a plan to meet the fluid and dietary restrictions for the child with a renal disorder.

26.5 Identify growth and developmental issues for the child with chronic renal failure.

26.6 Plan nursing care for the child with acute and chronic renal failure.

26.7 Summarize psychosocial issues for the child requiring surgery on the genitourinary system.

Many infections, structural disorders, and disease processes alter genitourinary function. Because the kidneys and other urinary system organs perform several essential body functions, including removal of waste products and maintenance of fluid and electrolyte balance, disorders that affect these organs pose a significant threat to the health of children.

Although the reproductive system is functionally immature until puberty, uncorrected structural defects can have both psychologic and physiologic implications for the developing child.

Urinary Tract Infection

An infection of the urinary tract may be of bacterial, viral, or fungal origin, and can occur in the lower or upper urinary tract. Cystitis is a lower urinary tract infection (UTI) that involves the urethra or bladder. Pyelonephritis is an upper UTI that involves the ureters, pelvis, and renal parenchyma. UTIs can be acute or chronic (the latter being either recurrent or persistent).

Urinary tract infections are very common in children, with 8% of girls and 2% of boys having at least one UTI by 7 years of age (White, 2011). It is further estimated that 1% of boys and 3% to 5% of girls will have a UTI during childhood and 30% to 50% of them will have at least more than one UTI (Paintsil, 2013).

Etiology and Pathophysiology

Most UTIs in children are caused by *Escherichia coli*, a common gram-negative enteric bacterium (White, 2011). Urinary stasis enhances the risk of UTI. Stasis may be caused by abnormal anatomic structures or abnormal function (e.g., **neurogenic bladder** in which an interrupted nerve supply from myelomeningocele or spinal cord trauma impairs the bladder's voiding function and leads to incomplete bladder emptying). Children normally void 5 to 6 times

Text continues on page 704

FOCUS ON:
The Genitourinary System

Anatomy and Physiology

The genitourinary system is made up of the urinary and reproductive organs. The urinary system—kidneys, ureters, bladder, and urethra—excretes wastes and maintains acid–base and fluid and electrolyte balance (Figure 26–1). The reproductive system consists of internal and external organs that at maturity promote the conception and healthy development of a fetus. Normal renal function requires the following: unimpaired renal blood flow, adequate glomerular ultrafiltration, normal tubular function, and unobstructed urine flow.

The functional unit of the kidney, the nephron, contributes to the formation of urine. The nephron is a tubular structure containing the renal corpuscle, proximal convoluted tubule, loop of Henle, distal convoluted tubule, and collecting duct. The renal corpuscle is composed of the glomerulus (a small group of capillaries) that loops into the Bowman capsule (Figure 26–2). The glomerular capillaries serve as the filtration membrane where metabolic wastes and fluids are separated from the blood cells and plasma proteins to form the urine. The kidney maintains the rate of blood flow to keep the glomerular filtration rate fairly constant. The urine flows through the proximal convoluted tubule, the loop of Henle, and into the distal convoluted tubule and collecting duct. Water, sodium, potassium, glucose, amino acids, bicarbonate, urea, hydrogen ions, and ammonia ions are among substances reabsorbed or secreted in the tubules.

The presence of antidiuretic hormone (ADH) secreted by the posterior pituitary gland causes more water reabsorption, leading to urine concentration. Absence of ADH leads to dilute urine. See Chapter 18 for more information about fluid and electrolyte physiology.

Urine from the nephron flows into the calyces in the renal pelvis and is funneled into the ureters. The lower end of the ureters connects into the posterior aspect of the bladder. The muscle cells of the ureters move urine to the bladder by peristalsis. Urine collects in the bladder until the internal urethral sphincter relaxes and allows urine to pass into the urethra. Voluntary control of the external urethral sphincter is gained as the child's nervous system matures. Contraction of the bladder during urination compresses the lower end of the ureter and prevents the reflux of urine back into the ureter.

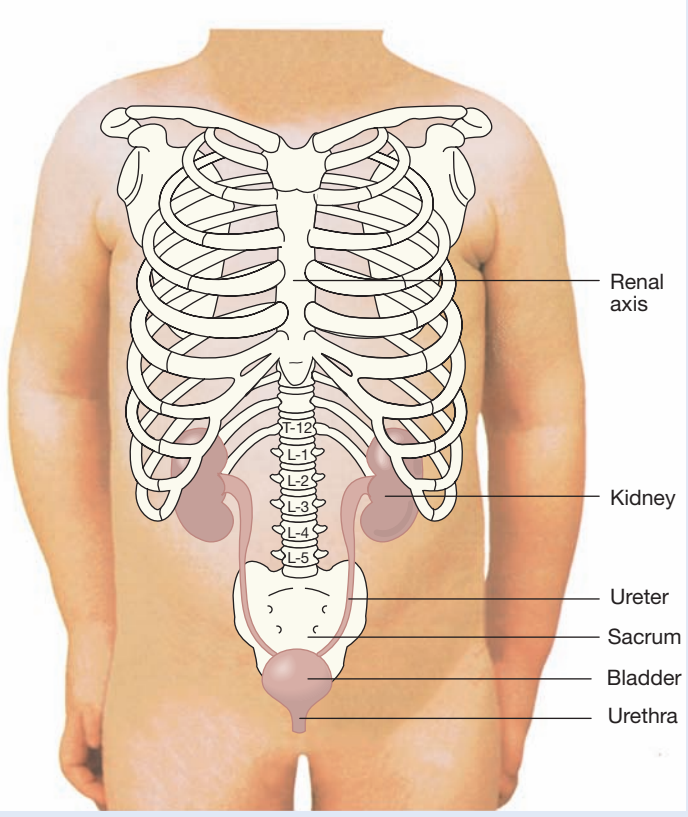

Figure 26–1 The urinary system is composed of the kidneys, ureters, bladder, and urethra. The kidneys are located between the twelfth thoracic (T12) and third lumbar (L3) vertebrae.

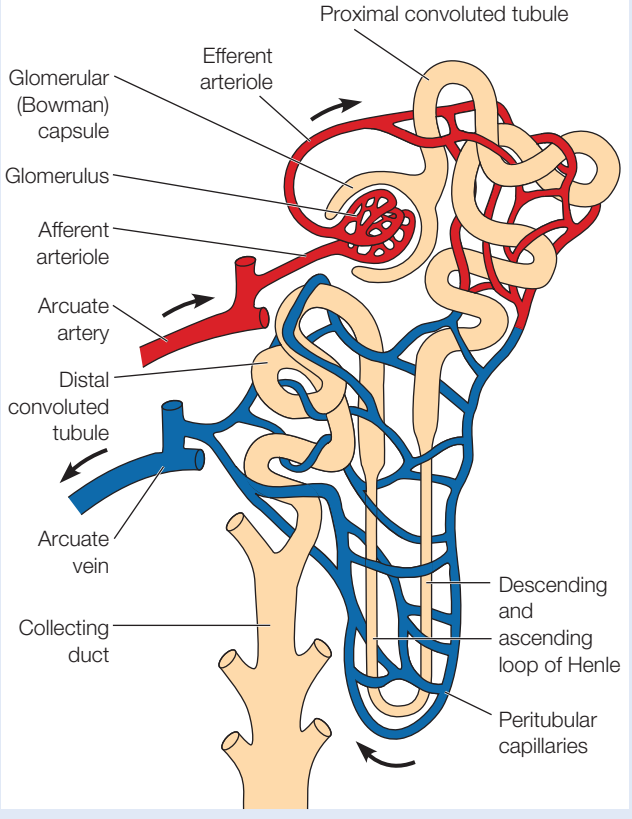

Figure 26–2 The nephron is the structural and functional unit of the kidneys. A nephron holds six glomeruli, Bowman capsule, proximal tubule, loop of Henle, distal tubule, and the collecting duct.

The kidney is essential in activating vitamin D, which is needed for the absorption of calcium and phosphorus from the small intestine. The kidney secretes erythropoietin to stimulate the bone marrow to produce red blood cells. The renin-angiotensin system of the kidney is a hormonal regulator that can increase the systemic blood pressure.

The male reproductive system is composed of the testes and scrotum, penis, prostate, and vas deferens, which drains into the urethra. The testes produce the primary male sex hormone, testosterone. The testes produce sperm after puberty.

The female reproductive system is composed of the ovaries, fallopian tubes, uterus, and vagina. The ovaries produce the primary female sex hormone, estrogen. Beginning between 8 and 12 years of age, the ovaries produce increasing amounts of sex hormones to initiate puberty and sexual maturation. After puberty, the ovaries produce the ovum that may be fertilized by the sperm during its passage through the fallopian tube into the uterus. Complex hormonal factors are involved in puberty, the menstrual cycle, and pregnancy.

Pediatric Differences

Urinary System

All the nephrons that will make up the mature kidney are present at birth. The kidneys grow and the tubular system matures gradually during childhood, reaching full size by adolescence. Most renal growth occurs during the first 5 years of life. This increase in size is due primarily to enlargement of the nephrons. The kidney's efficiency also increases with age. During the first 2 years of life, the kidneys are less efficient at regulating electrolyte and acid–base balance (see Chapter 18) and eliminating some drugs from the body. After the age of 2 years, the kidneys' efficiency markedly increases. Urinary output per kilogram of body weight decreases as the child ages, because the kidney becomes more efficient at concentrating urine. The expected output is as follows:

- Infants—2 mL/kg/hr
- Children—0.5 to 1 mL/kg/hr
- Adolescents—40 to 80 mL per hour

Bladder capacity increases with age from 20 to 50 mL at birth to 700 mL in adulthood. A child's bladder capacity (in ounces) can be estimated by adding 2 to the child's age (e.g., a 4-year-old has a bladder capacity of 6 ounces). Stimulation of "stretch receptors" within the bladder wall initiates urination. Simultaneous contraction of the detrusor muscle of the bladder and relaxation of the internal and external sphincters result in emptying of the bladder. Children less than 2 years of age cannot maintain bladder control because of insufficient nerve development (see *As Children Grow: Development of the Genitourinary System*).

As Children Grow: **Development of the Genitourinary System**

Pollock (Eds.), *Schwartz's principles of surgery* (10th ed.). Retrieved from http://www.accessmedicine.com

(*continued*)

Reproductive System

Throughout childhood the genitalia (with the exception of the clitoris in girls) enlarge gradually. The hormonal changes of puberty accelerate anatomic and functional development (see Chapter 5 for figures illustrating pubertal development). In girls, the mons pubis becomes more prominent, and hair begins to grow. The vagina lengthens, and the epithelial layers thicken. The uterus and ovaries enlarge, and the musculature and vascularization of the uterus also increase. In boys, downy hair begins to appear at the base of the penis, and the scrotum becomes increasingly pendulous as the testes enlarge. The penis increases in length and width.

Use *Assessment Guide: The Child With a Genitourinary Condition* to perform a nursing assessment of the genitourinary system. A list of diagnostic and laboratory tests commonly used to evaluate genitourinary conditions is provided in Table 26–1. See Appendices D and E for expected laboratory values and further information about specific diagnostic procedures.

TABLE 26–1 Diagnostic Tests and Laboratory Procedures for the Genitourinary System

DIAGNOSTIC PROCEDURES	LABORATORY TESTS
Computed tomography (CT)	Blood urea nitrogen (BUN)
Cystoscopy	Creatinine
Diuretic renogram (a type of nuclear scan)	Creatinine clearance
Intravenous pyelogram	Basic metabolic panel (electrolytes)
Magnetic resonance imaging (MRI)	Urinalysis
Radionucleotide renal scan with dimercaptosuccinic acid (DMSA)	Urine culture
Renal biopsy	Urine protein-to-creatinine ratio
Renal or bladder ultrasound	
Voiding cystourethrogram (VCUG) or radionuclide cystography	

Note: See Appendices D and E for information about these diagnostic procedures and tests.

ASSESSMENT GUIDE | The Child With a Genitourinary Condition

Assessment Focus	Assessment Guidelines
Urine characteristics	• Does the urine have a strong odor, a dark or unusual color, or appear cloudy?
Pain or discomfort	• Is there pain or burning with urination? • Is there flank or abdominal pain? • Is there scrotal or testicular pain?
Edema	• Is there generalized edema?
Appearance of genitalia	• What is the location of the urethra on the glans penis? • Is the scrotum large or underdeveloped? Are rugae present? Are testes palpable in the scrotum? • Do the genitalia have characteristic male or female appearance, or are the genitalia ambiguous? • Is there vaginal or urethral discharge? • Are there lesions on the genitalia?
Sexual development	• What is the stage of pubertal development? (See Figures 5–28, 5–29, and 5–30.)

a day. Infrequent voiding, common in school-age children, results in incomplete emptying of the bladder and urinary stasis. Other factors associated with increased risk of UTI include poor hygiene, inadequate cleansing after bowel movements, and an irritated perineum. Uncircumcised males have a higher incidence of UTIs than circumcised males (Dubrovsky, Foster, Jednak, et al., 2012). This increased incidence is highest in the first year of life (Morris & Wiswell, 2013). Constipation in children and sexual activity in adolescent females also contribute to the incidence of UTI in the pediatric population (Fisher et al., 2014). **Vesicoureteral reflux**, the backflow of urine from the bladder into the ureters during voiding, is another cause of UTI and is discussed later in this chapter.

Growth and Development

Urinary tract infections are more common in males than females in the first few months of life. It is estimated that the incidence of UTI in uncircumcised males during the first year of life is 7 to 14 of 1000 as compared to 1 to 2 of 1000 circumcised infants (American Academy of Pediatrics Task Force on Circumcision, 2012). By 1 year of age, the incidence of UTI is much higher in females than males (Fisher et al., 2014). This is related to the shorter female urethra (2 cm [1 in.] in young girls) being closer to the anus and vagina, which increases the risk of contamination by fecal bacteria.

Renal scarring can result from pyelonephritis because of the ischemic effects of infection. It has been associated with hypertension and chronic renal failure (White, 2011). The risk of renal damage increases in the following instances:

- UTI in infant less than 1 year of age
- Delay in diagnosis and effective antibacterial treatment for an upper UTI
- Anatomic obstruction or nerve supply interruption
- Recurrent episodes of upper UTIs

Clinical Manifestations

Symptoms depend on the location of the infection and the age of the child. Symptoms in the newborn period tend to be nonspecific (e.g., unexplained fever, hypothermia, failure to thrive, poor feeding, vomiting and diarrhea, strong-smelling urine, and irritability). Any child under 2 years of age with a fever of unknown origin should be tested for a UTI. The more "classic" symptoms of lower UTI are not seen until the preschool years, as listed in Table 26–2. Many UTIs are asymptomatic and are discovered incidentally on routine examination.

Clinical Therapy

A urine specimen is examined for the presence of bacteria. Dipsticks can be used to screen for urinary tract infection. A dipstick-positive leukocyte esterase test identifies white blood cells and pyuria, and a positive nitrite dipstick detects gram-negative bacteria. The UTI is diagnosed when a midstream clean-catch urine culture yields greater than 100,000 colony-forming units (cfu) of a single bacterium, or when greater than 10,000 cfu of a single bacterium are cultured from a sterile catheterized specimen (Ammenti et al., 2012). See the *Clinical Skills Manual* SKILLS for urine collection methods. Once the presence of bacteria is confirmed, antibiotic sensitivity for the specific organisms cultured is then determined. Urinalysis reveals white blood cells (WBCs) in the urine. A complete blood count reveals an elevated WBC count. A renal ultrasound is recommended after the first urinary tract infection with fever to rule out structural abnormalities (Newman, 2011). A voiding cystourethrogram (VCUG) may be obtained to test for vesicoureteral reflux if the ultrasound results are abnormal or the child has recurrence of a urinary tract infection with fever (Fisher et al., 2014).

Antibiotic therapy is begun as soon as urine samples have been collected. Antibiotics are selected based on the age of the child, sensitivity of the cultured organism, and the child's signs and symptoms. The antibiotic is changed, if necessary, after culture sensitivity is determined. Routine antibiotic prophylaxis is no longer recommended after the first urinary tract infection in infants and children (Paintsil, 2013).

Table 26–1 lists diagnostic tests commonly used to identify urinary tract conditions.

Clinical Tip

Several procedures are available for evaluation of kidney and bladder function. It is important for the patient and family to understand the procedure. Examples of these procedures and their purpose include:

- *Renal ultrasound*—Noninvasive procedure that uses sound waves to visualize the kidneys, ureters, and bladder. Renal ultrasound is useful in determining the size and shape of the kidneys, blood flow to the kidneys, signs of injury or damage, blockage, tumors, or kidney stones.
- *Voiding cystourethrogram*—Determines if there is reflux of urine into the ureters (see the discussion of vesicoureteral reflux later in this chapter). A catheter is placed prior to the procedure so that the bladder may be filled with dye. Radiographs are used to visualize the bladder during the procedure and see if dye moves into the ureters.

Children who appear ill and cannot tolerate oral antibiotics are often hospitalized because they need rehydration and initiation of parenteral antibiotic treatment until afebrile for 24 hours. Infants may develop permanent kidney damage or generalized sepsis if a UTI is not treated aggressively. If a structural defect is identified, surgical correction may be necessary to prevent recurrent infections that could lead to renal damage.

Children treated on an outpatient basis should receive follow-up by phone (or in person if needed) within 24 to 48 hours to validate the child's response to treatment and to make changes to the treatment plan, if needed, based on urine culture sensitivities. A follow-up visit 7 to 10 days after the initiation of treatment is important to see how the patient responded to treatment (Fisher et al., 2014).

Nursing Management

For the Child With Urinary Tract Infection

Nursing Assessment and Diagnosis

PHYSIOLOGIC ASSESSMENT

Obtain a history of urinary symptoms. Assess the infant for toxic (very ill) appearance, fever, and poor feeding. Evaluate the child's oral fluid intake. Assess for quality, quantity, and frequency of voiding. Assess the infant's or child's vital signs, including blood pressure. Palpate the abdomen and suprapubic and costovertebral areas for masses, tenderness, and distention. Assess for abdominal or flank pain, frequency, urgency, and dysuria. Observe the urinary stream, if possible, and perform a urinalysis,

TABLE 26–2 Clinical Manifestations of Urinary Tract Infection

TYPE OF UTI	CLINICAL MANIFESTATIONS
Lower UTI—cystitis	
Infants	Fever, diarrhea, vomiting, irritability, lethargy, foul-smelling diapers, poor feeding, failure to gain weight
Preschooler	Fever, hematuria, urgency, dysuria, frequency, cloudy urine, foul-smelling urine, dehydration, abdominal pain, enuresis
School-age	Fever, hematuria, urgency, dysuria, frequency, cloudy urine, foul-smelling urine, dehydration, abdominal pain, suprapubic or flank pain, enuresis
Upper UTI—pyelonephritis	High fever, chills, abdominal pain, nausea, vomiting, flank pain, costovertebral angle tenderness, moderate to severe dehydration

including specific gravity. Proper collection of the urine specimen is essential. Obtain a clean-catch urine specimen if the child is old enough to do this. If not, get a catheterized sample (see the *Clinical Skills Manual* SKILLS). An early morning urine specimen is preferred because the urine is more concentrated.

PSYCHOSOCIAL ASSESSMENT

Sexually active adolescents may deny having symptoms of a UTI because they fear disclosing their sexual activity to their parents. Careful questioning and a visit alone with the adolescent may be necessary to elicit these concerns. Be open and approachable and give the patient and family the chance to address their concerns.

Common nursing diagnoses for the child with a UTI include the following (NANDA-I © 2014):

- ***Urinary Elimination, Impaired,*** related to recurrent urinary tract infections
- ***Urinary Retention*** related to infrequent voiding habits or vesicoureteral reflux
- ***Health Management, Family, Ineffective,*** related to lack of knowledge of preventive UTI measures
- ***Fluid Volume: Deficient, Risk for,*** related to fever and inadequate intake

Planning and Implementation

Nursing care for the hospitalized child with a complicated UTI centers on administering prescribed medications, promoting rehydration, assessing renal function, and teaching parents and older children how to minimize the risk of future infection.

Administer antibiotics and antipyretics as prescribed to maintain therapeutic drug levels and reduce fever. Encourage fluid intake to dilute the urine and flush the bladder. Frequent voiding minimizes urinary stasis. Document intake and output. Assess renal function by comparing the child's output to the expected urine output and weigh the child daily.

Because bladder training is such an important milestone for young children, any disorder that affects voiding may have developmental implications. A toddler who has been toilet trained may regress and require diapers temporarily as a result of UTI-related incontinence. An older child may develop enuresis after a prolonged period of being dry at night. Reassure parents that this is normal and emphasize that the child needs support. A preschooler may perceive the infection and any parental disapproval as punishment for an imagined wrong.

DISCHARGE PLANNING AND HOME CARE TEACHING

Children with UTIs are usually cared for at home. Teach parents that all doses of the antibiotic must be taken as prescribed and that they may be continued even after the infection has cleared to prevent a recurrence. Teach prevention through proper hygiene and avoidance of risk behaviors.

Give parents specific guidelines for oral fluid intake. Make sure the amount of fluids recommended for a 24-hour period equals the maintenance fluids needed plus additional fluids required because of fever and diuresis to flush out pathogens (see Chapter 18). Suggest that the parents avoid giving the child caffeinated and carbonated beverages because these have the potential to irritate the bladder mucosa. Teach parents the signs and symptoms of recurrent infection and to seek care promptly.

The child with a neurogenic bladder requires a clean intermittent catheterization to be performed several times a day to reduce urinary stasis and the potential for UTI. Although the procedure for inserting the catheter is the same as that for catheterization using sterile technique, children and families are generally taught to use clean technique. See *Families Want to Know: Prevention of Urinary Tract Infections*.

Evaluation

Expected outcomes of nursing care include:

- The child increases fluid intake and number of times voiding each day.
- Future UTIs are prevented.

Structural Defects of the Urinary System

Bladder Exstrophy

Bladder exstrophy is a rare congenital defect in which the posterior bladder wall extrudes through the lower abdominal wall (Figure 26–3). Failure of the abdominal wall to close during fetal development results in eversion and protuberance of the bladder wall along with a wide separation of the rectus muscles and the symphysis pubis. The upper urinary tract is usually normal. The bladder mucosa appears as a mass of bright-red tissue, and urine continually leaks from the ureters onto the skin (Ring & Huether, 2014). Females have a bifid (split) clitoris. Males have a short, stubby penis, and the glans is flattened with dorsal chordee and a ventral prepuce. Undescended testicles and inguinal hernias are common in children with bladder exstrophy (Elder, 2016a).

The exposed bladder tissue is covered with plastic wrap to keep the bladder mucosa moist until surgery is performed (Elder, 2016a). The goal of primary closure of the bladder and anterior abdominal wall is an acceptable urinary reservoir (Bhatnagar, 2011). Primary closure is generally performed soon after birth but may be delayed if the bladder template is too small or other contraindications are identified (Inouye, Tourchi, DiCarlo, et al., 2014).

Families Want to Know

Prevention of Urinary Tract Infections

- Teach proper perineal hygiene. Girls should always wipe the perineum from front to back after voiding.
- Encourage the child to drink plenty of fluids and avoid long periods of "holding urine."
- Caution against tight underwear; children should wear cotton rather than nylon underwear.
- Encourage the child to void frequently and to fully empty the bladder.
- Discourage bubble baths, bath oils, and hot tubs, which can irritate the urethra.
- Encourage abstinence of sexual activity. However, if girls are sexually active, instruct them to void before and after sexual intercourse to prevent urinary stasis and flush out bacteria introduced during intercourse.

Figure 26–3 **This child has bladder exstrophy, noted by extrusion of the posterior bladder wall through the lower abdominal wall.**

The wound and pelvis are immobilized to promote healing. An osteotomy (see Chapter 29) to rotate the innominate bones of the pelvis to approximate the symphysis pubis reduces tension on the closed bladder and abdominal wall to promote healing. Epispadias repair is often performed between 1 and 2 years of age or at the same times as a surgical procedure to improve continence. Surgery to reconstruct the bladder neck and reimplant the ureters is performed when the bladder has achieved capacity of 80 to 90 mL (Elder, 2016a). The goals of surgical reconstruction include:

- Closure of the bladder and abdominal wall
- Urinary continence, with preservation of renal function
- Creation of functional and normal-appearing genitalia
- Correction to promote later sexual functioning

Some children require permanent urinary diversion because a functional bladder cannot be reconstructed.

Nursing Management

Preoperative nursing care centers on preventing infection and trauma to the exposed bladder. The bladder mucosa is protected with plastic wrap to keep the bladder mucosa moist (Elder, 2016a). The surrounding area is cleaned daily and protected from leaking urine with a skin sealant.

Postoperatively, the wound and pelvis are immobilized to facilitate healing. Internal and external immobilization techniques are used for pelvic closure (see Chapter 29). In addition to pain assessment and management, nursing care includes maintaining proper alignment, avoiding abduction of the infant's legs, monitoring peripheral circulation, and providing meticulous wound and skin care. Maintain aseptic technique for wound care and monitor for signs of infection including redness, drainage, and edema.

Monitor renal function by assessing the adequacy of urine output and blood and urine chemistries to detect signs of renal damage. Observe for any signs of obstruction in the drainage tubes such as increased intensity of bladder spasms, decreased urine output, or urine or blood draining from the urethral meatus. Promote comfort and give antibiotics as ordered.

Parents need emotional support to help them cope with the disfiguring nature of the infant's defect and the uncertainty of complete repair. To promote parent–infant bonding, encourage parents to participate in all aspects of the infant's care, including bathing, feeding, and wound care. Discharge teaching should include instructions about dressing changes and diapering and the need to immediately report any signs of infection or change in renal function. Emphasize the need for routine follow-up visits after surgery to assess urinary function and to ensure that the next stages of surgery for continence control are performed at the appropriate time in the child's development. The family should be aware that achievement of continence is more difficult in children with bladder exstrophy, and urinary diversion to achieve continence may be necessary if surgical procedures are not successful. Parents may require guidance to promote the child's self-esteem and self-confidence with sexual identity and function. Psychologic counseling may be beneficial to the child during adolescence.

Hypospadias and Epispadias

Hypospadias and epispadias are congenital anomalies involving the abnormal location of the urethral meatus (Figure 26–4). The reported incidence of hypospadias is 1 in 300 male births (Snodgrass & Bush, 2014). The incidence of epispadias is 1 in 40,000 to 118,000 births. Epispadias occurs twice as often in males as females (Ring & Huether, 2014). See the section on bladder exstrophy earlier in this chapter.

In hypospadias, the urethral meatus can be located anywhere along the course of the urethra on the ventral surface of the penile shaft, from the perineum to the tip of the glans. Most cases are mild, with the meatus slightly off center from the tip of the penis; in severe cases, the meatus is located on the scrotum.

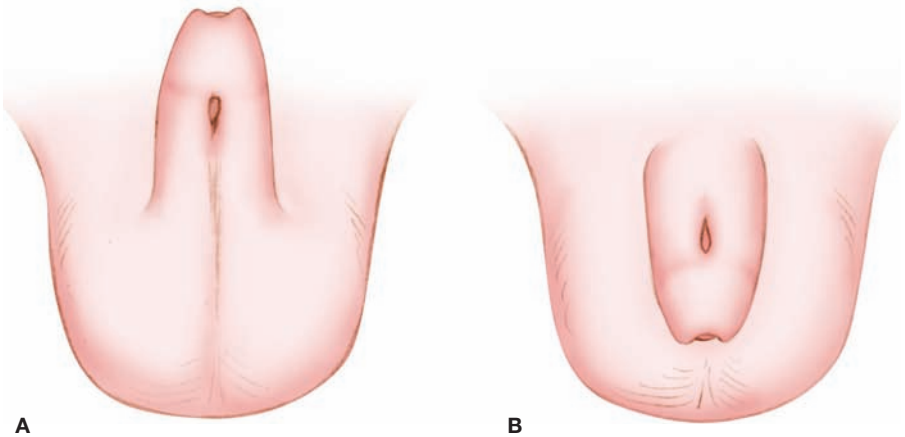

Figure 26–4 ***A,*** **In hypospadias, the urethral canal is open on the ventral surface of the penis.** ***B,*** **In epispadias, the canal is open on the dorsal surface.**

Hypospadias often occurs in conjunction with congenital *chordee,* a fibrous line of tissue that results in ventral curvature of the penile shaft. Associated defects may include inguinal hernia, cryptorchidism (undescended testes), and partial absence of the foreskin (Ring & Huether, 2014).

Clinical Tip

When children are not able to achieve continence, some type of urinary diversion may be created. A *vesicostomy* is a procedure in which an opening is created from the bladder to the skin. The urine drains from the opening (stoma) to the child's diaper or a drainage bag. In the *Mitrofanoff procedure*, a reservoir for urine and a stoma are created so that children can catheterize themselves through the umbilicus (see Chapter 27).

Epispadias and bladder exstrophy are the same condition, but epispadias is the milder expression of the condition. The opening may be small or a fissure may extend the entire length of the penis. Females with epispadias have a cleft of the ventral urethra that generally extends to the bladder neck (Ring & Huether, 2014). The remainder of this discussion will focus on hypospadias and males with distal epispadias because the treatment for severe epispadias in males and epispadias in females is similar to the final stage of repair of bladder exstrophy (Elder, 2016a).

The diagnosis of hypospadias is generally made at birth. If the parents would like to have their son to be circumcised, the procedure should be delayed until surgery to repair the hypospadias is performed (Chalmers, Wiedel, Siparsky, et al., 2014). Hypospadias is corrected surgically, usually during the first year of life, to minimize psychologic effects when the child is older. Surgery is usually performed in a single operation, often as an outpatient procedure. Surgery is recommended between 6 and 12 months of age (Kocherov et al, 2012). The goals of surgical repair are (1) placement of the urethral meatus at the end of the glans penis with satisfactory caliber and configuration for a urinary stream (enabling the child to void in a standing position), (2) release of chordee to straighten the penis (enabling future sexual function), and (3) satisfactory cosmetic appearance of the penis.

A caudal or penile nerve block is used for intraoperative and postoperative analgesia (Kundra, Yuvaraj, Agrawal, et al., 2011). Anticholinergic medications may be prescribed to relieve bladder spasms. A urethral **stent** (a device used to maintain patency of the urethral canal) or catheter is placed to maintain patency of the new urethral canal opening. The stent or catheter may drain directly into the diaper, using a double-diapering technique, or into a closed drainage collection bag.

Nursing Management

It is important to address parents' concerns at the time of birth. Preoperative teaching can relieve some of their anxiety about the future appearance and functioning of the penis.

Postoperative care focuses on protecting the surgical site from injury. The infant or child returns from surgery with the penis wrapped in a simple dressing, and a urethral stent or catheter for urinary drainage. Plan care to ensure that the stent does not get removed. Refer to the hospital's policy for the appropriate use of immobilizers in this situation.

Encourage fluid intake to maintain adequate urinary output and patency of the stent. Strict documentation of intake and output is essential to detect postoperative complications. Notify the healthcare provider if there is no urine drainage for 1 hour because this may indicate kinks in the system or obstruction. Pain may be associated with bladder spasms. Anticholinergic medications such as oxybutynin may be prescribed. Acetaminophen or other medications may also be given for pain. Antibiotics are often prescribed until the stent is out.

The child is often discharged the day of surgery. Discharge teaching should include instructions for parents about care of the reconstructed area, double-diapering to protect the operative site, fluid intake, medication administration, and signs and symptoms of infection (see *Families Want to Know: Caring for the Child After Hypospadias and Epispadias Repair* and the *Clinical Skills Manual* SKILLS). Tell parents when the child needs to see the healthcare provider for dressing removal.

Families Want to Know

Caring for the Child After Hypospadias and Epispadias Repair

- Use double-diapering to protect the operative site. See the *Clinical Skills Manual* SKILLS.
- Do not bathe the child in a tub until the stent (the small tube that drains the urine) or catheter is removed.
- Restrict the infant or toddler from activities (e.g., playing on riding toys) that put pressure on the surgical site. Avoid holding the infant or child straddled on the hip. Limit the child's activity for 2 weeks.
- Encourage the infant or toddler to drink fluids to ensure adequate hydration. Provide fluids in a pleasant environment or using a special cup. Offer fruit juice, fruit-flavored ice pops, fruit-flavored juices, flavored ice cubes, and gelatin.
- Administer the complete course of prescribed antibiotics to avoid infection.
- Observe for signs of infection: fever, swelling, redness, pain, strong-smelling urine, or change in flow of the urinary stream.
- The urine will be blood tinged for several days. Call the healthcare provider if urine is seen leaking from any area other than the penis.

A double-diapering technique protects the operative site after surgery for hypospadias repair. The inner diaper collects stool; the outer diaper, urine.

Obstructive Uropathy

Obstructive uropathy refers to structural or functional abnormalities of the urinary system that interfere with urine flow and result in urine backflow into the kidneys. The pressure caused by urine backup compromises kidney function and often causes **hydronephrosis** (accumulation of urine in the renal pelvis as a result of obstructed outflow). Physiologic changes that may occur as a result of hydronephrosis include the following:

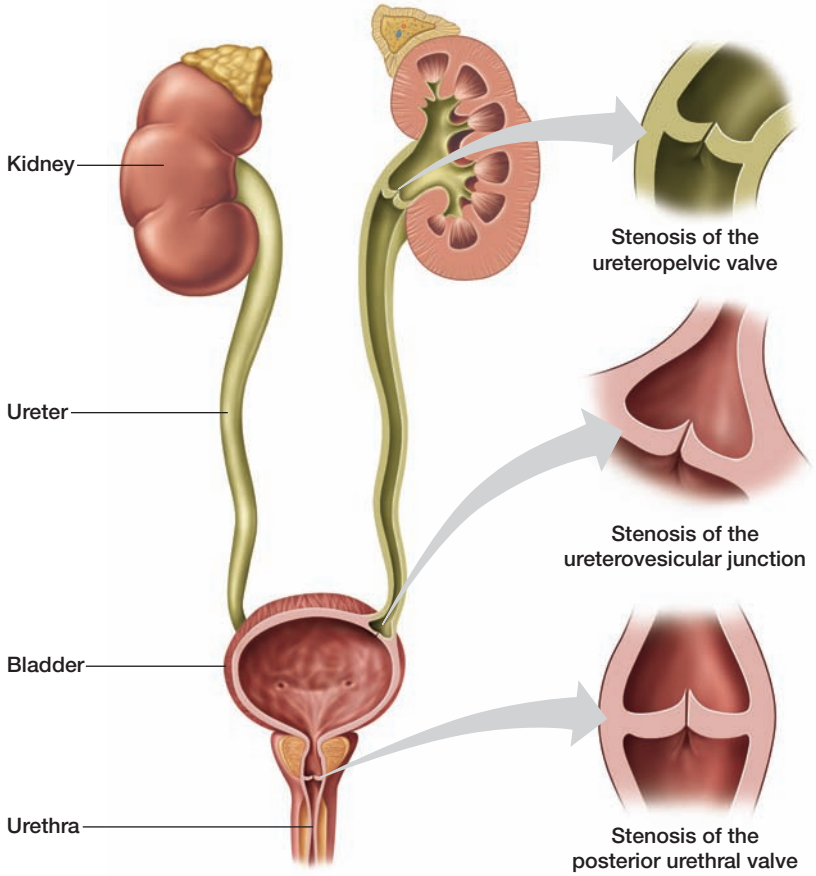
- Cessation of glomerular filtration occurs when the pressure in the kidney pelvis equals the filtration pressure in the glomerular capillaries. To compensate, the blood pressure increases to increase the glomerular filtration pressure; however, increasing pressure on the glomeruli leads to cell death.
- Metabolic acidosis results when the distal nephrons' ability to secrete hydrogen ions is impaired.
- Impairment of the kidney's ability to concentrate urine results in polydipsia and polyuria.
- Obstruction results in urinary stasis, promoting bacterial growth.
- Restriction of urinary outflow causes progressive renal damage and chronic renal failure if untreated.

Obstructive uropathy may be caused by several congenital lesions such as ureteropelvic junction (UPJ) obstruction, posterior urethral valves (PUVs), and stenosis or hypoplasia of the ureterovesicular junction (see *Pathophysiology Illustrated: Obstruction Sites in the Urinary System*). The UPJ is the most common site of obstruction of the upper urinary tract in infants and children. UPJ obstruction occurs in 1 of every 1000 to 2000 newborns, making it the most common cause of hydronephrosis in newborns (Lee, Han, & Rah, 2014). PUVs (abnormal folds of mucosa in the male urethra) occur in 1 of every 5000 children and are a significant cause of end-stage renal disease in children (Kari et al., 2013). Stenosis of the distal ureter at the ureterovesicular junction leads to dilation of the entire ureter, renal pelvis, and kidney (Ring & Huether, 2014).

Clinical manifestations vary depending on the cause and location of the obstruction (Table 26–3). Early diagnosis and treatment prevents kidney damage and deterioration of renal function. Prenatal ultrasound may detect hydronephrosis and PUV. A diuretic-enhanced radionuclide scan and voiding cystourethrogram are performed when UPJ or ureterovesicular obstruction is suspected.

The goals of surgical correction or diversion are to lower the pressure within the collecting system, which reduces renal damage, and to prevent stasis, which decreases the risk of infection. Surgical correction may necessitate **pyeloplasty** (removal of an obstructed segment of the ureter and reimplantation into the renal pelvis) or valve repair or reconstruction depending on the cause of the obstruction. Urinary incontinence resulting from sphincter weakness is a common problem after surgery.

Pathophysiology Illustrated: **Obstruction Sites in the Urinary System**



Obstruction may occur in either the upper or lower urinary tract. Common sites of obstruction occur at the ureteropelvic valve, the ureterovesicular junction, or the posterior urethral valve. Renal failure is most likely to occur when both kidneys are affected by hydronephrosis.

TABLE 26–3 Clinical Manifestations of Obstructive Lesions of the Urinary System

OBSTRUCTIVE LESION	CLINICAL MANIFESTATIONS
Ureteropelvic junction obstruction	*In infants:* Abdominal mass (enlarged kidney), hypertension, urinary tract infection *In children:* Hematuria, pain, intermittent nausea and vomiting
Posterior urethral valves	*In infants:* Abdominal mass (enlarged kidney), distended bladder, poor urinary stream, urinary tract infection, sepsis, low specific gravity, polyuria, increased creatinine level, failure to thrive *In children:* Urinary frequency and incontinence
Ureterovesicular junction obstruction	Urinary tract infection (recurrent or chronic), hematuria, pain, abdominal mass (enlarged kidney), enuresis

Nursing Management

Preoperative nursing care focuses on preparing the parents and child for the procedure and addressing parents' concerns about the postsurgical outcome. Provide parents with an opportunity to discuss concerns about how the disorder will affect the child's long-term renal functioning.

Postoperative care involves monitoring vital signs and intake and output and observing for signs of urine retention, such as decreased output and bladder distention. Many children are discharged with stents or catheters. Teach parents how to change dressings, double-diaper, care for catheters, assess pain and give analgesics, and recognize signs of possible obstruction or infection. Parents should encourage the child to participate in age-appropriate activities. However, children should avoid contact sports because of their potential to injure the bladder.

Vesicoureteral Reflux

In vesicoureteral reflux (VUR), there is a retrograde flow of urine from the bladder into the ureters. Severity ranges from reflux of urine into the ureter only (grade 1) to severe dilation of the ureter and renal pelvis with severely blunted calyces (grade 5) (Estrada & Cendron, 2013). The reflux prevents complete emptying of the bladder, and because urine returns to the bladder, it creates a reservoir for bacterial growth (Ring & Huether, 2014). Bacteria in the urine may be swept up to the kidneys, leading to pyelonephritis, which is the most common cause of kidney damage in children (Wadie & Moriarty, 2012).

Professionalism in Practice Screening Siblings for Vesicoureteral Reflux

Vesicoureteral reflux (VUR) occurs in 1% to 2% of the pediatric population and is present in 30% to 40% of children with a urinary tract infection (UTI). Research has shown that siblings of children with VUR have a much higher risk of having VUR than children without a family history, with a reported incidence of 26% to 50%. The American Urological Association Pediatric Vesicoureteral Reflux Guidelines have been revised to include recommendations related to screening siblings of children with VUR. It is especially important that siblings who present with a UTI be evaluated for VUR with a voiding cystourethrogram (Hunziker, Colhoun, & Puri, 2014). Nurses have opportunities to work with families of children being treated for urinary tract infections and/or VUR. Parents should be made aware of the increased incidence of VUR in siblings and the need for prompt attention to any signs of UTI. It is important that they include in the education of these families the relationship of recurrent UTI and subsequent kidney damage in children.

A renal ultrasound, voiding cystourethrogram (VCUG), and/or dimercaptosuccinic acid (DMSA) scan is used to diagnose, grade, and follow the progression of VUR. Note, however, that VCUG is the only test that provides a definitive diagnosis. The use of prophylactic antibiotics is controversial but may be prescribed to prevent UTIs. Surgical management with ureteral reimplantation may be needed depending on the grade of reflux (Passamaneck, 2011). Endoscopic management with the submucosal injection of Deflux has proven to be a successful alternative for some patients and may be considered as an alternative to surgery (Wadie & Moriarty, 2012).

Nursing Management

Following surgery to reimplant the ureters, a urinary catheter will be in place. The urine will be bloody initially and clear within 2 to 3 days. Intravenous fluids will be administered at a rate sufficient to maintain adequate urine output. Monitor the catheter for patency. Administer medications as prescribed, including antibiotics and antispasmodics such as oxybutynin.

The child can be discharged when the urinary catheter has been removed and the child can void spontaneously. An ultrasound or cystogram may be performed prior to discharge to evaluate the effectiveness of the surgery. Educate the family about the administration of medications including prophylactic antibiotics and antispasmodics if needed. Inform parents of the need for increased fiber in the diet to address the constipating effects of the antispasmodic medication. Guidelines for calling the physician include fever over 38.5°C (101.5°F), abdominal or back pain, or swelling and redness of the incision. The child may take a short shower or tub bath when returning home. The child should avoid active play for 3 weeks following surgery. Provide guidelines for follow-up.

Prune Belly Syndrome

Prune belly syndrome, also known as *Eagle-Barrett syndrome*, is a congenital defect characterized by failure of the abdominal musculature to develop. The skin covering the abdominal wall is thin and resembles a wrinkled prune. Other characteristics include urinary tract anomalies, poor ureteral peristalsis, enlarged bladder, high risk for recurrent UTI, vesicoureteral reflux, and bilateral cryptorchidism in males. Prune belly syndrome occurs predominantly in males (95%), with an incidence of 1 in 29,000 to 40,000 live births (Caldamone & Woodard, 2012).

The etiology of prune belly syndrome is unknown; however, it is thought to be related to a fetal urinary tract obstruction or a specific injury to the mesoderm during the first trimester. In addition to urinary tract anomalies, cardiac, pulmonary, gastrointestinal, and musculoskeletal anomalies also occur (Hassett, Smith, & Holland, 2012).

Prune belly syndrome is frequently diagnosed prenatally by ultrasound. Mortality in the neonatal period is related to

pulmonary hypoplasia and severe renal dysfunction (Hassett et al., 2012). Abdominal wall reconstruction and correction of genitourinary defects, including orchiopexy (or orchidopexy), are performed to repair defects. The mortality rate in infants has improved significantly in the past 3 decades with advances in surgical techniques. Approximately 30% of children with prune belly syndrome will develop end-stage renal disease in childhood or adolescence because of inadequate renal function (Elder, 2016b).

Nursing Management

Nursing management for the infant with prune belly syndrome is the same as for other defects of the genitourinary system, including preoperative and postoperative management. Additional management includes psychosocial support for the child and family related to the numerous congenital anomalies, body image concerns, and long-term consequences of the defect.

A discussion of Wilms tumor can be found in Chapter 24.

Enuresis

Enuresis is repeated involuntary voiding by a child old enough that bladder control is expected, usually about 5 to 6 years of age. (See Table 26–4 for bladder control milestones.) Enuresis can occur either at night (nocturnal), during the day (diurnal), or both night and day.

Enuresis is further categorized as primary or secondary:

- *Primary enuresis*—Child has never had a dry night; attributed to maturational delay and small functional bladder; not associated with stress or psychiatric cause.
- *Secondary enuresis*—Child who has been reliably dry for at least 6 months begins bed-wetting; associated with stress, infections, and sleep disorders.

Growth and Development

Nighttime wetting episodes usually decrease as the child ages. An estimated 21% of children ages 4.5 years and 8% of children 9.5 years of age average less than two episodes of nighttime wetting per week. Wetting episodes occur more than 2 times per week in 8% of children ages 4.5 years and 1.5% of children 9.5 years of age (Jacques, 2013).

TABLE 26–4 Milestones in the Development of Bladder Control

AGE	DEVELOPMENTAL MILESTONE
1.5 years	Child passes urine at regular intervals.
2 years	Child announces when voiding is taking place.
2.5 years	Child makes known the need to void; can hold urine.
3 years	Child goes to the bathroom alone; holds urge if preoccupied with play.
2.5–3.5 years	Child achieves nighttime control.
4 years	Child shows great interest in going to bathrooms when away from home (shopping centers, movies).
5 years	Child voids approximately 5 to 6 times a day; prefers privacy; is able to initiate emptying of bladder at any degree of fullness.

Primary nocturnal enuresis is the most common type of enuresis and occurs more frequently in males than females (Elder, 2016c). It occurs more often in children who have a positive family history and generally involves more than one causative factor. Factors may include maturational delay, sleep disorders, and reduced or small functional bladder capacity (Ray, 2011). Nocturnal enuresis is also more prevalent in children with obstructive sleep apnea syndrome (Bascom et al., 2011). Additionally, enuresis frequently occurs in children with constipation. The constipation should be treated prior to the implementation of any treatment for enuresis (Walle et al., 2012).

A thorough history can help identify potential causes of secondary enuresis. The child's lower spine is examined for fistulas, sacral dimples, or tufts of hair that could be signs of spina bifida occulta (see Chapter 27). Diabetes, urinary tract infection, and other conditions should also be ruled out. Prolonged hospitalization, family stressors, and preoccupation with school concerns also have been associated with secondary enuresis.

Clinical Tip

Questions to ask when taking an enuresis history include the following:

Family History

Is there a family history of renal or urinary structural abnormalities?

Is there a family history of bed-wetting? At what age did bed-wetting stop?

Family Management of Enuresis

How serious is the problem for the family?

What happens when the child wets? (Who gets up and changes sheets?)

How is the child treated? Is the child punished or blamed for wetting?

What remedies have been tried?

Toilet Training

When was it initiated and what method was used?

Has the child ever been dry during the day or night for an extended period?

How long was the child's longest dry period?

How often does the child void? Have a bowel movement?

Does the child have a history of constipation or encopresis?

Stressors

How is the child doing in school?

Are any new or chronic stressors present in the child's life?

How does the problem interfere with play and other activities?

Risk Factors

Diabetes—Are there any signs of polyuria or polydipsia?

Urinary tract infection—Does the child have frequency, urgency, burning on urination?

A multitreatment approach is usually most effective. Limiting excessive fluids at night, bladder training, enuresis alarms, and positive reinforcement are common approaches (Table 26–5). Alarms have about a 70% success rate but take 3 to 5 months to be effective (Ray, 2011).

TABLE 26–5 Treatment Approaches for Enuresis

APPROACH	DESCRIPTION
Limiting fluids	Fluid intake is limited in the evening and before the child goes to bed. Fluids with caffeine should be avoided.
Bladder exercises	The child drinks a large amount and then holds urine as long as possible. The child practices stopping voiding midstream. Exercises should continue for at least 6 months.
Timed voiding	The child with diurnal enuresis is instructed to void every 2 hr and to use a double voiding pattern; this trains the bladder to empty completely and avoid overdistention.
Enuresis alarms	A detector strip is attached to the child's pants. The alarm sounds a buzzer that alerts the child when wetting occurs, so the child can get up and finish voiding in the bathroom. This works best for children over 7 years old, and takes 3 to 5 months for success.
Reward system	Set realistic goals for the child and reinforce dry days or nights with stars and stickers on a chart.
Medications	Desmopressin, oxybutynin, and imipramine are used as discussed in the text.

Medications used in the treatment of primary nocturnal enuresis include desmopressin, imipramine, and oxybutynin:

- Desmopressin is the most common medication used for nocturnal enuresis and has an antidiuretic effect. Desmopressin is given at nighttime at the beginning of treatment. Once its effectiveness has been established, it may be used every night or as needed for times when the child is away from home for a short period (e.g., sleepovers or camp) (Nevéus, 2011).
- Oxybutynin, an anticholinergic medication, has an antispasmodic effect, improves storage function of the bladder, and decreases the overactivity of the detrusor muscle. Oxybutynin may also be used in combination with desmopressin in children who have not responded to desmopressin alone or in combination with an alarm (Norfolk & Wootton, 2012).
- Imipramine, a tricyclic antidepressant, has anticholinergic and antispasmodic effects and may be used in children who do not respond to other methods. This medication requires close monitoring because of its effects on mood and the associated danger of overdoses (Nevéus, 2011).

Nursing Management

Teach the child and parents about the physiologic development of bladder control and causes and treatment of enuresis. Explore feelings of guilt or blame. Make sure the parents are aware that the child cannot control the wetting. Psychosocial support is an essential part of care since stress is an important cause of secondary enuresis. Provide emotional support to the parents and child, and encourage the child's participation in the treatment plan. Refer the child for counseling or therapy if appropriate.

Assess the parents' and child's motivation and readiness for interventions. The child needs to be an active participant in the treatment plan for daytime and nighttime wetting. Before parents buy an enuresis alarm, suggest they use an alarm clock in the child's room for several nights to see if the child will arouse. Find out whether the child shares a room with others who will be disturbed by the alarm. Ask if the child and parents are willing to persist with an enuresis alarm because it may take months to work. Discuss potential strategies with the family to reduce stressors on the child or to help the child cope with the stressors. Expected outcomes of nursing care include:

- The child has an increased number of dry nights.
- The child and family choose one or more interventions that they prefer and persist in using them.

Renal Disorders

Nephrotic Syndrome

Nephrotic syndrome is an alteration in kidney function secondary to increased glomerular basement membrane permeability to plasma protein (see *Pathophysiology Illustrated: Nephrotic Syndrome*). Nephrotic syndrome does not refer to a specific disease, but rather to a clinical state characterized by edema, massive proteinuria, hypoalbuminemia, hypoproteinemia, hyperlipidemia, and altered immunity. Congenital nephrotic syndrome is generally related to a genetic defect (Holmberg & Jalanko, 2014). The term *primary nephrotic syndrome* is used when there is no identifiable cause. *Secondary nephrotic syndrome* results from a systemic disease, drugs, or toxins (Ring & Huether, 2014).

Approximately 85% of children with nephrotic syndrome have a type of primary disease called *minimal change nephrotic syndrome* (MCNS). It is estimated that more than 95% of these children respond to steroid therapy (Pais & Avner, 2016). MCNS derives its name from the normal or only minimally changed appearance of the glomeruli on light microscopic evaluation. MCNS is the focus of the following discussion.

ETIOLOGY AND PATHOPHYSIOLOGY

The cause of primary MCNS is not clearly understood but an immune system role is suspected (Pais & Avner, 2016). The mechanism of increased glomerular permeability is unknown because the glomeruli appear normal (Ring & Huether, 2014). In MCNS, increased permeability of the glomerular membrane permits large, negatively charged molecules such as albumin to pass through the membrane and be excreted in the urine. Proteinuria results in decreased oncotic pressure and edema because fluid remains in the interstitial spaces instead of being pulled back into the vascular compartment (Pais & Avner, 2016). Immunoglobulins are lost, resulting in altered immunity. Loss of protein in the urine, insufficient albumin production by the liver, and a decreased albumin concentration as a result of salt and water retention by the kidney contribute to hypoalbuminemia. Hypercoagulability occurs because of alterations in coagulation factors. The liver responds by increasing synthesis of lipoprotein, resulting in hyperlipidemia (Ring & Huether, 2014). Children who develop steroid-resistant nephrotic syndrome are at risk for end-stage renal disease (Lombel, Hodson, & Gipson, 2013).

CLINICAL MANIFESTATIONS

In most children, edema develops gradually over several weeks. Children may have a history of periorbital edema on waking that resolves during the day as fluid shifts to the abdomen and lower extremities. Other signs include snug fit of clothing and shoes, pallor, hypertension, irritability, anorexia, hematuria, decreased urine output, and nonspecific malaise. The child's urine may be

Pathophysiology Illustrated: **Nephrotic Syndrome**

Note the contrast between the normal glomerular anatomy and the changes that exist in nephrotic syndrome, which permit protein to be excreted in the urine. The lower albumin blood level stimulates the liver to generate lipids and excessive clotting factors. Edema results from decreased oncotic plasma pressure, renin-angiotensin-aldosterone activation, and antidiuretic hormone secretion.

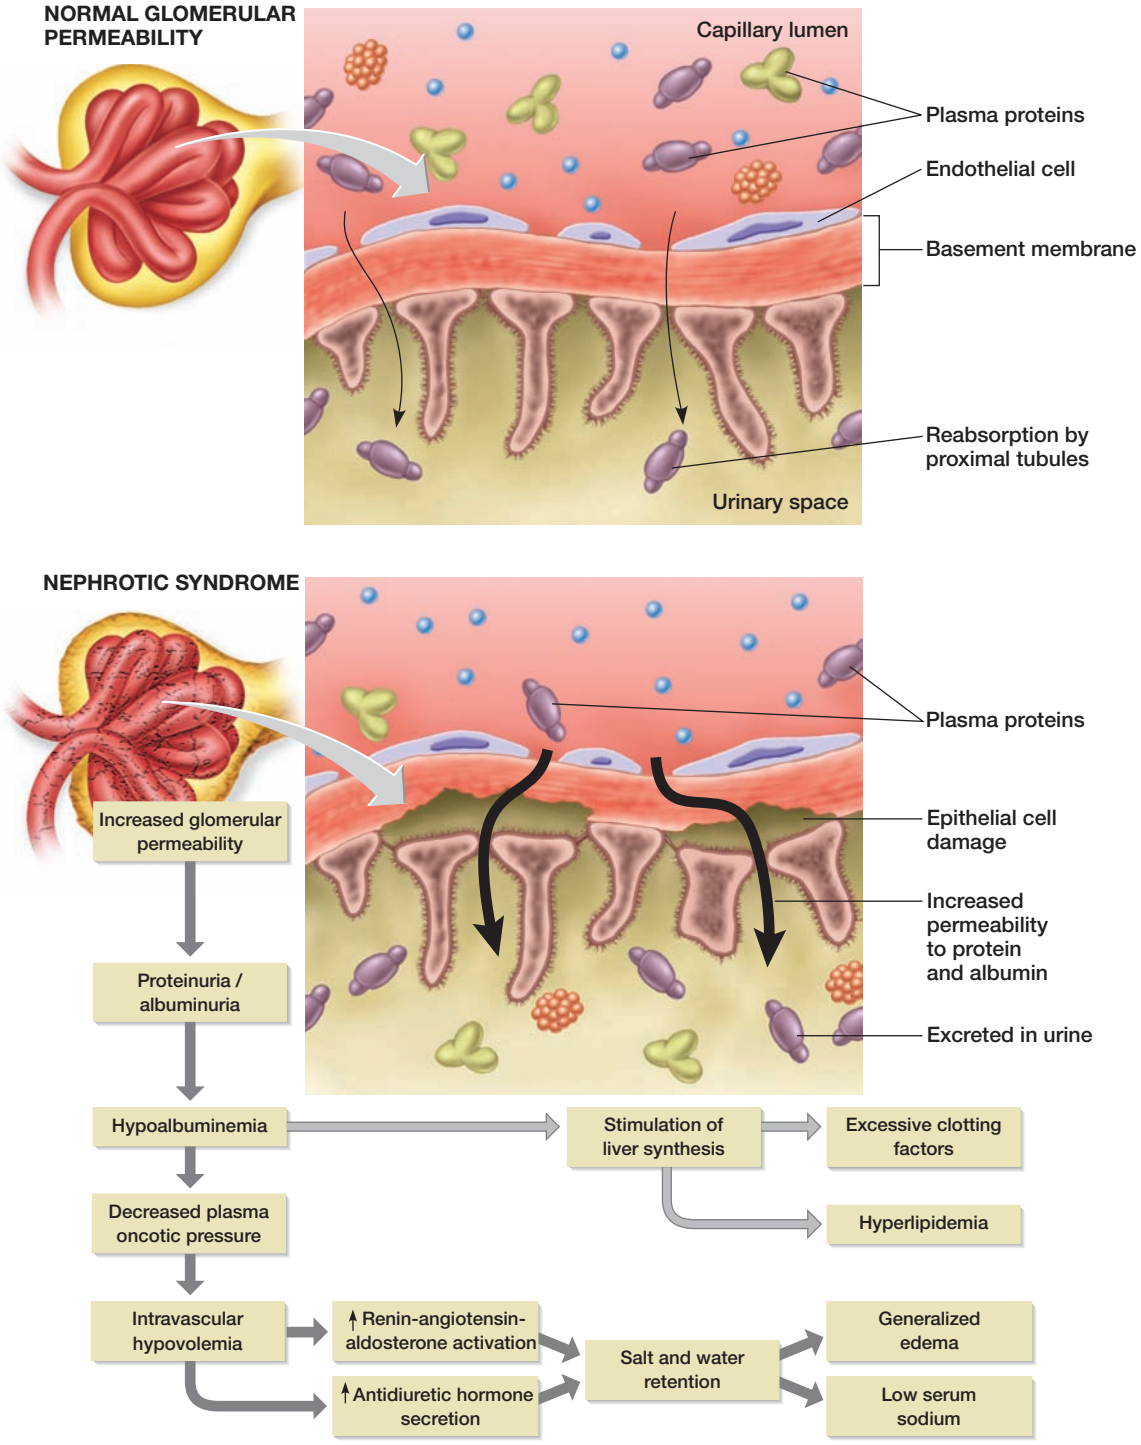


Figure 26–5 **This boy has generalized edema, a characteristic finding in nephrotic syndrome.**

frothy or foamy. Parents often do not seek medical treatment until generalized edema develops on the child's extremities, abdomen, or genitals (Figure 26–5). Respiratory distress from pleural effusion may occur in some cases.

Massive edema resulting in a dramatic weight gain and abdominal pain, with or without vomiting, may occur depending on the amount of albumin lost and the amount of sodium ingested. The child becomes malnourished as a result of protein loss in the urine. The skin is pale and shiny with prominent veins, and the hair becomes more brittle. An increased risk of thrombosis is present.

CLINICAL THERAPY

Diagnosis is based on the history, characteristic symptoms, and laboratory findings. Urinalysis, serum albumin, sodium, BUN, cholesterol, and electrolytes tests are ordered. Urinalysis shows large protein. Microscopic hematuria may also be present. Other values that confirm the diagnosis include hypoalbuminemia indicated by serum albumin levels of less than 2.5 g/dL and urinary protein excretion of greater than 3.5 grams per 24 hours (Pais & Avner, 2016).

Children may be hospitalized when severe edema or a major infection is present, but are usually treated as outpatients. Clinical therapy focuses on decreasing proteinuria, relieving edema, managing associated symptoms, improving nutrition, and preventing infection. A corticosteroid (such as prednisone) is prescribed to decrease proteinuria. In most children, urine protein levels fall to trace or negative values within 2 to 3 weeks of the start of therapy. Children who respond successfully to therapy continue to take corticosteroids daily for 6 weeks, followed by at least 4 weeks of alternate-day treatment. The medication is then slowly tapered and discontinued over a 1- to 2-month period of time. Approximately 80% to 90% of children respond to steroid therapy within 4 weeks (Pais & Avner, 2016). Intravenous methylprednisolone may be used in children not responsive to oral steroids (Nachman, Jennette, & Falk, 2012). Intravenous administration of albumin followed by furosemide may be ordered in the child with massive edema who is unresponsive to fluid restriction and parenteral diuretics (Pais & Avner, 2016). Analgesics may be ordered for pain related to edema or flank pain from a urinary tract infection.

Relapses occur in many children with nephrotic syndrome (Pais & Avner, 2016). Children who have a relapse after drug therapy is discontinued receive repeat therapy. Other medications used include diuretics, antihypertensive agents, and antibiotics. Immunosuppressive or immunomodulator medications, including cyclophosphamide, cyclosporine, tacrolimus, and mycophenolate, may be used to prolong remissions in children with nephrotic syndrome who have frequent relapses (Pais & Avner, 2016). Since diuretics can precipitate hypovolemia, hyponatremia, and hypokalemia, electrolyte levels should be carefully monitored.

Nursing Management

For the Child With Nephrotic Syndrome

Nursing Assessment and Diagnosis

PHYSIOLOGIC ASSESSMENT

Careful assessment of the child's hydration status and edema is essential. Carefully monitor intake and output. Weigh the child daily using the same scale, and measure abdominal girth to monitor changes in edema and ascites (see the *Clinical Skills Manual* SKILLS). Monitor vital signs at least every 4 hours to watch for signs of respiratory distress, hypertension, or circulatory overload. Test urine for proteinuria and specific gravity at least once each shift. In addition, assess for skin breakdown from edema, for hypovolemia during periods of diuresis as well as for indications of infection.

PSYCHOSOCIAL ASSESSMENT

Children and parents are often fearful or anxious on admission. Because edema often develops gradually, parents may feel guilty if they did not seek medical attention immediately. School-age children with generalized edema are often concerned about their appearance. Careful questioning may be necessary to elicit these concerns. The child hospitalized for a recurrence of nephrotic syndrome may be frustrated or depressed. Assess individual and family coping mechanisms, support systems, and level of stress.

Common nursing diagnoses for the child with MCNS include the following (NANDA-I © 2014):

- ***Infection, Risk for,*** related to immunosuppressive therapy
- ***Skin Integrity, Risk for Impaired,*** related to edema, lowered resistance to infection and injury, immobility, and malnutrition
- ***Fluid Volume: Excess*** related to renal dysfunction and sodium retention
- ***Nutrition, Imbalanced: Less than Body Requirements,*** related to loss of appetite and protein loss in urine
- ***Fatigue*** related to fluid and electrolyte imbalance, albumin loss, altered nutrition, and renal failure
- ***Activity, Deficient Diversional,*** related to fatigue, immobility, and social isolation

Planning and Implementation

Nursing care is mainly supportive and focuses on administering medications, preventing infection, preventing skin breakdown, meeting nutritional and fluid needs, promoting rest, and providing emotional support to the parents and child.

ADMINISTER MEDICATIONS

It is important to give prescribed medications at the scheduled times. Monitor closely for side effects of corticosteroids such as moon face, increased appetite, increased hair growth, abdominal distention, and mood swings, as well as adverse effects of corticosteroids such as hypertension, nausea, and hyperglycemia. Corticosteroids should be tapered rather than abruptly discontinued. If the child is receiving albumin intravenously, monitor

closely for hypertension or signs of volume overload caused by fluid shifts. If diuretics are used, observe for shock. The child may need to have albumin infused simultaneously with diuretics.

PREVENT INFECTION

Children with MCNS are at risk for infection because of the loss of immunoglobulins in the urine and corticosteroid therapy. Implement careful hand hygiene and standard precautions. Strict aseptic technique is essential during invasive procedures. Monitor the child's white blood cell count when cytotoxic drugs are given because bone marrow suppression is a side effect. Monitor vital signs carefully to detect early signs of infection that may be masked by corticosteroid therapy. Decrease the child's social contacts during immunosuppressive treatment, and caution parents and children to avoid exposure to people with respiratory infections and communicable diseases. Emphasize the importance of avoiding shopping malls, sporting arenas, grocery stores, game stores, and other public areas where the risk of exposure to such infections is increased. Provide instructions to the parents on signs of infection, including fever and changes in behavior. Discuss with parents the need for maintenance of annual recommended influenza immunizations and avoiding those who have recently been vaccinated with live viruses.

PREVENT SKIN BREAKDOWN

Meticulous skin care is essential to prevent skin breakdown and potential infection. Assess the skin repeatedly, turn the child frequently, and use therapeutic mattresses (e.g., egg crate, airflow) to help prevent skin breakdown. Keep the skin clean and dry.

MEET NUTRITIONAL AND FLUID NEEDS

Keep the child's food preferences in mind when planning menus. Encourage the child to eat by presenting attractive meals in small portions. Socialization during meals may improve the child's appetite. Fluids are not usually restricted except during severe edema.

PROMOTE REST

Provide opportunities for quiet play as tolerated, such as drawing, playing board games, listening to CDs, and watching movies. Adjust the child's daily schedule to allow rest periods after activities. Signs of fatigue may include irritability, mood swings, or withdrawal. Tell the parents and child about the importance of rest. Limiting visitors during the acute phase of the illness may be necessary. Telephone and computer contacts may be encouraged as an alternative to visitors. To provide a sense of control, encourage these children to set their own limits on activity.

PROVIDE EMOTIONAL SUPPORT

Parents and children often need support to cope with this chronic disease. Thoroughly explain the child's disease and treatment regimen to parents. Parental anxiety in combination with the hospitalization may interfere with the child's independence. Help parents promote the child's independence by allowing the child to choose from the menu or to select the daily activity schedule. This gives the child some sense of control.

Children with MCNS may have a distorted body image because of sudden weight gain and edema. They may refuse to look in the mirror, refuse to participate in care, and take less interest in their appearance. Encourage children to express their feelings. Help them maintain a normal appearance by promoting normal grooming routines. Encourage children to wear their own pajamas rather than hospital gowns. Scarves or hats may be used to lessen the child's edematous appearance. Adolescents can be encouraged to write their feelings in a journal as a coping mechanism. These children may have a long-term psychosocial adjustment because of having a chronic condition with concerns about potential relapse.

DISCHARGE PLANNING AND HOME CARE TEACHING

Explain the disease process, prognosis, and treatment plan to parents and school-age children. Make sure parents know how to administer medications and can identify potential side effects. Inform parents about restricting fluid intake until the edema resolves. Instruct parents about the need to monitor urine daily for protein, and have them keep a diary to record results. Monitoring the child's weight each week may help parents identify early stages of fluid retention and signs of relapse before edema occurs.

Tutoring may be required for a short period after discharge. Encourage parents to allow the child to return to normal activities once the acute episode has resolved. Emphasize the importance of avoiding contact with people with infectious diseases because of the child's reduced immunity. Reinforce to parents that as long as the child is receiving corticosteroid therapy or shows signs of MCNS, a no-added-salt diet should be followed.

Most children do well with corticosteroid therapy; however, relapses are common. These relapses decrease as the child gets older. Children should have periodic bone density evaluations because of the repeated steroid therapy, which can weaken bones and lead to osteoporosis.

Evaluation

Expected outcomes of nursing care may include:

- The child responds to corticosteroid therapy.
- The child does not acquire an infection.
- Fluid, electrolyte, and acid–base balance is restored and maintained.
- Skin integrity is maintained.
- The child meets nutritional requirements and follows dietary guidelines.

Acute Postinfectious Glomerulonephritis

Glomerulonephritis is the most common inflammation of the glomeruli of the kidneys. In children, it is most often a response to a group A beta-hemolytic streptococcal infection of the skin or pharynx. It is also caused by other organisms, including *Staphylococcus* and *Pneumococcus* bacteria and coxsackieviruses. The incidence of acute postinfectious glomerulonephritis (APIGN) is highest in children between 2 and 6 years of age, and the disorder is more common in boys than in girls (Nachman et al., 2012).

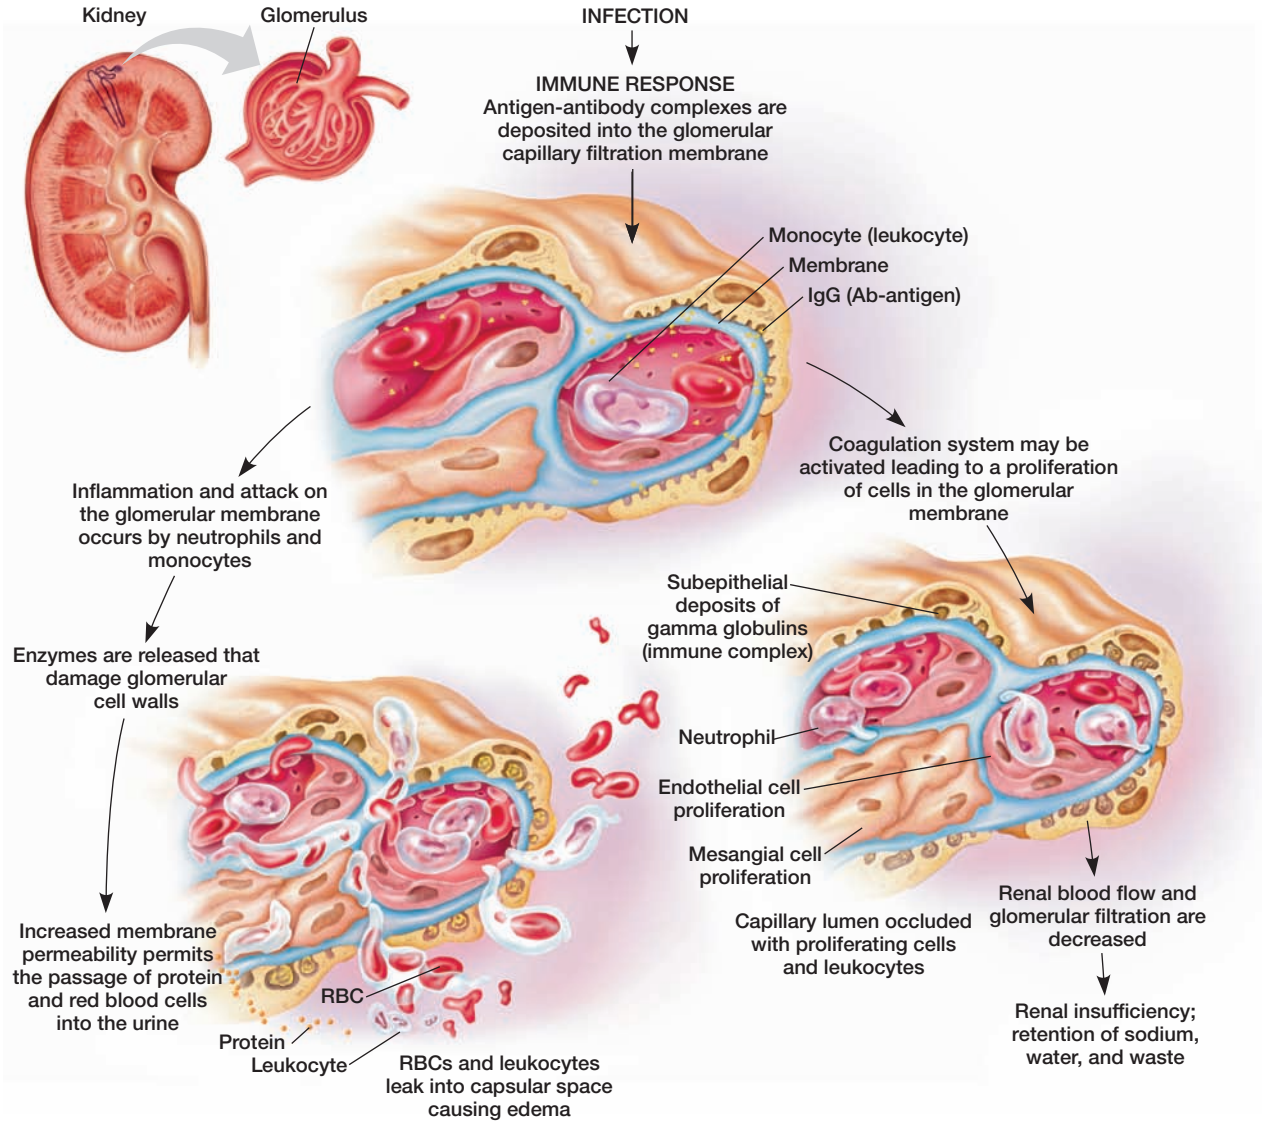
ETIOLOGY AND PATHOPHYSIOLOGY

The child with APIGN usually becomes ill after contracting a nephrogenetic strain of group A beta-hemolytic streptococcal infection of the upper respiratory tract or the skin. Often the child contracts a streptococcal infection (e.g., strep throat), recovers, and then develops signs of APIGN after an interval of 10 to 21 days.

Glomerular damage occurs as a result of an immune complex reaction that localizes on the glomerular capillary wall. See *Pathophysiology Illustrated: Acute Postinfectious Glomerulonephritis*. Antibody–antigen complexes become lodged in the glomeruli, leading to inflammation and obstruction. The glomerular membranes thicken, and capillaries in the glomeruli become obstructed by damaged tissue cells, leading to a decreased glomerular filtration rate. Vascular permeability increases, allowing red blood cells and red cell casts to be excreted. Sodium and water are retained, expanding the intravascular and interstitial compartments and resulting in the characteristic finding of edema.

Pathophysiology Illustrated: **Acute Postinfectious Glomerulonephritis**

Infection from group A beta-hemolytic streptococci causes an immune response that leads to inflammation and damage to the glomeruli. Protein and red blood cells are allowed to pass through the glomeruli. Blood flow to the glomeruli is reduced because of obstruction with damaged cells. Renal insufficiency results, leading to the retention of sodium, water, and waste.



CLINICAL MANIFESTATIONS

Many children are asymptomatic. In other children, the onset is usually abrupt with flank or midabdominal pain, irritability, malaise, and fever. Microscopic hematuria is present in nearly all cases, and gross hematuria, resulting in tea-colored urine, is found in up to 50% of cases. Mild periorbital edema occurs early, along with dependent edema of the feet and ankles. Edema may progress in severity to cause pulmonary congestion or ascites (Nachman et al., 2012). Acute hypertension may lead to headache, nausea, vomiting, lethargy, seizures, and other CNS symptoms. Oliguria may or may not be present (Ring & Huether, 2014).

CLINICAL THERAPY

The serum BUN and creatinine concentrations are elevated. Serum protein is decreased as a result of mild or moderate proteinuria. The white blood cell count and erythrocyte sedimentation rate may be elevated. An elevated antistreptolysin O (ASO) titer reflects the presence of antibodies from a recent streptococcal respiratory infection, but the ASO level associated with a recent skin infection is low. The anti-DNAse B titer is helpful for detecting antibodies associated with recent skin infections. Most children have a reduced serum complement (C3) level due to the initial infection (Nachman et al., 2012). Urinalysis reveals hematuria, proteinuria, and red blood cell casts. Anemia is common in the acute phase, usually because extracellular fluid dilutes the serum. Hemoglobin and hematocrit levels reveal anemia, which is common in the acute phase and is generally caused by dilution of the serum by the extracellular fluid (Bhimma, 2014).

Treatment focuses on relief of symptoms and supportive therapy. Bed rest is a key component of the treatment

plan during the acute phase. Edema and mild to moderate hypertension should be treated with sodium restriction and a diuretic such as furosemide (Nachman et al., 2012; Ring & Huether, 2014). A course of antibiotics may be given to ensure eradication of the original infectious agent. Immediate emergency care is needed for severe hypertension with cerebral dysfunction.

The prognosis for most children with APIGN is good. Clinical signs, proteinuria, and hematuria resolve within several weeks. Over 95% of children recover completely (Ring & Huether, 2014).

Nursing Management

For the Child With Acute Postinfectious Glomerulonephritis

Nursing Assessment and Diagnosis

As with other renal disorders, care of the child with APIGN requires careful monitoring of vital signs and fluid–electrolyte balance to evaluate renal functioning and identify complications. Frequent blood pressure monitoring is required since it can rise as high as 200/120 mmHg. With severe hypertension, assess for signs of central nervous system problems (headache, blurred vision, vomiting, decreased level of consciousness, confusion, and convulsions). Monitor urine for proteinuria and hematuria. Record output. Assess edema, which may be periorbital or dependent and may shift as the child's position is changed. Assess for a pulmonary effusion (crackles, dyspnea, and cough).

Nursing diagnoses may include the following (NANDA-I © 2014):

- ***Fluid Volume: Excess*** related to decreased glomerular filtration and increased sodium
- ***Infection, Risk for,*** related to renal impairment and corticosteroid therapy
- ***Skin Integrity, Risk for Impaired,*** related to tissue edema
- ***Nutrition, Imbalanced: Less than Body Requirements,*** related to loss of appetite and proteinuria
- ***Activity Intolerance*** related to fluid and electrolyte imbalance, infectious process, and altered nutrition
- ***Health Management, Family, Ineffective,*** related to child's medication schedule and treatment regimen after discharge

Clinical Tip

Antibiotics are *not* a treatment for APIGN. Instead, antibiotics are prescribed to treat the original infection (such as strep throat) if the infection is still present.

Planning and Implementation

MONITOR FLUID STATUS

Monitor vital signs, fluid and electrolyte status, and intake and output. Hypovolemia can occur as a result of fluid shifting from vascular to interstitial spaces despite the outward clinical signs of excess fluid retention. Monitor the degree of ascites by measuring abdominal girth. Document urine specific gravity. Make sure parents and visitors understand the need to limit fluids to prevent excessive intake.

PREVENT INFECTION

Impaired renal function puts the child at risk for infection. Monitor for signs of infection, including fever, increased malaise, and an elevated white blood cell count. Screen family members for the presence of streptococcal infection and refer for treatment if necessary. Instruct the family in good hand hygiene technique. Limit visitors, and screen for upper respiratory infections.

PREVENT SKIN BREAKDOWN

Bed rest is required during the acute phase. Dependent areas and other pressure areas are vulnerable to skin breakdown. Turn the child frequently. Pad bony prominences or susceptible areas with sheepskin, or protect skin with a transparent dressing. Elevate lower extremities on pillows when in the dependent position or when the child is lying in bed. Make sure the child's bed is free of crumbs or sharp toys. Keep sheets tight and free of wrinkles. Maintain proper hygiene and dry skin.

MEET NUTRITIONAL NEEDS

A team approach (including the nurse, renal dietitian, parents, and child) is often needed to meet the child's nutritional needs. In most cases, the child follows a no-added-salt and low-protein diet. This diet may be challenging since the child may refuse to eat foods that taste different. Anorexia presents the greatest challenge to meeting daily nutritional requirements during the acute phase of the disease. To increase the child's appetite, encourage parents to bring the child's favorite foods from home, serve foods in age-appropriate quantities, and allow the child to eat with other children or with family members.

PROVIDE EMOTIONAL SUPPORT

Parents of a child with APIGN commonly feel guilty. Parents may blame themselves for not responding more quickly to the child's initial symptoms or may believe they could have prevented the development of glomerular damage. Discuss the etiology of the disease and the child's treatment, and correct any misconceptions. Emphasize that it is not possible to predict which of the few children with streptococcal infections will develop APIGN.

DISCHARGE PLANNING AND HOME CARE TEACHING

Children are hospitalized for a few days, although it may require 3 weeks for hypertension and gross hematuria to resolve and longer for the disorder to resolve completely. Discharge planning focuses on teaching parents about the child's medication regimen, potential side effects of medications, dietary restrictions, and signs and symptoms of complications. Teach parents how to take the child's blood pressure and how to test urine for blood or protein. Emphasize that it is important to avoid exposing the child to people with upper respiratory tract infections. Children should be allowed to return to their normal routines and activities after discharge, with periods being allowed for rest.

Evaluation

Expected outcomes of nursing care are the following:

- The child receives appropriate fluid volume each day and maintains normal urine output.
- The child develops no areas of redness, abrasions, or skin breakdown over pressure points.
- The child's temperature remains within normal limits and the child is free of secondary infection.

- The child maintains pre-illness weight and tolerates daily intake that meets nutritional requirements.
- The parents administer medications as prescribed. The child's sodium and potassium levels reflect adherence to dietary restrictions.

Renal Failure

Renal failure, which may be acute or chronic, occurs when the kidney is unable to excrete wastes and concentrate urine. Acute renal failure occurs suddenly (over days or weeks) and may be reversible, whereas in chronic renal failure, kidney function diminishes gradually and permanently over months or years.

Both types of renal failure are characterized by **azotemia** (accumulation of nitrogenous wastes in the blood) and sometimes **oliguria** (reduced urine volume for age), indicating the kidney's inability to excrete metabolic waste products. Chronic renal failure eventually results in **anuria** (absence of urine output).

Acute Renal Failure

Acute renal failure (ARF), also called *acute kidney injury*, is a sudden loss of adequate renal function in which the kidneys are unable to clear metabolic wastes and to regulate extracellular fluid volume, sodium balance, and acid–base homeostasis. Potential causes include hemolytic-uremic syndrome, acute glomerulonephritis, sepsis, poisoning, nephrotoxic medications, hypovolemia, obstructive uropathy, and complication of cardiac surgery.

ETIOLOGY AND PATHOPHYSIOLOGY

Acute renal failure may be caused by prerenal or postrenal factors as well as actual kidney damage. Prerenal ARF is a result of decreased perfusion to an otherwise normal kidney in association with a systemic condition. Hypovolemia secondary to dehydration is generally the cause; however, alterations in renal vasculature or cardiac function may also precipitate prerenal ARF. This is the most common type of ARF in infants and young children (Lum, 2014).

TABLE 26–6 Clinical Manifestations of Acute Versus Chronic Renal Failure

TYPE OF RENAL FAILURE	CLINICAL MANIFESTATIONS
Acute renal failure	Dark urine or gross hematuria, headache, edema, fatigue, crackles, gallop heart rhythm, hypertension, hematuria, lethargy, nausea and vomiting, oliguria Mass in flank area if a cyst, tumor, or obstructive lesion is present
Chronic renal failure	Fatigue, malaise, poor appetite, nausea and vomiting, failure to thrive or short stature May have oliguria or polyuria Headache, decreased mental alertness or ability to concentrate Chronic anemia, hypertension, edema Fractures with minimal trauma, rickets, valgus deformity

Primary kidney damage (intrinsic factors) may result from infection, diseases such as hemolytic-uremic syndrome, acute glomerulonephritis, and acute tubular necrosis, and nephrotoxic injury (Lum, 2014).

Postrenal ARF is generally found in newborns with urologic anatomic anomalies (Lum, 2014). Children may have oliguria or normal or increased urine output. Renal failure without oliguria usually indicates a less severe renal injury. Children who recover from ARF may have residual kidney damage and compromised renal function.

CLINICAL MANIFESTATIONS

Characteristically, a healthy child suddenly becomes ill with nonspecific symptoms that indicate a significant illness or injury (e.g., nausea, vomiting, lethargy, edema, gross hematuria, oliguria, and hypertension). These symptoms are a result of electrolyte imbalances, uremia, and fluid overload. The child appears pale and lethargic. See Tables 26–6 and 26–7 for more information.

Hyperkalemia is the most life-threatening electrolyte disorder associated with ARF. Hyponatremia affects central nervous system function, resulting in symptoms that range from fatigue to seizures. Edema occurs as a result of sodium and water retention. (Refer to Chapter 18 for a discussion of these fluid and electrolyte alterations.) Children with ARF are also more susceptible to infection because of depressed immune functioning. **Uremia** occurs when there is an excess of urea and other nitrogenous waste products in the blood. Neurologic symptoms from accumulating wastes may include headache, seizures, lethargy, and confusion.

CLINICAL THERAPY

Diagnosis of renal failure is based primarily on urinalysis and blood chemistry results, including BUN, serum creatinine, sodium, potassium, and calcium levels (Table 26–8). The kidneys are normal in size, and no signs of renal **osteodystrophy** (a complex bone disease process of chronic kidney disease in which there is increased resorption of bone caused by chronic hyperparathyroidism) are found on radiography. Various imaging studies to assess kidney structures, renal blood flow, and renal perfusion and function may be performed to determine whether the child has ARF or chronic renal failure. A renal biopsy may be required.

Treatment depends on the underlying cause of the renal failure. The goal is to minimize or prevent permanent renal damage while maintaining fluid and electrolyte balance and managing complications. Initial emergency treatment of children with fluid depletion focuses on rapid fluid replacement of saline or lactated Ringer solution at 20 mL/kg given rapidly over 5 to 10 minutes and repeated as needed to ensure renal perfusion and stabilize blood pressure. Albumin may also be administered when blood loss is the cause of circulatory depletion. If oliguria persists after restoration of adequate fluid volume, intrinsic renal damage is suspected.

Children with fluid overload, such as those with pulmonary edema, require diuretic therapy, and dialysis if they respond poorly to diuretics. Once the child is stabilized, fluid requirements are calculated to maintain zero water balance (intake should equal urine output and insensible fluid loss). All potential sources of potassium should be eliminated until hyperkalemia is controlled. Other electrolyte imbalances are treated. Nutrition must be maintained with extra carbohydrate intake during the catabolic state. Antibiotics are prescribed for infection if applicable. Nephrotoxic antibiotics such as aminoglycosides (e.g., gentamicin, vancomycin) should be avoided.

TABLE 26–7 Clinical Manifestations of Electrolyte Imbalances in Acute and Chronic Renal Failure

ELECTROLYTE IMBALANCE AND CAUSE	CLINICAL MANIFESTATIONS
HYPERKALEMIA	
Results from inability to adequately excrete potassium derived from diet and catabolized cells. In metabolic acidosis, there is also movement of potassium from intracellular fluid to extracellular fluid.	• Peaked T waves, widening of QRS waves on ECG • Dysrhythmias • Muscle weakness
HYPONATREMIA	
In the acute oliguric phase, hyponatremia is related to the accumulation of fluid in excess of solute.	• Change in level of consciousness • Muscle cramps • Anorexia • Abdominal reflexes, depressed deep tendon reflexes • Cheyne-Stokes respirations • Seizures
HYPOCALCEMIA	
Phosphate retention (hyperphosphatemia) depresses the serum calcium ion concentration. Calcium is deposited in injured cells. Hyperkalemia and metabolic acidosis may mask the common clinical manifestations of severe hypocalcemia.	• Muscle tingling • Changes in muscle tone • Seizures • Muscle cramps and twitching • Positive **Chvostek sign** (contraction of facial muscles after tapping facial nerve just anterior to parotid gland)

Note: See Chapter 18 for more information related to these alterations in electrolytes.

Source: Data from Hines, E. Q. (2012). Fluid and electrolytes. In *The Harriet Lane handbook* (19th ed., pp. 271–292). Philadelphia, PA: Elsevier Saunders; Sreedharan, R., & Avner, E. D. (2016). Renal failure. In R. M. Kliegman, B. F. Stanton, J. W. St. Geme, & N. F. Schor (Eds.), *Nelson textbook of pediatrics* (20th ed., pp. 2539–2547). Philadelphia, PA: Elsevier; Verive, M. J. (2013). *Pediatric hyperkalemia*. Retrieved from http://emedicine.medscape.com/article/907543-overview

Some children whose ARF is unresponsive to management require dialysis to correct severe electrolyte imbalances, manage fluid overload, and cleanse the blood of waste products. The clinical situation and age of the child determine whether hemodialysis or peritoneal dialysis is used. Refer to the *Renal Replacement Therapy* section later in this chapter.

Prognosis depends on the cause of ARF. When renal failure results from drug toxicity or dehydration, the prognosis is generally good. However, ARF that results from diseases such as hemolytic-uremic syndrome or acute glomerulonephritis may be associated with residual kidney damage.

TABLE 26–8 Diagnostic Tests for Renal Failure

DIAGNOSTIC TESTS	FINDINGS IN RENAL FAILURE
URINALYSIS	
pH	Acidic urine
Osmolarity	Greater than 500: prerenal ARF Less than 350: intrinsic ARF
Specific gravity	Greater than 1.020: prerenal ARF Less than 1.010: intrinsic ARF
Protein	Positive
Blood	Positive
SERUM CHEMISTRY*	
Potassium	Elevated
Sodium	Normal, low, or high; depends solely on the amount of water in the body
Calcium	Low
Phosphorus	High
Urea nitrogen	Increased
Creatinine	Increased
pH	Low acidic

Note: *Please refer to Appendix D for normal values for various ages.
ARF = acute renal failure.

Source: Data from Sreedharan, R., & Avner, E. D. (2016). Renal failure. In R. M. Kliegman, B. F. Stanton, J. W. St. Geme, N. F. Schor, & R. E. Behrman (Eds.), *Nelson textbook of pediatrics* (20th ed., pp. 2539–2547). Philadelphia, PA: Elsevier; Workeneh, B. T., Agraharkar, M., & Gupta, R. (2014). *Acute kidney injury*. Retrieved from http://emedicine.medscape.com/article/243492-overview

SAFETY ALERT!

Nephrotoxic drugs include the following:

- Antimicrobials: aminoglycosides, cephalosporins, tetracycline, sulfonamides
- Radiographic contrast media with iodine (typically used for CT scans)
- Heavy metals: lead, barium, iron
- Nonsteroidal anti-inflammatory drugs: indomethacin, aspirin, ibuprofen

Nursing Management

For the Child With Acute Renal Failure

Nursing Assessment and Diagnosis

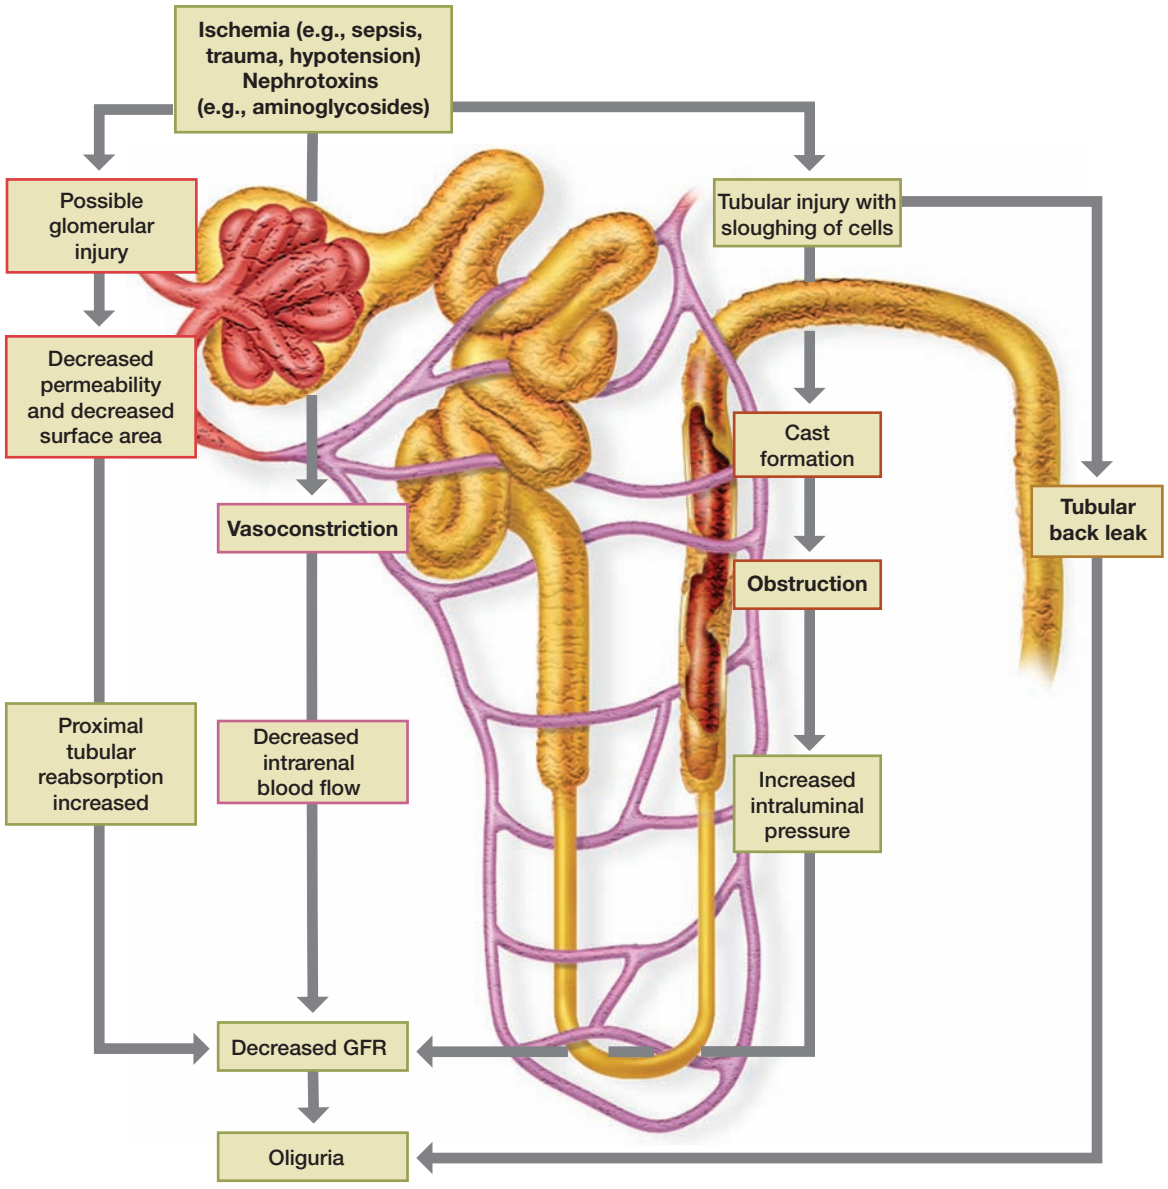
A complete history and physical examination are necessary to identify progression of symptoms and possible causes of renal failure.

PHYSIOLOGIC ASSESSMENT

Assess vital signs, level of consciousness, and other neurologic indicators to help identify clinical signs of electrolyte imbalance (see Table 26–7). Measure the child's weight on admission to

Pathophysiology Illustrated: **Acute Renal Failure**

The initial kidney injury is usually associated with an acute condition such as sepsis, trauma, or hypotension or is the result of treatment for an acute condition with a nephrotoxic medication. Injury to the kidney can occur because of glomerular injury, vasoconstriction of capillaries, or tubular injury. All consequences of injury lead to decreased glomerular filtration and oliguria.



provide a baseline for evaluating changes in fluid status. Monitor urinalysis, urine culture, and blood chemistry studies. Inspect urine for color, specific gravity, amount, and odor. Cloudy urine may indicate infection; tea-colored urine suggests hematuria. Assess urine specific gravity and intake and output.

PSYCHOSOCIAL ASSESSMENT

The unexpected and acute nature of the child's hospitalization creates anxiety for both parents and child. Assess for feelings of anger, guilt, or fear associated with the hospitalization. Such feelings are likely if ARF developed as a result of dehydration, a preventable injury, or poisoning. Assess coping mechanisms, family support systems, and level of stress.

Several nursing diagnoses may apply to the child with ARF, including the following (NANDA-I © 2014):

- ***Perfusion: Renal, Risk for Ineffective,*** related to hypovolemia, sepsis, or drug
- ***Fluid Volume: Excess*** related to renal dysfunction and sodium retention
- ***Nutrition, Imbalanced: Less than Body Requirements,*** related to anorexia, nausea, vomiting, and catabolic state

- ***Infection, Risk for,*** related to invasive procedures and monitoring equipment, and diminished immune functioning
- ***Coping: Family, Compromised,*** related to sudden hospitalization and uncertain prognosis of child

Planning and Implementation

Nursing care focuses on preventing complications, maintaining fluid balance, administering medications, meeting nutritional needs, preventing infection, and providing emotional support to the child and parents.

PREVENT COMPLICATIONS

Complications are best prevented by ensuring compliance with the treatment plan. Careful monitoring of vital signs, intake and output, serum electrolytes, and level of consciousness can alert the nurse to changes that indicate potential complications.

MAINTAIN FLUID BALANCE

Estimate the child's fluid status by monitoring of intake and output and blood pressure 2 or 3 times daily. Also obtain a weight at least daily on the same scale at the same time of day. Monitor serum chemistry values, especially for sodium and potassium.

If the child has oliguria, limit fluid intake (including parenteral nutrition) to replacement of insensible fluid loss (what is excreted by the lungs, skin, and gastrointestinal tract), which is about one third the daily maintenance requirements in afebrile children. If the child is febrile, fluid requirements are increased. See Chapter 18.

Clinical Tip

The child with **renal insufficiency** is at greater risk for fluid loss with illness. In cases of acute gastrointestinal illness, children are at greater risk for dehydration.

ADMINISTER MEDICATIONS

Because the kidney's ability to excrete drugs is impaired in ARF, dosages of all medications should be adjusted. The actual dosage of the drug can be reduced or the time interval between doses may be increased. Check drug levels to monitor for drug toxicity and know the signs of drug toxicity for each medication the child is receiving.

MEET NUTRITIONAL NEEDS

Children are at risk for malnutrition because of their high metabolic rate during ARF. Parenteral or enteral feeding may be used initially to minimize protein catabolism. The diet is tailored to the individual child's need for calories, carbohydrates, fats, and amino acids or protein hydrolysates. Depending on the degree of renal failure, sodium, potassium, and phosphorus may be restricted. Initiate oral feeding as soon as tolerated.

PREVENT INFECTION

The child with ARF is extremely susceptible to hospital-acquired infections because of altered nutritional status, compromised immunity, and numerous invasive procedures. Thorough hand hygiene and standard precautions are imperative to decrease the risk of infection. Use sterile technique for all invasive procedures and when caring for lines. Drainage from catheter sites should be cultured to check for the presence of infectious organisms. Assess vital signs and lung sounds frequently.

PROVIDE EMOTIONAL SUPPORT

The sudden onset of ARF presents parents with an unexpected threat to their child's life. Both the child and the parents experience anxiety because of the unexpected hospitalization and the uncertainty of the prognosis. Parents often feel guilty, regardless of the cause of renal failure. Guilt is intensified if the parents feel there is something they could have done to prevent the condition. Encourage parents to verbalize their fears and help them work through feelings of guilt. Explain procedures and treatment measures to decrease anxiety. Encouraging parents and older siblings to participate in the child's care can increase their sense of control.

Developing Cultural Competence **Reducing Sodium in the Child's Diet**

Special effort is often needed to reduce the sodium in the diet of an Asian child. Sauces and seasonings for foods (soy sauce, mustards, monosodium glutamate, and garlic salt) are sodium rich even though the foods seasoned (rice, vegetables, shrimp, and chicken) are low in sodium. A child eating a diet of predominantly Mexican cuisine may also require significant modification because many of the foods are high in sodium and potassium. Individualized counseling and motivation are needed to encourage families to reduce the child's sodium intake and to use spices low in sodium when preparing meals.

DISCHARGE PLANNING AND HOME CARE TEACHING

Encourage parental involvement early in the child's hospitalization. Be sure parents understand the importance of administering medications correctly. Teach family members proper technique for measuring blood pressure so they can monitor the child's hypertension, if ordered. Make sure the parents can identify signs of progressive renal failure (see the following chronic renal failure discussion).

Diet counseling is a key component of discharge planning and is usually performed by a renal nutritionist. Depending on the degree of renal failure, the child's diet may include restrictions on protein, water, sodium, potassium, and phosphorus.

The parents should be given written guidelines listing appropriate food choices to assist in menu planning. Ethnic and cultural preferences should be considered when listing menu options.

Continued monitoring of renal function during follow-up examinations is critical as deterioration may occur over time. Referral to support groups can be helpful for both parents and children. The National Kidney Foundation is a source of numerous publications that are helpful to the child and family.

Evaluation

Expected outcomes of nursing care include:

- Kidney function is restored.
- Fluid, electrolyte, and acid–base balance is restored and maintained.
- Nutritional needs are met.
- The child does not acquire a secondary infection.

Chronic Renal Failure

Chronic renal failure (CRF) (also called chronic kidney disease) is a progressive, irreversible reduction in kidney function. The prevalence of CRF in children is approximately 18 per 1 million (Sreedharan & Avner, 2016).

ETIOLOGY AND PATHOPHYSIOLOGY

In children, CRF usually results from developmental abnormalities of the kidney or urinary tract, obstructed urine flow and reflux, hereditary diseases such as polycystic kidney disease, infections such as hemolytic-uremic syndrome, and glomerulonephritis (Lum, 2014).

The gradual, progressive loss of functioning nephrons ultimately results in **end-stage renal disease (ESRD)**. In ESRD, the kidneys can no longer maintain homeostasis and the child requires dialysis (Sreedharan & Avner, 2016).

The kidneys excrete excess acid in the body and regulate the body's fluid and electrolyte balance. Renal failure disrupts this fluid and electrolyte balance. As renal failure progresses, metabolic acidosis occurs because the kidneys cannot excrete the acids that build up in the body. Renal osteodystrophy occurs because the kidneys are unable to produce activated vitamin D or to excrete phosphorus, causing phosphorus levels to rise and serum calcium levels to fall. The parathyroid gland responds by drawing calcium and phosphorus from the bones to maintain the adequate serum calcium and phosphorus levels. Hypocalcemia may occur as the parathyroid glands become less responsive to vitamin D and lower serum calcium levels. Osteodystrophy increases the child's risk for spontaneous fractures (Sreedharan & Avner, 2016).

Growth retardation is caused by disturbances in the metabolism of calcium, phosphorus, and vitamin D; decreased caloric intake; and metabolic acidosis. Healthy kidneys also produce erythropoietin (the growth factor responsible for the production and maturation of red cells); lack of erythropoietin and progressive renal disease are the underlying causes of the anemia of CRF.

CLINICAL MANIFESTATIONS

Children with CRF frequently have no symptoms initially. As progression continues, renal insufficiency occurs with polyuria as the kidneys become unable to concentrate the urine. Symptoms such as pallor, headache, nausea, and fatigue become more common. Decreased mental alertness and ability to concentrate may be seen. The child may have anemia leading to tachycardia, tachypnea, and dyspnea on exertion. As the disease progresses, the child experiences a loss of appetite and has complications of renal impairment, including hypertension, pulmonary edema, growth retardation, osteodystrophy, delayed fine and gross motor development, and delayed sexual maturation. Refer to Table 26–6 to see how these signs contrast with signs of acute renal failure.

In ESRD, renal failure adversely affects all body systems. As the severity of the clinical and biochemical disturbances resulting from progressive renal deterioration increases, uremic symptoms develop. Signs and symptoms of uremic syndrome include nausea and vomiting, progressive anemia, anorexia, dyspnea, malaise, *uremic frost* (urea crystals deposited on the skin), unpleasant (uremic) breath odor, headache, progressive confusion, tremors, pulmonary edema, and congestive heart failure.

CLINICAL THERAPY

Laboratory evaluation, including serum electrolytes, phosphate, BUN, creatinine levels, and pH, is used to confirm the diagnosis of CRF. An early morning urine sample is collected for culture and to calculate the protein-to-creatinine ratio. The child's glomerular filtration rate is calculated from prediction equations using the serum creatinine level and the patient's height and gender. Imaging studies are performed to identify renal diseases that could be causing the renal failure. A renal biopsy may sometimes be performed.

Chronic renal failure is irreversible; however, the course of the disease is variable. Some children progress quickly to renal failure, necessitating dialysis. Other children are managed with a combination of medication and diet therapy for some time before significant renal impairment occurs. Frequent modifications in the treatment plan are often necessary to address the child's changing status.

Dietary management focuses on maximizing caloric intake for growth while limiting phosphorus, potassium, and sodium intake as needed to maintain electrolytes in balance (Sreedharan & Avner, 2016). Adequate calcium needs to be part of the meal plan. Enteral or parenteral feedings may be required to achieve optimal protein intake, especially in children under 1 year of age. Complex carbohydrates should be chosen along with vegetables and fruits that are lower in potassium. Vegetable oils, hard candy, sugar, honey, and jelly may be recommended to add calories to the child's diet. Medications used to treat children with CRF are discussed in the next table.

Children who progress to ESRD require renal replacement therapy. The timetable for dialysis or renal transplantation is different from that of adults; transplantation is the goal so the child has an optimal chance for a more normal childhood. Earlier initiation can prevent some complications of ESRD. In addition to the GFR, nonspecific signs such as uremic syndrome, poorly controlled hypertension, renal osteodystrophy, failure of head circumference measurement to increase normally, developmental delay, and poor growth are used in determining when to initiate renal replacement therapy. (Refer to the *Renal Replacement Therapy* section later in this chapter.)

Nursing Management

For the Child With Chronic Renal Failure

Nursing Assessment and Diagnosis

Nursing assessment focuses on identifying signs and symptoms of renal failure and associated complications as well as assessing the psychosocial effects of renal failure on the child and family.

PHYSIOLOGIC ASSESSMENT

The initial and ongoing assessment of the child focuses on identifying complications of renal failure. Observe for signs of hypertension, edema, poor growth and development, osteodystrophy, and anemia. Assess vital signs, particularly the blood pressure. Observe for signs of alterations in electrolyte balance.

PSYCHOSOCIAL ASSESSMENT

As renal disease progresses, the number of stressors on the child and family increases. Denial and disbelief are commonly the first reactions. A thorough family assessment can help to identify particular needs of the child and family. The development of ESRD is particularly challenging during childhood and adolescence because of differences in appearance and social, psychologic, and physical issues. Nonadherence to treatments can endanger the adolescent's life.

Nursing diagnoses for the child with CRF are similar to those previously listed for ARF. Additional diagnoses might include the following (NANDA-I © 2014):

- ***Social Interaction, Impaired,*** related to impaired immunity and hemodialysis schedule during school hours
- ***Activity Intolerance*** related to anemia and fatigue
- ***Health Management, Family, Ineffective,*** related to complexity of care plan and economic difficulties
- ***Body Image, Disturbed,*** related to short stature and visible external catheter for dialysis

Medications Used to Treat: Chronic Renal Failure

MEDICATION AND ACTION/INDICATION	NURSING IMPLICATIONS
Vitamin and mineral supplement (Nephrocaps) Adds vitamins and minerals missing from heavily restricted diet.	Only prescribed vitamins should be used; over-the-counter brands may contain elements that are harmful.
Phosphate binding agents: calcium carbonate (Tums), calcium acetate (PhosLo), or sevelamer hydrochloride (Renagel) Reduces absorption of phosphorus from the intestines.	Ensure that phosphate binding agent is aluminum-free.
Calcitriol (Rocaltrol) Replaces the calcitriol that kidneys are no longer producing to keep calcium balance normal.	Monitor serum calcium level. Ensure that calcium supplement is provided.
Epoetin alfa (Epogen, Procrit) Stimulates bone marrow to produce red blood cells, treats anemia due to CRF.	Given by IV or subcutaneous injection. Monitor blood pressure because hypertension is an adverse effect. Monitor hematocrit and serum ferritin levels according to facility guidelines.
Iron supplementation Treats iron deficiency when epoetin alfa is prescribed.	Give without food or other medications to maximize absorption.
Growth hormone (rhGH) Used to stimulate growth in children with CRF.	Record accurate height measurements at regular intervals.
Antihypertensive agents: angiotensin-converting enzyme (ACE) inhibitor (Enalapril, Lisinopril) Used with proteinuric kidney disease because it slows the progression to ESRD.	Monitor blood pressure.
Loop diuretics (Furosemide) Used when volume overload is present.	Monitor urine output and electrolyte balance.

Hoboken, NJ: Pearson Education.

Planning and Implementation

Children with CRF are usually hospitalized for one or more of the following reasons: initial diagnostic evaluation, dialysis treatment initiation, or problems with the treatment plan or infection. Nursing care for the hospitalized child with CRF focuses on monitoring for side effects of medications, preventing infection, meeting nutritional needs, and providing emotional support and anticipatory teaching.

MONITOR FOR SIDE EFFECTS OF MEDICATIONS

Assess for signs of electrolyte imbalance such as weakness, muscle cramps, dizziness, headache, and nausea and vomiting in children who are taking diuretics. Supervise the child's activities closely to prevent falls resulting from dizziness, especially at the beginning of diuretic therapy. If antihypertensive medications such as hydralazine are being administered, monitor the child's weight to detect excessive gain resulting from water and sodium retention.

PREVENT INFECTION

The child with CRF is susceptible to infections. Be alert for signs of infection, such as elevated temperature; cloudy, strong-smelling urine; dysuria; changes in respiratory pattern; or productive cough. Emphasize to the child and family the importance of good hand hygiene practices. Make sure the child receives the 23-valent pneumococcal vaccine and meningococcal vaccines in addition to usual childhood immunizations.

TABLE 26–9 Nutritional Information for the Child With Kidney Disease

Children with kidney disease have restricted diets, generally low in sodium, potassium, and phosphorus. A renal dietitian works with families of children with chronic renal failure to develop meal plans that fit a restricted diet. The nurse can help families remember that certain foods must be avoided or eaten in very small quantities by reviewing this table.

HIGH-SODIUM CONTENT FOODS	HIGH-POTASSIUM CONTENT FOODS	HIGH-PHOSPHORUS CONTENT FOODS
Soups and sauces: e.g., gravy, spaghetti and tomato sauce, barbeque sauce, steak sauce	*Fruit:* apricots, avocados, bananas, citrus fruits, fresh pears, nectarines, dates, figs, cantaloupe and other melons, prunes, and raisins	*Dairy products:* milk, cheese, yogurt, custard, pudding, ice cream
Processed lunch meats: e.g., bologna, ham, salami, hot dogs	*Vegetables:* celery, dried beans, lima beans, potatoes, leafy greens, spinach, tomatoes, winter squash	Dried beans, peas
Smoked meat and fish: bacon, chipped beef, corned beef, ham, lox	*Whole grains:* especially those containing bran	Nuts, peanut butter
Sauerkraut, pickles, and other pickled foods	Sardines, clams	Chocolate
Seasonings: horseradish, soy sauce, Worcestershire sauce, meat tenderizer, and monosodium glutamate (MSG)	Peanuts	Dark cola
	Dairy products: milk, ice cream, pudding, yogurt	Sausage, hot dogs
	Potassium-containing salt substitutes	

MEET NUTRITIONAL NEEDS

Maintaining adequate nutritional intake in a child with CRF who has dietary restrictions is challenging. Provide small, frequent feedings and present meals attractively to encourage the child to eat. A nutritionist works with the child and family to develop meal plans that meet the nutritional requirements and acknowledge the child's preferences. See Table 26–9 for foods that children with CRF should avoid.

MAINTAIN FLUID RESTRICTIONS

Plan the child's oral intake through the entire 24 hours to ensure that the child has some fluids with meals, when taking medications, and when thirsty. Keep in mind that many foods have a high fluid content (gelatin, fruit-flavored ice pops) and must be counted toward the daily fluid allowance. Use medicine cups or small cups for fluids given. Encourage parents and visitors to avoid drinking in the child's presence. Ensure that all visitors know and understand the importance of maintaining the child's fluid restriction.

PROVIDE EMOTIONAL SUPPORT

Progressive CRF requires a total lifestyle change for the child and family. The parents and child need opportunities to express and work through their feelings related to the disease, prognosis, and treatment restrictions. Help children express their feelings through drawings or therapeutic play.

The need for ongoing dialysis treatments and the wait for a suitable donor kidney are stressful for both parents and children. Identify effective coping methods and family support systems to promote treatment compliance. The National Kidney Foundation and local support groups for kidney disease can give the family information or additional support.

DISCHARGE PLANNING AND HOME CARE TEACHING

Parents need to understand the necessity of long-term treatments and follow-up care. Help the family develop a schedule for medication administration that fits with their routine. Emphasize the importance of consistency in administration times. Teach parents how to recognize medication side effects and complications.

Appropriate referrals are made to home care nursing agencies as indicated. Parents of children receiving peritoneal dialysis at home are taught how to perform the treatment and how to identify complications. Strict aseptic technique is necessary to prevent infection at the catheter site and peritonitis.

COMMUNITY-BASED NURSING CARE

Children with CRF require frequent outpatient visits to monitor the progression of signs and symptoms, and to evaluate the effectiveness of current treatments. The blood pressure is monitored. Blood and urine tests are performed to monitor renal function. Radiographs of the bones are often taken at 6-month intervals to assess changes caused by osteodystrophy. See *Health Promotion: The Child With Chronic Renal Failure*.

Encourage parents to register the young child for an early intervention program to promote development and interaction with other children. The dialysis schedule for school-age children should enable the child to participate in school, or home tutoring should be provided.

School-age children and adolescents are often embarrassed about being seen as different from peers. Ask them how they feel about the need to follow a special diet, take medications, and undergo dialysis treatments. To minimize the psychologic consequences of coping with a chronic disease, encourage parents to promote the child's participation in age-appropriate activities. Attendance at school and contact with peers promote normal growth and development. Work to promote the child's self-worth and a healthy self-esteem. Encourage adolescents to participate in a program that helps them transition to adult health services and job skill training. Begin teaching the child during early adolescence about the health condition, about medications taken and their actions, how to access emergency help, and about problems caused by not adhering to treatment. As the adolescent ages, have the family begin giving more responsibility for self-care, such as making appointments for health care, obtaining prescription refills, and seeking out healthcare providers for adult patients and a dialysis program. (See *Evidence-Based Practice: Living With Chronic Kidney Disease*.) As the child's renal impairment progresses, give the parents timely information about the disease process, dialysis treatments, and issues related to renal transplantation.

Health Promotion The Child With Chronic Renal Failure

Growth and Development Surveillance

- Compare the child's height, weight, and head circumference to age-specific norms to identify growth retardation and to plot progress.
- Assess developmental progress using the Denver II or another screening tool (refer to Chapter 6).
- Educate the parents on normal developmental milestones and measures to promote achieving those milestones.
- Assess the adolescent for signs of delayed sexual maturation and, in girls, amenorrhea.

Nutrition

- Review the dietary restrictions with the child and parents.
- Partner with the family to assist the child to make good food selections and to restrict fluids and sodium as necessary, taking into account the child's likes and dislikes and cultural background. Encourage the child and family to take a list of a few favorite foods to the dietitian to see if they can be integrated into the child's meal plan.
- Make mealtime pleasant and make foods taste more appealing with permitted spices.
- Discuss possible behavioral responses by older children and adolescents to dietary restrictions and limitations imposed by the treatment plan. Involve the child and adolescent in discussions about dietary restrictions, and when possible integrate their recommendations for dietary restrictions and fluid management throughout the day.
- Emphasize to the school-age child that dietary and other restrictions are not punishment.
- Use enteral feeding at night to provide the needed calories for growth.

Physical Activity

- Encourage the child to participate in developmentally appropriate activities as tolerated.
- Partner with the child to establish a routine plan for physical activity as tolerated that will help promote strong bones.

Oral Health

- Promote good dentition and oral hygiene.
- Schedule regular dental visits for examinations and cleaning to reduce infections.
- Partner with the family to ensure they understand the need for antibiotic prophylaxis before certain invasive procedures, including dental care.

Mental and Spiritual Health

- Ask children how they feel about the need to follow a special diet, take medications, and undergo dialysis treatments. Ask what might make it easier for them to cope with the treatments, and integrate at least one idea into the care plan.
- Encourage parents to promote their child's participation in age-appropriate activities to minimize the psychologic consequences of coping with a chronic disease.
- Adolescents often resent the dietary restrictions and ongoing dialysis treatments, which pose a threat to their independence, evolving sense of self, and their need for independence. Noncooperation, depression, and hostility are common responses.
- Assist adolescents to begin the transition to adult health services.

Relationships

- Attendance at school and contacts with peers promote normal growth and development.
- Work to promote the child's self-worth and a healthy self-esteem.
- Prepare the child for peer conflict.
- Ensure that parents understand the importance of encouraging normal socialization of their child.

Disease Prevention Strategies

- Partner with the child and family to establish plans to avoid large crowds, people with infections, or other risks that expose the child to infection.
- If possible, all immunizations should be provided before renal transplantation, as long-term immunosuppressive therapy will then be prescribed.
- Live vaccines should not be given to the child taking immunosuppressive agents.
- Encourage the family to maintain scheduled appointments for routine serum and urine diagnostic tests performed to monitor renal function.

Evaluation

Expected outcomes of nursing care include:

- The child's fluid status is maintained.
- The child eats foods that meet nutritional needs while adhering to dietary restrictions.
- Growth and developmental milestones are achieved.

Renal Replacement Therapy

Renal replacement therapy is the treatment for renal failure and includes both dialysis and renal transplantation. The preferred method of dialysis is generally dependent on the age of the child. Currently, 88% of children 5 years of age and younger are treated with peritoneal dialysis, while 54% of children older than 12 years of age are treated with hemodialysis (Sreedharan & Avner, 2016).

EVIDENCE-BASED PRACTICE | Living With Chronic Kidney Disease

Clinical Question

Chronic kidney disease is a serious chronic condition that requires significant adaptations in lifestyle and complex medical treatments that take a toll on the child and family. What is the impact of this condition on children?

The Evidence

Heath et al. (2011) used the Generic Children's Quality of Life Measure to explore the impact of chronic kidney disease (CKD) on 225 pediatric patients ranging in age from 6 to 18 years. Of these patients, 49 had advanced CKD, 128 were posttransplant, and 47 were on dialysis. Results of the study showed that there was no difference between the mean quality-of-life scores in children who were in different treatment modalities. Age and gender did not affect the mean score. The study also showed that children ages 6 to 14 with CKD had significantly higher quality-of-life scores than children of the same age in the general population. While this was a surprising finding, it emphasized the fact that children with chronic conditions can perceive their quality of life as good despite having challenges with their health. These results could also be related to the psychosocial care provided by the renal team.

Al-Uzri et al. (2013) evaluated the effect of short stature on the health-related quality of life (HRQoL) in children with CKD. Short stature is common in children with CKD. Data collected as part of a larger multicenter Chronic Kidney Disease in Children study was used for the focus of this study. The participants were 483 children and/or parents who were enrolled in the larger study and had completed at least 2 evaluations of their HRQoL. The Pediatric Qualilty of Life Inventory (pedsQL) was used to assess physical, emotional, social, and school functioning. Parents completed the parent proxy version of the form. Results of the study demonstrated that parent-reported physical HRQoL was lower in the short stature group than the normal height group, although this was not statistically significant. Assessment of catch-up growth and its impact on HRQoL revealed that an increase in the height *z*-score was related to a 7-point increase in the parents' perception of the child's physical and social functioning; however, there was no association between catch-up growth and the child's pedsQL score. Analysis of pedsQL scores in the 58 children who were taking growth hormone versus those who were not did not reveal a relationship; however, there was a significant impact of improved height *z*-scores with growth hormone use on parents' perceptions of physical and social functioning. Additionally, children ages 15 to 17 with CKD had significantly higher rates on the pedsQL inventory than their parents in all areas except for school functioning. There was a high level of agreement between children ages 8 to 14 and their parents on all aspects of the inventory except emotional functioning, with the child having lower scores than their parents' perception. The results of this study support the need for interventions that improve height in children with CKD. It also demonstrates the importance of evaluating both the perception of the child and the parents.

Research by Kilis-Pstrunsinska et al. (2013) evaluated the HRQoL in Polish children with CKD using the Pediatric Quality of Life Inventory. Participants in the study were 203 children with CKD and 388 parent/proxies. This study found that children with CKD had significantly lower HRQoL scores compared to international population norms for healthy children. Results also showed that children on dialysis had lower scores in physical and social functioning than those treated conservatively. Additionally, patients on hemodialysis had significantly lower overall scores than children treated conservatively or with peritoneal dialysis. In children who were treated conservatively, stage of disease did not affect scores. Differences were also noted between parent/proxy scores and the child. The differences varied depending on the severity of the disease and the intensity of the treatment plan.

Best Practice

Effects of chronic illness in children and adolescents can be both physically and psychosocially overwhelming. It is important to evaluate quality of life in children with chronic illness in order to better understand their responses to the illness and treatment (Heath et al., 2011). Children of different ages may view their quality of life differently. Their view may also be different depending on the severity of their disease, their current treatment plan, and the amount of support they have received. Parents' views of their child's quality of life may vary from that of the child. It is essential that nurses assess each child and family member individually to determine their view of the illness and its impact on their life. This will assist the nurse to develop an effective care plan for the child and family and coordinate additional support for them as needed.

Clinical Reasoning

Initiate a discussion with an older school-age child or adolescent with CKD. Listen to their description of living with the condition. Develop a nursing care plan to help the child take the next steps in self-management.

PERITONEAL DIALYSIS

In peritoneal dialysis, the peritoneum of the abdomen is the membrane through which the body's waste products pass from the blood to the abdominal cavity. A catheter is inserted through the abdominal wall into the peritoneal cavity. In children receiving peritoneal dialysis for ARF, a percutaneously placed catheter can be used for a few weeks. In children with CRF, a catheter is placed surgically for long-term use. The dialysis solution (**dialysate**) that enters the abdomen typically contains dextrose that pulls body wastes and extra fluid into the abdominal cavity. These wastes and extra fluid leave the body with the drained dialysate. This method of dialysis is beneficial to small children since it allows continuous removal of fluids and waste products, decreasing the toxic effects of waste products on the child's developing body. The child can ambulate and interact with the environment. The timing of the treatment can be set to minimize the interruption of school, play, or other social events.

Two types of peritoneal dialysis are commonly used: continuous ambulatory peritoneal dialysis (CAPD) and automated

TABLE 26–10 Complications of Peritoneal Dialysis

COMPLICATIONS AND MANIFESTATIONS	CAUSE
PERITONITIS	
Cloudy dialysate, abdominal pain, tenderness, leukocytosis, fever (neonatal hypothermia), constipation	*Staphylococcus aureus, S. epidermidis,* fungal infections, gram-negative rods (risk is proportional to duration of dialysis and inversely proportional to age)
PAIN	
During inflow	Too rapid a rate of infusion, too large a volume of dialysate, encasement of catheter in a false passage, extremes in temperature of dialysate
During outflow at end of emptying	Omentum entering catheter at end of outflow
LEAKAGE	
Fluid around catheter, edema of penis or scrotum secondary to leakage into abdominal subcutaneous tissue, fluid leakage to pleural spaces through diaphragm	Overfilling of abdomen, catheter that has migrated from peritoneal cavity
RESPIRATORY SYMPTOMS	
Shortness of breath, decreased breath sounds in lower lobes, inadequate chest expansion	Abdominal fullness that compromises diaphragm movement, hole in diaphragm allowing dialysate into chest cavity

peritoneal dialysis (APD). Graduated cylinders are used to monitor the volume of fluid exchanged.

- CAPD uses gravity to instill prefilled bags of dialysate into the peritoneal cavity 4 or 5 times a day. The fluid remains in the cavity for 4 to 8 hours. The attached bag is folded under the child's clothes, permitting normal activity. After the allotted time, the dialysate is drained by hanging the bag lower than the pelvis. The repeated connections and disconnections with this method are time consuming for the child and family and increase the risk of infection.
- APD uses an automatic cycler to instill and drain the dialysate about 5 times over a 10-hour period, usually overnight. One additional exchange may be needed during the day. With this method, the number of connections and disconnections is minimized, which reduces demands on the family as well as the risk of infection. Infants and young children on peritoneal dialysis generally receive APD while they sleep (Zaritsky & Warady, 2011).

Peritonitis is a common complication of peritoneal dialysis. See Table 26–10. Peritonitis is treated with antibiotics infused in the dialysate (Mehrazma, Amini-Alavijeh, & Hooman, 2012).

Teach the family to perform peritoneal dialysis and to use sterile technique when performing dialysis and when doing catheter care. Peritoneal dialysis is time consuming, and family members must be committed to managing this procedure daily. Help the family develop home routines that minimize disruptions to daily family life. For additional information, refer to *Nursing Care Plan: The Child Receiving Home Peritoneal Dialysis*.

HEMODIALYSIS

Hemodialysis is a process in which the blood flows from the patient through a machine with a special filter that removes body wastes and extra fluids. Blood is pumped out of the body and through a dialyzer, where waste products and extra fluids diffuse out across a semipermeable membrane, before the blood is returned to the body. Dialysate is pumped in the direction opposite blood flow to promote waste extraction. Differences in osmolarity and concentration between the child's blood and the dialysate alter the intravascular electrolyte concentration and reduce the intravascular volume.

Clinical Tip

The dominant sign of peritonitis associated with peritoneal dialysis is cloudy dialysate. Other signs and symptoms may include fever, vomiting, diarrhea, abdominal pain, and tenderness. The nurse monitors for these symptoms and ensures that the child and family can recognize the symptoms and report them immediately.

Hemodialysis is used in the critical care setting and for those children with CRF when peritoneal dialysis is not possible for technical reasons, after repeated peritonitis, or when the family is unable to provide peritoneal dialysis safely. Hemodialysis for children is offered in a special dialysis center on an outpatient basis, or it can be performed at bedside during hospitalization. Treatment is usually performed 3 times a week, with each session lasting approximately 3 to 4 hours.

Children over 20 kg (44 lb) often have an arteriovenous (AV) fistula (connection between an artery and a vein) created for long-term vascular access. Alternatively, a synthetic tube can be implanted under the skin, creating a graft between the arterial and venous circulation to provide vascular access. Two needles are inserted into the arteriovenous fistula or the graft: one to carry blood to the dialyzer and one to return cleaned blood to the body. In emergencies and for infants, a double-lumen cannula is inserted into a large vein (e.g., the femoral, jugular, or subclavian vein) for hemodialysis.

Hemodialysis is more efficient than peritoneal dialysis but requires close monitoring for symptoms related to hypotension or rapid changes in fluid and electrolyte balance. Uncommonly, a **disequilibrium syndrome** (rapid changes in the body's water and electrolyte balance during treatment) may occur during or soon after the dialysis procedure is first initiated. Other complications include access thrombosis and infection. Heparin is used to reduce the risk of thrombosis.

Nursing management focuses on care of the child during dialysis and teaching the child and family about the administration of heparin and the control of bleeding from minor trauma. Carefully monitor fluid balance in the child undergoing hemodialysis. Check vital signs and blood pressure every half hour. Monitor oral intake and urinary output every half hour when the child is on the dialysis equipment. Weigh the child before and

Nursing Care Plan: The Child Receiving Home Peritoneal Dialysis

1. Nursing Diagnosis: *Nutrition, Imbalanced: Less than Body Requirements,* related to poor appetite, feeling of fullness after a small amount, and loss of protein in dialysate (NANDA-I © 2014)

GOAL: The child will obtain adequate nutrients each day.

INTERVENTION	RATIONALE
• Develop a meal plan in collaboration with a nutritionist to identify the amounts of essential nutrients needed.	• Parents need concrete guidelines for food preparation.
• Provide small, frequent meals of needed nutrients.	• The child will feel full with smaller amounts of food because of the dialysate.
• Make mealtimes pleasant and avoid battles over the child's intake.	• The child will be more inclined to eat if there is less stress.
• Provide supplements by tube feeding if adequate oral intake is not possible.	• Adequate nutrition is important for growth and development, and must be supported if oral intake is inadequate.

EXPECTED OUTCOME: Child's intake will be adequate to maintain an expected growth pattern.

2. Nursing Diagnosis: *Infection, Risk for,* related to daily invasive procedure (NANDA-I © 2014)

GOAL: The child will not develop peritonitis.

INTERVENTION	RATIONALE
• Wash hands, use sterile gloves and aseptic technique for connection and disconnection of catheters.	• Aseptic technique reduces chance of introducing bacteria into the abdomen.
• Perform daily catheter site care.	• Skin around the catheter site will have fewer organisms that could potentially cause infection.

EXPECTED OUTCOME: Child will not develop peritonitis.

GOAL: If peritonitis occurs, it will be treated appropriately.

INTERVENTION	RATIONALE
• Observe for signs of infection (fever, abdominal pain, cloudy dialysate).	• Early identification of infection will reduce complications.
• Report signs of infection to healthcare provider immediately.	• Rapid intervention may reduce need for hospitalization.

EXPECTED OUTCOME: Hospitalization will not be needed for peritonitis because of early identification and prompt treatment.

3. Nursing Diagnosis: *Caregiver Role Strain* related to daily dialysis treatments (NANDA-I © 2014)

GOAL: The family will cope with daily demands for the child's dialysis treatments.

• Discuss the importance of daily, consistent dialysis treatments for the child's overall health status.	• If parents understand the need for consistent dialysis treatments, they are more likely to adhere to guidelines.
• Collaborate with the family to identify strategies that could reduce the impact of dialysis on the family's life.	• When the family participates in planning care, adherence is more likely.
• Refer the family to local support groups for emotional support, treatment strategies, and respite care.	• Support groups may help the family develop effective coping strategies.

EXPECTED OUTCOME: Family will adhere to daily dialysis treatment guidelines.

after the dialysis to determine any fluid imbalances that require adjustment during the next hemodialysis session.

SAFETY ALERT!

Monitor the child receiving hemodialysis for complications such as these that can occur suddenly:

- Hypotension—sudden nausea and vomiting, abdominal cramping, tachycardia, and dizziness
- Rapid fluid and electrolyte exchange—muscle cramping, nausea and vomiting, and dizziness
- Disequilibrium syndrome—restlessness, headache, nausea and vomiting, blurred vision, muscle twitching, and altered level of consciousness

Because fluid and dietary limitations (reduced intake of foods containing potassium, sodium, and phosphorus) are needed more often with hemodialysis than with peritoneal dialysis, make sure the family knows how to plan and provide for the child's daily nutritional needs. Review ways to reduce the risk of infection, including the daily care of the catheter site. Encourage showering rather than tub baths. Activities such as swimming may be discouraged.

KIDNEY TRANSPLANTATION

Kidney transplantation provides the only alternative to long-term dialysis for children with ESRD and generally yields good outcomes. The transplanted kidney can normalize physiology and provide a potential for normal growth. Because of the adverse effects on growth and development resulting from the delay of transplantation, children are given some priority over adults awaiting transplantation. Blood type compatibility between the donor and recipient is essential for a transplant to be successful. A human leukocyte antigen (HLA) system match also improves survival of the graft. A living relative donor kidney has a higher survival rate than a cadaver kidney (Scheinman, 2012). Children and their families are carefully screened prior to transplantation in an effort to identify problems that could lead to rejection of the kidney or infection that could be life threatening if the immune system is suppressed (Figure 26–6).

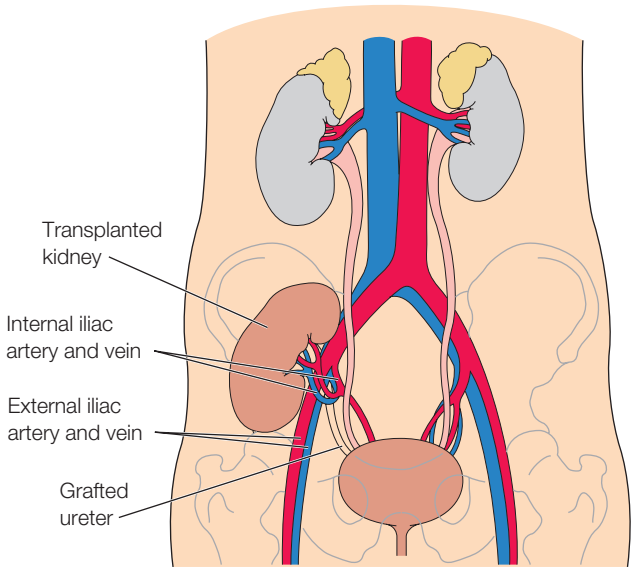

Figure 26–6 **The transplanted kidney is placed in the iliac fossa with anastomosis to the hypogastric artery, iliac vein, and bladder.**

Clinical Reasoning **The Child on Hemodialysis**

Terrell, who is now 5 years old, was born with posterior urethral valves, which caused damage to his kidneys. Despite undergoing surgery to correct the defect during infancy, his kidney function continued to deteriorate. End-stage renal disease was diagnosed 2 years ago, and dialysis treatment was initiated. Terrell requires a kidney transplant, but in the meantime he is being treated with hemodialysis. He visits the dialysis center 3 afternoons a week for treatments lasting approximately 3 to 4 hours. This schedule permits him to attend kindergarten classes in the morning.

At his scheduled visit to the nephrologist, Terrell has gained weight and is edematous. In talking with him, the nurse discovers that Terrell has been drinking sodas and eating "junk food" at school. Terrell asks the nurse not to tell his mother because she will be mad, but that he just can't help eating and drinking what he isn't supposed to.

How does Terrell's growth and development level affect his adherence to the treatment regimen? What immediate intervention should the nurse take with Terrell? What approach should the nurse take when discussing this nutritional issue with the family?

After transplantation, the child must take immunosuppressive medications such as corticosteroids, azathioprine, cyclosporine, tacrolimus, and monoclonal antibodies to suppress rejection. Immunosuppression regimens use various combinations and sequences of these drugs to reduce the incidence of acute and chronic rejection.

Complications of immunosuppressive therapy include opportunistic infection, lymphomas and skin cancer, and hypertension. Adherence with therapy is essential for survival of the graft and for optimal medical outcomes after transplant. Nonadherence to the medication regimen in pediatric transplant patients ranges; it may be as high as 70% (Guilfoyle, Goebel, & Pai, 2011; Ingerski, Perrazo, Goebel, et al., 2011). Nonadherence is related to several factors, including forgetting to take medication and refusal to take medication because of expected side effects. Family dynamics, functioning, and flexibility also affect adherence (Guilfoyle et al., 2011). Adherence is higher in adolescents when their parents are knowledgeable and supportive, and when they promote the adolescent to become competent in self-care. Some primary kidney diseases, such as glomerulonephritis and hemolytic-uremic syndrome, can also recur in the transplanted kidney.

Nursing management includes teaching parents about the transplantation process before it occurs to help prepare them for the experience. Discuss all aspects of the child's care that will have an impact on the family's life, including follow-up appointments, medications, and general health promotion. Monitor adherence to immunosuppression treatment at each visit in an effort to identify issues early. Teach parents about the signs of acute rejection and infection, including when and how to notify the child's healthcare provider if immediate care is required.

Hemolytic-Uremic Syndrome

Hemolytic-uremic syndrome (HUS) is the most common cause of acute renal failure in young children, occurring primarily in those under 4 years of age (Ring & Huether, 2014). HUS has a classic triad of signs: (1) hemolytic anemia, (2) thrombocytopenia, and (3) acute renal failure (Tan & Silverberg, 2014).

Hemolytic-uremic syndrome is most often caused by *Escherichia coli* strain O157:H7, which is found in undercooked meat and unpasteurized milk and juices (Tan & Silverberg, 2014). The bacteria has also been linked to petting zoos and other animal exhibits (Anderson & Weese, 2012).

E. coli strain O157:H7 produces a toxin that attaches to the glomeruli, collecting ducts, and distal tubules. The toxin damages the lining of the glomerular arterioles, causing the endothelial cells to swell and become occluded with platelets and fibrin clots. This partial occlusion damages the red blood cells, resulting in hemolytic anemia. Platelets cluster in areas of vascular endothelial damage, causing thrombocytopenia. Glomerular filtration is decreased, resulting in hematuria and proteinuria. Oliguria and ARF develop in nearly 50% of children with HUS (Ring & Huether, 2014).

An episode of severe gastroenteritis with diarrhea precedes the development of typical HUS by 1 to 2 weeks followed by 1 to 5 days without symptoms. Signs and symptoms of the onset of HUS include purpura, pallor, bruising, oliguria, and irritability. The child may have a fever, anorexia, abdominal pain, vomiting, watery blood-stained diarrhea, mild jaundice, and circulatory overload. Signs of central nervous involvement include seizures and lethargy (Ring & Huether, 2014).

Treatment focuses on the complications of ARF and includes fluid restrictions and a high-calorie, high-carbohydrate diet that is low in protein, sodium, potassium, and phosphorus. Enteral nutrition is sometimes needed. Medications may include calcium gluconate or calcium chloride, aluminum hydroxide gel to bind to phosphorus, Kayexalate (sodium polystyrene) to remove excess potassium, and antihypertensive agents. Transfusions of fresh-packed red blood cells may be ordered to treat severe anemia. Platelets are given if the child is bleeding or if surgery is needed.

Transfusions are carefully administered to prevent hypertension caused by hypervolemia. Approximately 50% of children with typical HUS will need dialysis in the acute phase (Balestracci, Martin, Toledo, et al., 2012). Peritoneal dialysis is preferred unless the child has severe colitis and abdominal tenderness. Some children may develop chronic renal failure; however, most regain normal renal function (Ring & Huether, 2014).

Nursing Management

Monitor vital signs, neurologic signs, and laboratory values including electrolytes and blood counts. Monitor daily weights and assess intake and output. Observe the child carefully for signs of progressive renal impairment such as oliguria, elevated serum potassium, and elevated creatinine. Monitor for signs of bleeding related to thrombocytopenia, including petechiae and ecchymosis. Monitor the child for abdominal discomfort from diarrhea or other gastrointestinal disturbances.

Discharge planning focuses on teaching parents about medications and dietary and fluid restrictions. Follow-up visits are necessary to evaluate the effectiveness of the treatment plan. Make sure that parents understand that ground beef should be cooked to an internal temperature of 160°F (71°C) (U.S. Department of Agriculture, 2013). Teach the family to wash hands carefully when handling raw ground meats, and to make sure utensils touching raw meat do not come into contact with cooked meats. Encourage the use of a meat thermometer since the absence of pink in the center of the meat does not ensure that the appropriate temperature has been achieved.

Polycystic Kidney Disease

Polycystic kidney disease (PKD) is a genetic disorder that has autosomal recessive and dominant forms. Liver abnormalities are associated with both forms of the disease. The incidence of the autosomal recessive form is 1 per 20,000 live births (Zhou & Pollak, 2015). The autosomal dominant form is one of the most frequently inherited diseases with a prevalence of 1 in 800 live births in the United States (Watnick & Dirkx, 2015).

In PKD, cellular hyperplasia of the collecting ducts causes dilation of the ducts. Fluid secreted into these ducts enables cyst sacs to form. Initially, cysts are usually less than 2 mm in size and do not obstruct urinary flow. As the child grows, however, the cysts become larger and fibrosis occurs. The cysts slowly replace much of the kidney's mass and reduce kidney function. Tubular atrophy may occur in some children, whereas others have minimal changes in renal function. PKD is associated with liver abnormalities that progress in severity with age to fibrosis, portal hypertension, and biliary infection.

Newborns with autosomal recessive PKD may have enlarged kidneys, which are detected at birth. Approximately 60% of neonates with this disorder die within the first month from pulmonary hypoplasia. This complication is a result of deficient amniotic fluid (*oligohydramnios*) in utero secondary to severe intrauterine kidney disease (Zhou & Pollak, 2015).

Clinical manifestations in infants with autosomal recessive PKD include low-set ears, small jaw, and a flattened nose. Hypertension develops in early infancy and is often severe. Infants may have expected urine output or oliguria. Respiratory distress and feeding intolerance may develop from the enlarged kidneys (Porter & Avner, 2016). As uremia develops, infants and children develop renal osteodystrophy and progressive developmental delay and growth failure.

Sonography or renal biopsy confirms the diagnosis. The disease is often diagnosed on prenatal ultrasound. Liver function tests are usually normal initially. A liver biopsy may also be performed. Other family members should be screened for subclinical cases of PKD.

Treatment is supportive. Medications such as diuretics are prescribed for hypertension. Fluid and electrolyte abnormalities are managed. Antibiotics treat urinary tract infection. Growth hormones may be used in some children to promote growth. Renal osteodystrophy is treated to suppress the parathyroid hormone. Many children develop end-stage renal disease (ESRD) by 10 years of age. Dialysis or a kidney transplant will prolong survival; however, liver problems may continue to complicate the child's health, even when the kidney condition is well controlled. Fifteen-year survival is estimated to be at 70% to 80% of these children (Porter & Avner, 2016).

Nursing Management

Nursing care is the same as that for the child with renal insufficiency and chronic renal failure. See the discussion earlier in this chapter. Observe the child for signs of progressive renal impairment. Make sure the family schedules follow-up appointments to assess growth, developmental progress, and the effectiveness of the treatment plan. Family teaching for home management focuses on medications, diet adequate in protein and calories to support growth, management of acute gastrointestinal illnesses, and care for the child with progressive renal insufficiency and a liver disorder. Since the disease is inherited, the family should be referred for genetic counseling.

Structural Defects of the Reproductive System

Phimosis

In **phimosis**, the foreskin over the glans penis cannot be retracted. As a result of natural adhesion, phimosis is a normal finding in uncircumcised infants and young males. Circumcision, surgical removal of the foreskin, has long been a common practice performed in some countries and cultures during the newborn period. It is performed to prevent phimosis, for ease of proper male hygiene, and to prevent urinary tract infections and penile cancer. The procedure removes the skin covering the end of the penis. Circumcision is considered comparatively safe; however, complications such as damage to the urethra and disfigurement to the penis may occur. Nonsurgical treatment of phimosis involves the topical application of steroid cream and is an effective alternative to surgery (Shahid, 2012).

Cryptorchidism

Cryptorchidism (undescended testes) occurs when one or both testes fail to descend through the inguinal canal into the scrotum. Normally, the testes descend during the seventh to ninth month of gestation.

Cryptorchidism may be the result of a congenital defect of the gonads, a narrow inguinal canal, short spermatic cord, adhesions, insensitivity to gonadotropins, or lack of maternal gonadotropins. This disorder occurs in approximately 3% of term male infants and has a higher incidence in premature males (Rodway & McCance, 2014).

The higher temperature in the abdomen than in the scrotum results in morphologic changes to the testis. Complications of cryptorchidism include infertility and malignancy (Connolly & McComiskey, 2013; Lee & Houk, 2013).

Cryptorchidism is usually detected during the newborn examination when palpation of the scrotum fails to reveal one or both testes. It is not unusual for boys with cryptorchidism to have an inguinal hernia as well. In a majority of cases, the testes descend spontaneously by 3 months of age.

Although diagnosis is made on physical examination, diagnostic studies, including ultrasound, CT scan, and MRI, are utilized to determine the location of the testes. A diagnostic laparoscope may also be needed to locate the testis. When neither testis can be palpated, hormonal and chromosomal evaluation may be performed to detect an intersex disorder.

If the testes do not descend spontaneously, an orchiopexy should be performed. Timing of surgery may vary among healthcare providers. The current recommendation is that this procedure be performed at 6 months of age in full-term infants. Surgery may be delayed until 12 months of age in premature infants (Barthoid, 2012).

With an orchiopexy, an incision is made at the location of the testis, either in the abdomen or in the inguinal area. Blood vessels are disentangled to allow the testis to reach into the lower scrotum. A second incision is made in the scrotum at the point where the testis is stitched to the inside wall to keep it in place. A protective sealant is often put over the incision that peels off in 3 to 5 days. If the testis is defective or undeveloped, it may be removed surgically to decrease the risk of later malignancies and a prosthesis may be placed in the scrotum.

The goals of surgery are to repair any existing hernia, improve fertility, decrease the risk of malignancy, prevent testicular torsion, and provide the psychologic benefit of a normal appearing scrotum (Connolly & McComiskey, 2013). The risk of testicular cancer is 35 to 50 times greater in men with a history of cryptorchidism (Rodway & McCance, 2014).

Nursing Management

Preoperative nursing care includes preparing the parents and child for the procedure and addressing parents' concerns about the postsurgical outcome. Orchiopexy is often performed as an outpatient procedure. If the child is hospitalized, postoperative nursing care focuses on maintaining comfort and preventing infection. Encourage bed rest, and monitor voiding. Apply ice to the surgical area, and administer prescribed analgesics to relieve pain.

Discharge instructions should include demonstration of proper incision care. The diaper area should be cleaned well with each diaper change to decrease chances of infection. Sponge bathe the child for 2 days after surgery, and then a tub bath may be given. No medicine or ointment should be placed over the incision. Teach parents to identify signs of infection such as redness, warmth, swelling, and discharge and to notify the healthcare provider if present. Ibuprofen or acetaminophen may be given for pain. Inform parents to avoid straddling the infant across the hip and to permit no strenuous activity or straddle toy riding for 2 weeks after surgery to promote healing and to prevent injury.

Inguinal Hernia and Hydrocele

An **inguinal hernia** is a painless inguinal or scrotal swelling of variable size that occurs when abdominal tissue, such as bowel, extends into the inguinal canal. An inguinal hernia is found in 3.5% to 5.0% of full-term infants and 9% to 11% of preterm infants and occurs more often in boys than girls by an 8:1 ratio (Aiken & Oldham, 2016).

A hydrocele is a fluid-filled mass in the scrotum. The condition is found in 1% to 2% of male neonates. Most hydroceles resolve spontaneously by reabsorption by 1 year of age (Elder, 2016d).

During fetal development a peritoneal sac precedes the testicle's descent to the scrotum. The lower sac enfolds the testis to become the tunica vaginalis, and the upper sac atrophies before birth. Fluid may become trapped in the tunica vaginalis and cause the hydrocele. When the tunica vaginalis does not atrophy, an abdominal structure may move into it. Inguinal hernias are often associated with abdominal wall defects such as bladder exstrophy and prune belly syndrome, and are a common occurrence with undescended testes.

Diagnosis is made by physical examination at birth or in early infancy. Palpation of the scrotum reveals a round, smooth, nontender mass, which is noted with either a hernia or hydrocele. Parents may report an intermittent bulge in the groin or swelling in the scrotum. Swelling associated with a hernia may become more apparent with straining and reduced in size when quiet or asleep.

Outpatient surgery is performed as an elective procedure at an early age (usually after 3 months of age to reduce anesthesia risks) to avoid **incarceration** (hernia cannot be reduced and circulation is impaired), which is a medical emergency. A nerve block may be given in the operating room to reduce postoperative pain. The prognosis is generally excellent.

Nursing care for hydroceles and inguinal hernias includes assessment, explaining the disorder and its treatment, and providing preoperative and postoperative teaching, care, and support.

The incision is covered with a protective sealant rather than a dressing. Provide pain medication as ordered. Inform parents that the scrotum may be edematous and may appear bruised after surgery. Incision care involves careful cleaning of the diaper area.

Clinical Tip

Inguinal hernias can become incarcerated when a bit of bowel becomes trapped in the inguinal opening and the blood supply is constricted. Symptoms in the infant include irritability, poor feeding, and abdominal distention. An older child may complain of pain. Additional symptoms in infants and children may include an edematous, erythematous scrotum accompanied by fever, vomiting, and bloody stools (Aiken & Oldham, 2016). Efforts are made to reduce the hernia before surgery by applying pressure on the affected side, followed by semiurgent surgery. If the hernia cannot be reduced, emergency surgery is performed (Mishra et al., 2014).

Testicular Torsion

Testicular torsion is an emergency condition in which the testis suddenly rotates on its spermatic cord, cutting off its blood supply. The arteries and veins in the spermatic cord become twisted and interrupt the blood supply, leading to vascular engorgement and ischemia. Testicular torsion occurs in 3.8 per 100,000 males under 18 years of age each year (Sharp, Kieran, & Arlen, 2013). Often the testicles are positioned transversely in the scrotum, secondary to a congenital anomaly known as a *bell clapper deformity*. In this deformity, the tunica vaginalis has an inappropriately high attachment to the testes, allowing them to rotate freely and twist spontaneously on the spermatic cord. Approximately 12% of males have this deformity (Datta, Dhillon, & Voci, 2011; Govindarajan & Nelson, 2013).

Manifestations include severe pain and erythema in the scrotum, nausea and vomiting, abdominal pain, and scrotal swelling that is not relieved by rest or scrotal support. The testes are tender on palpation and become edematous. The cremasteric reflex is absent. Symptoms generally start when the child is sleeping or inactive, but they can occur after trauma, sexual activity, or exercise. Color Doppler ultrasonography is frequently used to confirm the diagnosis (Sharp et al., 2013).

Testicular torsion is a surgical emergency. When surgical treatment is implemented within 6 hours of the onset of symptoms, there is a 90% to 100% chance that the testicle can be saved. During surgery (orchiopexy), the testis is untwisted and stitched to the side of the scrotum in the correct position. The procedure is usually performed bilaterally to prevent future torsion in the other testis. If the testicle does not regain blood flow or is already necrotic, it is removed via orchiectomy (Sharp et al., 2013).

Nursing management involves psychologic support for the child and family related to the need for emergency surgery and concern about the child's future fertility. Reassure parents that because only one testis is usually involved, fertility should not be affected. The child often goes home within a few hours of surgery; thus the child and family need to be taught about proper care of the incision and pain management. Explain to parents that the child should not lift heavy objects for 4 weeks or participate in strenuous activity for 2 weeks after surgery to promote healing. Teach the adolescent testicular self-examination.

Sexually Transmitted Infections

Sexually transmitted infections (STIs) are a major national public health concern, and they pose a significant health risk to children and adolescents. The Centers for Disease Control and Prevention (CDC) reports that approximately 20 million new cases of STIs occur each year, with young people ages 15 to 24 years accounting for almost half the infections (CDC, 2013). Children and adolescents can become infected with sexually transmitted organisms through sexual experimentation, sexual play, molestation, and sexual abuse.

SAFETY ALERT!

When a child younger than 10 years is found to have gonorrhea or another sexually transmitted infection, consider the possibility of sexual abuse. When anorectal symptoms are found, suspect molestation (see Chapter 17).

Results from the CDC National 2011 Youth Risk Behavior Survey revealed that 47.4% of high school students had engaged in sexual intercourse and 60.2% of sexually active adolescents had used a condom at last sexual intercourse (CDC, 2012a). Adolescents are considered an at-risk population because of their inexperience and lack of knowledge about STIs. They may disregard the importance of using barrier protection, may have multiple sexual partners, may have sex frequently, and often do not seek medical treatment until symptoms are well advanced.

Frequently diagnosed STIs include chlamydia, genital herpes (herpes simplex type 2), gonorrhea, genital warts (human papillomavirus), trichomoniasis, and syphilis. Refer to Table 26–11 for more information.

State and local health departments are responsible for controlling the spread of STIs through health promotion programs, staff training, reporting systems, diagnosis, treatment, patient counseling, and the notification of sex partners. To reduce all sexually transmitted infections, the CDC recommends abstinence from sexual contact or a long-term mutually monogamous relationship with a partner who has been tested for STIs and is known to be uninfected (Workowski & Bolan, 2015).

Nursing Management

For the Child With an STI

Nursing Assessment and Diagnosis

Nursing assessment focuses on identifying signs and symptoms indicative of sexually transmitted infections, assessing for the potential for asymptomatic sexually transmitted infections, and assessing the psychosocial impact on the child or adolescent with a sexually transmitted infection.

The nurse usually encounters the child or adolescent and family in the emergency department, outpatient clinic, or nursing unit. Because adolescents are often afraid of the consequences of reporting symptoms, good assessment and communication skills are important considerations for the nurse, particularly when asking questions about sexual activity, partners, and the possibility of abuse. Essential to communication is maintaining a warm, encouraging, nonjudgmental approach and conveying acceptance when discussing sexual health issues with the child or adolescent. In order to achieve the adolescent's cooperation, confidentiality must be ensured. Offer support to the adolescent and encourage the seeking of parental guidance and involvement.

Clinical Tip

Key areas to discuss when obtaining a sexual history include information related to partners, pregnancy prevention, protection from sexually transmitted infections, sexual practices, and past history of STIs (Workowski & Bolan, 2015).

TABLE 26–11 Clinical Manifestations of Common Sexually Transmitted Infections

SEXUALLY TRANSMITTED INFECTION	CLINICAL MANIFESTATIONS AND COMPLICATIONS	CLINICAL THERAPY AND PATIENT EDUCATION
Chlamydia *Chlamydia trachomatis*	Asymptomatic infection is common in males and females. *Females:* vaginal discharge, dysuria, pelvic pain, mild abdominal pain, vaginal spotting, cervicitis, salpingitis, pelvic inflammatory disease (PID). *Males:* **urethritis** (an infection of the urethra), discharge from the penis, dysuria, proctitis, epididymitis. Complications associated with chlamydia in females include PID, ectopic pregnancy, and infertility. Chlamydia is a leading cause of early pneumonia and conjunctivitis in newborns.	Diagnosis is by culture or a nucleic acid-amplified test on the urine. Recommended medication therapy includes doxycycline twice a day for 7 days or single-dose azithromycin. All sexual partners should be evaluated, tested, and treated. Infected persons should abstain from sexual intercourse until they and their sex partners have completed treatment to prevent reinfection. Encourage use of condoms. All sexually active female adolescents should be screened at least annually for chlamydia.
Genital herpes *Herpes simplex virus 1* (HSV-1) or *2* (HSV-2)	Most infected with HSV-2 are not aware of their infection. Presentation can be variable and ranges from no symptoms to systemic involvement. Common symptoms include dull pain, itching, and small lesions or pimples on genitalia, buttocks, or thighs. Two types of lesions develop, either fluid-filled blisters on an erythematous base or more commonly, painful papules and ulcers. Ulcers can appear between vaginal folds, in posterior cervix, on glans penis, on shaft of penis, in rectum, or in anus. Ulcers heal within 2–4 weeks. Repeat outbreaks are common. Triggers include stress, menses, or trauma.	Diagnosis is confirmed by virology and type-specific serologic tests. There is no permanent cure. Recommended drug therapy includes acyclovir, famciclovir, or valacyclovir for 7–10 days. Antiviral medications can shorten and prevent outbreaks during the period of time the person takes the medication. Daily suppressive therapy for herpes can reduce transmission to partners. A cesarean delivery is usually performed for pregnant women who are infected. Discourage oral sex if ulcers are present in mouth, on lips, in vagina, or on penis. Discourage anal sex when lesions are active. Encourage use of condoms, although they may not prevent transmission. Emphasize that the patient remains contagious, even after lesions are healed.
Gonorrhea *Neisseria gonorrhoeae*	May be asymptomatic. *Females:* symptoms include dysuria, vaginal discharge, vaginal bleeding between periods. *Males:* dysuria, white, yellow, or green discharge from the penis, may have painful or swollen testicles. Complications associated with gonorrhea in females include PID, ectopic pregnancy, and infertility. Gonorrhea can be spread to the infant during childbirth and can result in serious health problems for the infant.	Diagnosed by culture of vaginal or urethral discharge or nucleic acid-amplified test on the urine. Recommended drug therapy includes a single dose of ceftriaxone IM and a single dose of oral azithromycin. Sexual partners should be treated if the adolescent has had sexual contact within 60 days of onset of symptoms. Encourage use of condoms or abstinence. Emphasize the importance of taking all the medication prescribed to cure gonorrhea. The individual and all sex partners must avoid sex until they have completed their treatment for gonorrhea.
Human papillomavirus (HPV)	May be asymptomatic. Males and females may have genital warts. HPV can lead to cervical cancer.	Diagnosis is based on physical findings or biopsy. The Pap smear may be abnormal. No cure exists. Treatment for external genital warts may include patient-applied imiquimod 3.75% or 5% cream, podofilox 0.5% solution or gel, or sinecatechins 15% ointment. Healthcare provider–administered treatments include cryotherapy, surgical removal of anogenital warts, or trichloroacetic acid (TCA) or bichloroacetic acid. Encourage abstinence or condom use, but condoms are not sufficient to prevent contact transmission. The disorder is transmissible even after treatment. HPV vaccine (see Chapter 16).

(*continued*)

TABLE 26–11 Clinical Manifestations of Common Sexually Transmitted Infections (*continued*)

SEXUALLY TRANSMITTED INFECTION	CLINICAL MANIFESTATIONS AND COMPLICATIONS	CLINICAL THERAPY AND PATIENT EDUCATION
Trichomoniasis *Trichomonas vaginalis*	May be asymptomatic. *Females:* thin discharge that has an unusual odor and is clear, white, yellow or green, dysuria, vulvar pruritus. *Males:* most common site is the urethra; urethral discharge, pruritus, dysuria.	Diagnosis is by culture. Treatment includes metronidazole or tinidazole orally as a single dose or metronidazole orally twice a day for 7 days. Both partners should be treated at the same time to eliminate the parasite. Avoid drinking alcohol during and for several days after treatment if a single dose is used. Sexual contact should be avoided until both partners are cured. No follow-up test is needed if symptoms resolve after treatment.
Syphilis *Treponema pallidum*	Appearance of classic signs and symptoms of syphilis depends on stage of disease. *Primary stage*: Firm, round, painless sore that appears at the location where the infection entered the body. Ulcer spontaneously heals within 3–6 weeks; however, if infection not treated, progresses to secondary stage. *Secondary stage*: Skin rash or sores in mouth, vagina, or anus. Other symptoms include fever, lymphadenopathy, weight loss, headache, muscle aches, fatigue. *Latent stage*: asymptomatic, can last for several years. *Late stage:* Can appear 10–30 years after initial infection. Damage of the internal organs occurs and can lead to death.	Diagnosis is by serologic tests or direct fluorescent antibody tests of lesion exudates. Due to the risk of fetal death, every pregnant woman should have a blood test for syphilis. Syphilis is easy to cure in its early stages. Recommended drug therapy includes single IM injection of penicillin G. Treat all sexual contacts within the past 90 days of diagnosis, depending on stage when diagnosed. During syphilis treatment, abstain from sexual contact with new partners until the syphilis sores are completely healed. Encourage abstinence or the use of condoms plus spermicidal foams, cream, or jelly to prevent infection.

Assess the child or adolescent for manifestations as described in Table 26–11. When a child or adolescent is diagnosed with one STI, it is essential to screen for the presence of other STIs, because these diseases may coexist. Adolescents who are symptomatic may postpone care due to feeling uncomfortable about genital examinations. Given that many adolescents have subclinical cases or are asymptomatic, routine screening of sexually active adolescents is recommended.

Nursing diagnoses that may apply to the child or adolescent with a sexually transmitted infection include the following (NANDA-I © 2014):

- ***Anxiety*** related to presence of sexually transmitted infection
- ***Pain, Acute,*** related to genital irritation
- ***Knowledge, Deficient (Sexually Transmitted Infections),*** related to cause, transmission, treatments, and prevention
- ***Body Image, Disturbed,*** related to genital lesions or presence of genital infection

Planning and Implementation

The nurse focuses on identifying adolescents at risk for STIs, providing appropriate education, and preventing transmission and complications.

When counseling the adolescent, reinforce the importance of treating all sexual partners and modifying high-risk sexual behaviors. Partner notification is essential in order to provide treatment if the partner is infected and to reduce the risk of reinfection. Encourage sexually active adolescents to receive hepatitis B immunization if not already obtained.

CARE IN THE COMMUNITY

Education includes promoting abstinence, which means avoiding *any* type of sexual contact with a partner. (See *Families Want to Know: Preventing STIs and Their Consequences*.) The nurse, in partnership with schools and community organizations, is active in sexual health promotion.

Work with sexually active adolescents to identify methods of reducing the risk of contracting STIs. Suggestions include the use of latex condoms (though the possibility of STI transmission still exists even with the use of latex condoms), voiding immediately after sexual intercourse, and appropriate genital hygiene with soap and water. Assist adolescents to avoid sexual partners who are at higher risk for STIs, such as intravenous drug users and those who have multiple sexual partners. Emphasize to the adolescent that even with applying these measures, there is no guaranteed protection against STIs

Families Want to Know

Preventing STIs and Their Consequences

Collaborate with the child and family to promote the following recommendations in preventing STIs and their consequences:

- Abstinence is the best method to prevent STIs.
- Limit the number of sexual contacts; practice mutual monogamy.
- Always use condoms and spermicidal gels or foams for vaginal and anal intercourse.
- Refrain from oral sex if the partner has active sores in the mouth, vagina, anus, or penis.
- Reduce high-risk sexual behaviors. Use of recreational drugs and alcohol can increase sexual risk taking.
- Seek care as soon as symptoms are noticed and make sure your partner gets treatment.
- Seek annual screening for STIs.

except when using abstinence. Explain to the adolescent that some STIs, such as chlamydia, are asymptomatic.

Additional teaching includes dispelling myths of how STIs are spread. Instruct the child or adolescent that STIs are not contracted from sharing bath towels, clothing, and drinking glasses or from sitting on toilet seats. Inform the female taking contraceptives that birth control offers no protection against STIs.

Evaluation

Expected outcomes for the child or adolescent with a sexually transmitted infection are:

- The child or adolescent remains free from pain.
- An understanding of the transmission, prevention, and treatment of sexually transmitted infections is demonstrated by the adolescent.
- The adolescent has a positive body image.
- Reduced anxiety is displayed by the child or adolescent.

Pelvic Inflammatory Disease (PID)

Pelvic inflammatory disease (PID) is a serious infection of the upper genital tract caused by the ascending spread of organisms in the cervix and vagina. Many cases of PID are caused by complications of sexually transmitted infections, primarily gonorrhea and chlamydia (Workowski & Bolan, 2015).

The infection ascends into the uterus and fallopian tubes during the menses when the cervix mucosal plug is open and retrograde menstrual blood can flow into the fallopian tubes. Signs and symptoms of PID may include fever, mild or dull bilateral lower abdominal pain, dysmenorrhea that is worse or longer lasting than usual, dysuria, vaginal discharge, pain with sexual activity, and prolonged or increased menstrual bleeding. Most cases are mild.

No specific laboratory test exists for PID. During a pelvic examination, uterine or adnexal tenderness or tenderness with cervical motion is present. Other criteria that help support the diagnosis of PID include an elevated erythrocyte sedimentation rate, elevated C-reactive protein level, white blood cells seen on microscopic examination of vaginal secretions, and documented cervical infection with gonorrhea or chlamydia. A transvaginal sonogram may reveal thickened and fluid-filled fallopian tubes with or without free pelvic fluid (Workowski & Bolan, 2015).

Intravenous cefotetan or cefoxitin plus oral or intravenous doxycycline is recommended as initial treatment for 24–48 hours. With clinical improvement, the patient can be transitioned to oral doxycycline to complete a 14-day course. Another option for treatment is intravenous clindamycin and intravenous or intramuscular gentamicin as initial treatment, followed by oral doxycycline or oral clindamycin to complete a 14-day course. Follow-up physical examination is performed in 72 hours to ensure treatment adherence and to detect improvement in symptoms. Rehospitalization and adjustment of the antibiotic regimen is initiated if no improvement is noted (Workowski & Bolan, 2015).

Nursing Management

A sexual history should be obtained from all adolescent females to identify the risk for sexually transmitted infection and PID. Risk factors for adolescents include those who have a history of an STI, multiple sexual partners, and lack of consistent use of barrier protection (Shepherd, 2013).

Administer medications intravenously for the first 24 hours. Provide education for the ongoing treatment with oral antibiotics, ensuring that the adolescent understands the importance of taking all medications on schedule for the full 14 days. Provide signs of adverse effects and actions to take if they occur.

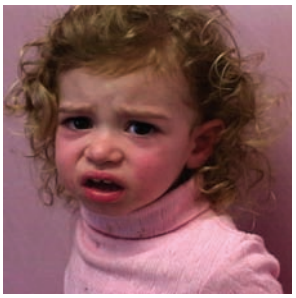
Determine if the adolescent's parents have been informed about the illness and assist the adolescent in discussing the health problem with the parents. If parents are unaware of the health problem, discuss the importance of telling the parents so that they can help identify any problems that develop during treatment.

Provide counseling about methods to reduce the risk for reinfection with a sexually transmitted infection. Provide information about the potential consequences of infertility, ectopic pregnancy, and chronic abdominal pain for this infection and the increased risk for these consequences with subsequent infections. Encourage regular health visits with screening for sexually transmitted infections, because future chlamydia and gonorrhea infections may be asymptomatic.

Chapter Highlights

- Functions of the urinary system include excretion of wastes, maintenance of acid–base and fluid and electrolyte balance, regulation of blood pressure, production of erythropoietin, and regulation of calcium metabolism.
- Expected urine output for a neonate and infant is 1 to 2 mL/kg per hour while an adult should have 0.5 mL/kg per hour.
- Urinary tract infections are common infections in children. Factors placing the child at risk for a UTI include urinary stasis, infrequent voiding, irritated perineum, constipation, sexual abuse, and sexual activity in adolescent females.
- Structural defects of the urinary system—including bladder exstrophy, hypospadias and epispadias, obstructive uropathy, vesicoureteral reflux, and posterior ureteral valves—generally require surgical treatment.
- Bladder exstrophy is a congenital defect in which the abdominal wall does not fuse during fetal development, leading to exposure of the bladder wall, a separation of the rectus muscles, and widening of the symphysis pubis.
- Surgical correction of hypospadias and epispadias generally occurs during the first year of life to minimize psychologic effects on the child.
- Obstruction of the urinary tract interferes with urine flow and results in hydronephrosis or urine backflow into the kidneys. This results in significant damage to the kidney and is a common cause of renal failure in children.
- Vesicoureteral reflux may result from a structural anomaly in which the ureters insert in an abnormal position into the bladder. Urinary tract infections are often a complication of this disorder.
- Prune belly (Eagle-Barrett) syndrome is a rare congenital disorder in which the skin covering the abdominal wall is thin and resembles a wrinkled prune. Anomalies associated with this syndrome include urinary tract anomalies, poor ureteral peristalsis, enlarged bladder, high risk for recurrent UTI, vesicoureteral reflux, and bilateral cryptorchidism in males.
- Nocturnal enuresis often occurs in children whose parents have a history of enuresis. Very few children have a structural or neurologic cause. Higher rates of enuresis have been noted in children with obstructive sleep apnea and constipation.
- Minimal change nephrotic syndrome is characterized by edema that develops over several weeks, weight gain, hypertension, irritability, hematuria, malaise, anorexia, and foamy or frothy urine.
- Acute postinfectious glomerulonephritis results most often from a beta-hemolytic group A streptococcal infection of the skin or pharynx. It is also caused by other organisms, including *Staphylococcus* and *Pneumococcus* bacteria and coxsackieviruses. Most children have a complete recovery of kidney function.
- Hemolytic-uremic syndrome is often associated with ingestion of *E. coli* strain O157:H7, which produces a toxin that attacks the kidneys. The child develops hemolytic anemia, thrombocytopenia, and acute renal failure that can progress to chronic renal failure.
- Polycystic kidney disease is a genetic disorder with both autosomal recessive and autosomal dominant forms that lead to chronic renal failure. It may be detected prenatally or in young children by ultrasound.
- Acute renal failure occurs when kidney function diminishes abruptly and is often reversible. It may occur as a complication of trauma, sepsis, cardiac surgery, or drug toxicity. It is also seen in critically ill neonates with asphyxia, sepsis, or shock.
- Chronic renal failure is progressive and irreversible reduced function of the kidneys, eventually resulting in end-stage renal disease. It often results from developmental abnormalities of the kidneys or urinary tract.
- Children with end-stage renal disease are treated with renal replacement therapy, including hemodialysis, peritoneal dialysis, or kidney transplant.
- Structural defects of the male reproductive system include phimosis, cryptorchidism, inguinal hernia, hydrocele, and testicular torsion.
- Nursing care of sexually transmitted infections includes identifying the cause and organism, providing appropriate treatment, preventing transmission and complications, and educating the child, adolescent, and family.
- Pelvic inflammatory disease (PID) is an infection of the upper genital tract (uterus and fallopian tubes) caused by the ascending spread of organisms (usually chlamydia or gonorrhea) in the cervix and vagina.

Clinical Reasoning in Action



Kendra, a 2-year-old who appears ill, is brought into the urgent care center for a skin rash, fever, irritability, and edema. Her father is concerned she might also be dehydrated because her urine output is decreased. The healthcare provider determines her skin rash does not blanch when pressure is applied and notes a purplish color. Last week, Kendra was treated for an episode of abdominal pain, diarrhea, and vomiting. The healthcare provider immediately admits her to the hospital and orders a urine culture, blood work, and stool tests. The stool comes back positive for the strain of *E. coli* usually found in contaminated hamburger meat. Kendra has hemolytic-uremic syndrome (HUS) and is in acute renal failure (ARF). She also has low hemoglobin, elevated BUN and creatinine, hematuria, and electrolyte imbalances.

Kendra is given medication for her electrolyte imbalances, antihypertensive medications, and is placed on a high-calorie, high-carbohydrate diet with restrictions on protein, sodium, potassium, and phosphorus. You explain to her parents the extreme importance of adhering to her dietary and fluid restrictions to help keep her electrolytes and fluid level balanced. You educate them that in some cases children with HUS need dialysis and some children have long-term kidney damage. You teach them how to take her blood pressure, and how to observe for edema so that Kendra can be monitored after she goes home.

1. How is drug administration adjusted for Kendra since she has ARF? What is an important nursing role when administering various medications to her?
2. What is the reason ARF develops in HUS?
3. What is one way Kendra's condition could have been prevented?
4. Renal failure is characterized by azotemia and oliguria. Describe what these are.

Chapter 27
Alterations in Neurologic Function

Mel Curtis/Getty Images

It's so hard to watch your child experience a brain injury and lie in a coma. All we can do is be here every day for Kirani. We keep talking to him and trying to get him to respond to us. We hope he will wake up soon.

—Mother of Kirani, 7 years old

Learning Outcomes

27.1 Describe the pediatric differences associated with the anatomy and physiology of the neurologic system.

27.2 Choose the appropriate assessment guidelines and tools to examine infants and children with altered levels of consciousness and other neurologic conditions.

27.3 Differentiate between the signs of a seizure and status epilepticus in infants and children, and describe appropriate nursing management for each condition.

27.4 Differentiate between signs of bacterial meningitis, viral meningitis, encephalitis, and Guillain-Barré syndrome in infants and children.

27.5 Develop a plan of nursing care for the child hospitalized with an acute neurologic condition.

27.6 Develop a nursing care plan for the infant with hydrocephalus and spina bifida.

27.7 Plan family-centered nursing care for the child with cerebral palsy in a community setting.

27.8 Contrast the appropriate initial nursing management for mild versus severe traumatic brain injury.

27.9 Discuss initiatives to prevent drowning in children.

Altered States of Consciousness

Level of consciousness (LOC) is the most important indicator of neurologic dysfunction. *Consciousness* the responsiveness to or awareness of sensory stimuli, has two components: *alertness* or the ability to react to stimuli, and *cognitive power,* or the ability to process the data and respond either verbally or physically. *Unconsciousness* is depressed cerebral function, or the inability of the brain to respond to stimuli. Altered levels of consciousness can be further categorized as:

- *Confusion:* disorientation to time, place, or person; loss of clear thinking. Answers to simple questions may be correct, but responses to complex ones may be inaccurate.
- *Delirium:* state characterized by disorientation, fear, irritability or agitation, and mental or motor excitement.

Text continues on page 743

FOCUS ON:
The Neurologic System

Anatomy and Physiology

The brain, spinal cord, and nerves are the major structures of the nervous system (Figure 27–1). The brain is protected by the skull and covered by three layers of tissue called the meninges—the dura mater, arachnoid, and pia mater. Cerebrospinal fluid circulates within the ventricles of the brain and around the brain and spinal cord.

The brain is a complex organ that controls, regulates, or coordinates many body functions, including cognition, behaviors, the senses, and motor skills. See Table 27–1 for the primary functions of the brain's structures. Stimuli are received from the environment, and the brain enables response for adaptation, survival, and maintenance of body functions. The 12 cranial nerves arise from the brainstem and have many important sensory and motor functions (Table 27–2).

The spinal cord, covered by the vertebrae, transmits impulses to and from the brain, conveying sensory information and relaying impulses that stimulate motor responses. Spinal nerves send and receive information to specific body locations. Nerve impulses are transmitted by chemical substances (e.g., norepinephrine, acetylcholine, dopamine, histamine, and serotonin) and electrical conduction, enabling the impulse to travel through the synapses from neuron to neuron.

The peripheral nerves transmit impulses from the nerve pathways to the cerebral cortex through simple spinal reflex arcs. The upper motor neurons consist of the fibers originating in the anterior horn of the spinal cord that travel to the brainstem and the nerve cells in the cerebral cortex. The lower motor neurons consist of the peripheral nerves and branches that transmit impulses to the anterior horn of the spinal cord.

The autonomic nervous system maintains a steady state of the internal body organs' and glands' involuntary functions. It is divided into the sympathetic nervous system, which mobilizes the body to respond in times of need or stress, and into the parasympathetic nervous system, which works to conserve and restore energy.

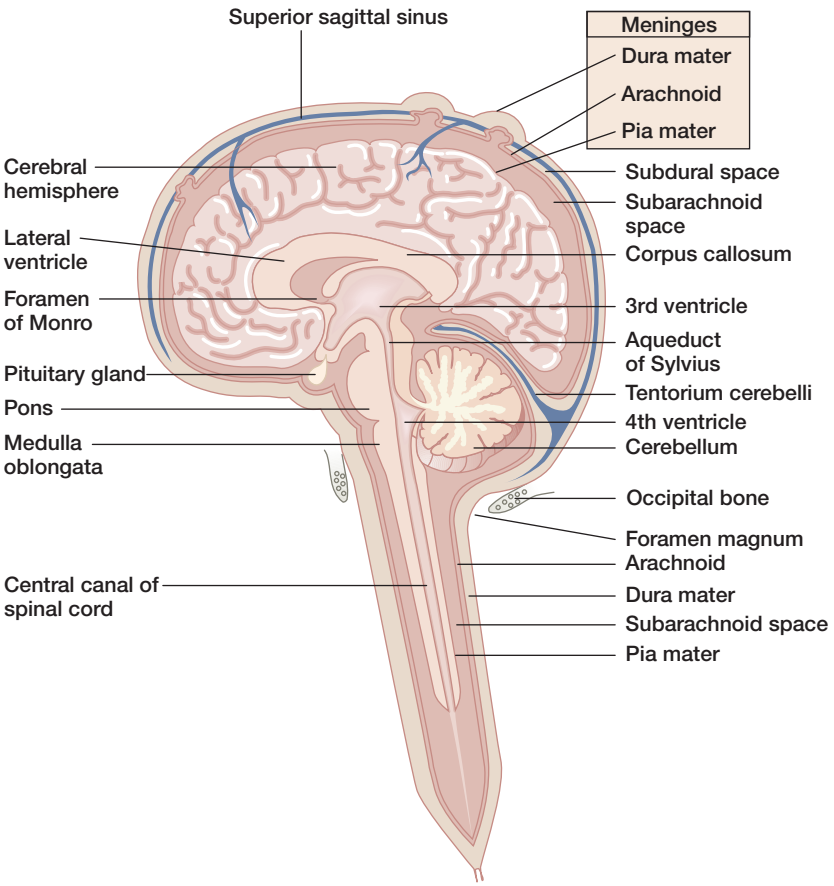

Figure 27–1 **Transverse section of the brain and spinal cord. The brain is protected by the skull and covered by three layers of tissue called the *meninges*. Cerebral spinal fluid circulates within the ventricles of the brain and around the brain and spinal cord.**

TABLE 27–1 The Primary Functions of Brain Structures

BRAIN STRUCTURE	FUNCTIONS AND CONTROL
Cerebrum	Higher mental functions, general movement, perception, and integration of all functions in lobes below
Frontal lobe	Voluntary skeletal muscle movement, fine repetitive motion, eye movements, motor aspects of speech
Parietal lobe	Interpretation of sensations (taste, visual, smell, hearing, temperature, pressure, pain, texture, and two-point discrimination); recognition of body parts, proprioception
Occipital lobe	Vision center and interpretation of vision
Temporal lobe	Hearing or the perception, reception, and interpretation of sounds, long-term memory
Insula (corpus callosum)	Coordination of activities between the two hemispheres of the cerebrum
Limbic system	Mediation of certain primitive behavior responses, visceral emotional responses, feeding behaviors, biologic rhythms, and sense of smell
Thalamus	Interpretation of most sensations except smell; relay center for sensory motor information
Hypothalamus	Maintenance of temperature, autonomic nervous system function, endocrine function, wakefulness; regulation of emotional expression
Cerebellum	Conscious and reflexive control of muscle tone, maintenance of balance and posture
Brainstem	Location of the descending and ascending motor and sensory pathways; connects the cerebrum, cerebellum, and spinal cord; origin of the 12 cranial nerves

TABLE 27–2 The Cranial Nerves and Their Functions

CRANIAL NERVES	FUNCTION
Olfactory (I)	Reception and interpretation of smell
Optic (II)	Visual acuity, visual fields
Oculomotor (III)	Many eye movements, raise the eyelids, pupil constriction
Trochlear (IV)	Inward and downward eye movement
Trigeminal (V)	Opening and closing the jaw, chewing; eyelid and corneal sensation; sensation of the face, mouth and nose mucosa, tongue, and ear
Abducens (VI)	Lateral eye movement
Facial (VII)	Facial expression, eye closure, and lip speech sounds; taste sensation on anterior two thirds of tongue; pharyngeal sensation
Acoustic (VIII)	Sense of hearing and equilibrium
Glossopharyngeal (IX)	Muscles for swallowing and guttural speech; gag reflex; taste sensation of posterior one third of tongue, nasopharyngeal sensation
Vagus (X)	Sensation behind ear and in a portion of the external ear canal; involuntary control of the heart and lungs
Spinal accessory (XI)	Shrug the shoulders and turn the head
Hypoglossal (XII)	Tongue movement; swallowing, tongue speech sounds

Pediatric Differences

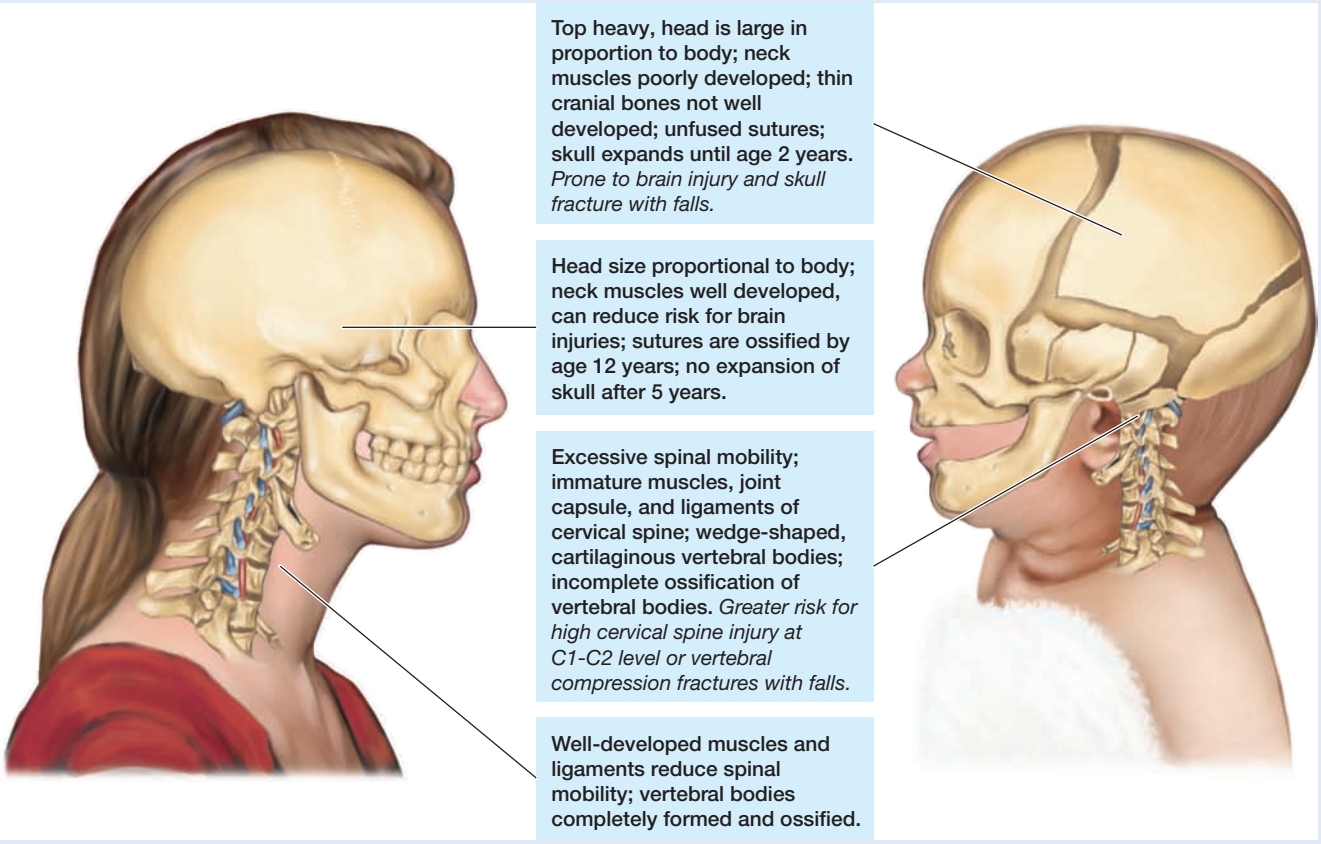
The **neural tube**, the embryonic origin of the central nervous system (CNS), develops by the fourth week of gestation as the neural folds close. The brain forms in the cranial end, and the spinal cord forms in the remainder of the neural tube (Kerr & Huether, 2014). Any insult (such as inadequate folic acid) or critical event (teratogen, infection, substance abuse, or trauma) during this early gestational period can result in a neural tube defect such as spina bifida.

The anatomic and physiologic differences between the nervous systems of children and adults help explain why children and adults have different neurologic problems (see *As Children Grow: Anatomic Differences Between Children's and Adults' Nervous System Structures*). For example, the brain and spinal cord are protected by the skeletal structures of the skull and vertebrae. In infants, however, the cranial bones and vertebrae are not completely ossified. The infant's brain and spinal cord are thus at greater risk for injury. The bones of the skull are separated but held together with bands of connective tissue to allow for normal brain growth. Fontanels are spaces of connective tissue covering the brain at the junction of skull bones that gradually close and ossify. The posterior fontanel closes at 3 months of age, and the anterior fontanel closes by 18 to 24 months of age. (See *As Children Grow: Sutures* in Chapter 5.) The suture lines between the skull bones interlock as early as 6 months of age; by 12 years of age the sutures are completely ossified and cannot be separated (Kerr & Huether, 2014).

A full-term newborn has a complete but immature nervous system. The infant is born with all the nerve cells that will exist

(*continued*)

As Children Grow: **Anatomic Differences Between Children's and Adults' Nervous System Structures**



The skull and brain grow and develop rapidly during early childhood. Infants and young children are at higher risk for injury to the brain and spinal cord because of developing anatomic structures.

throughout life, but maturation of these nerve cells continues after birth. The number of glial cells and dendrites, which enable receipt of nerve impulses, continues to increase until approximately 4 years of age. Brain growth results in increasing head circumference in infants and toddlers and continues until the child is 5 to 8 years of age.

Myelination, the progressive covering of axons with layers of myelin (a lipid protein sheath), is also incomplete at birth. Lack of myelination is associated with the presence of common newborn reflexes (see Table 5–20). As the myelination progresses, the newborn reflexes disappear. The myelination process proceeds in a cephalocaudal direction, and it accounts for the progressive acquisition of fine and gross motor skills and coordination during early childhood; it is ultimately responsible for the speed and accuracy of nerve impulses.

The brain depends on a continuous blood flow to meet its high demands for oxygen. Through an autoregulatory process, the cerebral blood vessels dilate to maintain the cerebral blood flow in response to physiologic changes such as decreased cardiac output, increased intracranial pressure, or constriction of the neck's blood vessels due to positioning. Brain cells become damaged very quickly when blood flow and oxygenation are not maintained. Because the nervous system helps to control and coordinate many body functions, alterations in neurologic function can have widespread effects on the body's metabolism.

Use *Assessment Guide: The Child With a Neurologic Condition* to perform a nursing assessment of the neurologic system. A list of diagnostic and laboratory tests used to evaluate neurologic system function is provided in Table 27–3. See Appendix D for laboratory values and Appendix E for nursing management associated with diagnostic procedures.

TABLE 27–3 Diagnostic Procedures/Laboratory Tests Used to Evaluate Neurologic Conditions*

DIAGNOSTIC PROCEDURES	LABORATORY TESTS
Computed tomography (CT)	Arterial blood gases
Electroencephalogram (EEG)	Complete blood count
Intracranial pressure (ICP) monitoring	Cultures
Lumbar puncture	Toxicology screening
Magnetic resonance imaging (MRI)	
Positron emission tomography (PET) scan	
Radiograph (x-ray)	
Ultrasonography	

*See Appendices D and E for information about these diagnostic procedures and expected laboratory values.

ASSESSMENT GUIDE | The Child With a Neurologic Condition

Assessment Focus	Assessment Guidelines
Level of consciousness	• Is the infant or child lethargic or hard to arouse? • Is the infant or child irritable or difficult to console? • Use the Glasgow Coma Scale when a numeric score is important for future comparison. See Table 27–5.
Cognitive function	• Are the child's verbal skills appropriate for age? Can the child tell you his or her name and age? • Does the child follow directions appropriately?
Cranial nerves	• Assess the cranial nerves. See Table 5–19. See also Table 27–6 for methods to assess cranial nerves in the unconscious child.
Skull	• Palpate the fontanelles for bulging and suture lines for separation.
Pupils	• Check the pupils for size, reaction to light, and accommodation.
Vital signs	• Assess the heart rate, respiratory rate, and blood pressure. • Monitor for late signs of increased ICP (increased systolic blood pressure, a widened pulse pressure, bradycardia, and irregular respirations).
Posture and movement	• Assess the common newborn reflexes in the infant less than 4 months of age to evaluate posture and movement. See Table 5–20. • Observe the child's play or other spontaneous activity to assess strength, coordination, symmetry, and smoothness of movements. Are muscle tone and strength equal bilaterally? Is any weakness present? • Are the child's motor skills developmentally appropriate and acquired at the appropriate age? Has the child lost a previously acquired skill? • Assess the plantar reflex and deep tendon reflexes. See Table 5–21.
Neck stiffness	• Assess for neck stiffness (nuchal rigidity). See Figure 27–6.
Pain	• Assess level of pain when present.
Family history	• Is there a family history of headaches, seizures, neurofibromatosis, or other neurologic conditions?

- *Lethargy:* profound slumber in which speech and movement are limited. The child is aroused with moderate stimulation, but falls asleep easily once stimulation is removed.
- *Stupor:* deep sleep or unresponsiveness; the child is aroused only with repeated vigorous stimulation, but returns to the unresponsive state when the stimulus is removed.
- *Coma:* unconsciousness; cannot be aroused even by painful stimuli.

Etiology and Pathophysiology

Infection of the brain and meninges is a common cause of altered level of consciousness in children. Other causes include trauma, hypoxia, poisoning, seizures, alcohol or substance abuse, endocrine or metabolic disturbances (e.g., diabetic ketoacidosis), electrolyte or acid–base imbalance, brain tumor, stroke, or a congenital structural defect. Any of these pathologic processes can cause increased **intracranial pressure (ICP)** (force exerted by brain tissue, cerebrospinal fluid, and blood within the cranium). The **cerebral perfusion pressure**, the amount of pressure needed to ensure that adequate oxygen and nutrients are delivered by the blood to the brain, can be affected when increased ICP reduces brain arterial blood flow. Rapid diagnosis of the cause of altered consciousness and immediate treatment are essential to prevent poor outcomes.

Clinical Manifestations

Decline in a child's level of consciousness often follows a sequential pattern of deterioration. Initial changes may be subtle: a slight disorientation to time, place, and person. The child may become restless or fussy, and actions that normally calm or soothe only increase irritability. As responsiveness decreases, the child may become drowsy but still respond to loud verbal commands and withdraw from painful stimuli. Keeping the child awake is sometimes difficult. Then response to pain progresses from purposeful to nonpurposeful. The child may exhibit flexor or extensor **posturing**, the abnormal positions sometimes seen after serious injury to the brain (Figure 27–2). Clinical manifestations of increased ICP are provided in Table 27–4.

Clinical Therapy

Clinical therapy focuses on early diagnosis of the cause of altered consciousness and intervention to prevent further insult to the central nervous system (CNS). The Glasgow Coma Scale (GCS) is used to quantify the level of consciousness, most often for acute injury, and pediatric criteria for preverbal children are also available. See Table 27–5.

Laboratory tests may include a complete blood cell count, blood chemistry, clotting factors, and blood culture; toxicology assessments of blood and urine; and urinalysis with culture.

A B

Figure 27–2 **Posturing associated with severe brain injury.** *A,* **Flexor posturing (decorticate), characterized by rigid flexion, is associated with lesions above the brainstem in the corticospinal tracts.** *B,* **Extensor posturing (decerebrate), distinguished by rigid extension, is associated with lesions of the brainstem.**

A lumbar puncture may be performed if infection is suspected. An electroencephalogram (EEG) identifies damaged or nonfunctioning areas of the brain. Computed tomography (CT) or magnetic resonance imaging (MRI) is used to detect any lesions, structural abnormalities, vascular malformations, or edema. Skull radiographic studies may detect fractures or bony malformations.

TABLE 27–4 Signs of Increased Intracranial Pressure

TIMING OF SIGNS	SIGNS
Early signs	Headache Visual disturbances, diplopia Nausea and vomiting Dizziness or vertigo Slight change in vital signs Pupils not as reactive or equal Sunsetting eyes (cranial nerve IV palsy; the iris of eye appears to be setting into the lower eyelid leaving sclera visible above the iris) Slight change in level of consciousness, restlessness
Infant has above signs plus:	Irritability Bulging fontanelle Wide sutures, increased head circumference Dilated scalp veins High-pitched, catlike cry
Late signs	Significant decrease in level of consciousness Seizures **Cushing triad** • Increased systolic blood pressure and widened pulse pressure (systolic pressure increases as the diastolic pressure stays the same or decreases) • Bradycardia • Irregular respirations Fixed and dilated pupils, papilledema

SAFETY ALERT!
The lumbar puncture should be postponed if any signs of increased ICP (e.g., papilledema) are present, which could place the child at risk for brain **herniation** (protrusion of brain contents into the brainstem area).

The child is treated with oxygen, and assisted ventilation is provided when gas exchange is inadequate. Any metabolic, acid–base, or electrolyte imbalances are corrected. Antibiotics are initiated for suspected infection.

Maintenance of the cerebral perfusion pressure is important so that adequate oxygen and nutrients are supplied to the brain. Intravenous (IV) fluids or blood products are given if the child is hypovolemic. When poor perfusion and fluid overload exist, a vasopressor medication such as dopamine is administered to increase cardiac output and perfusion of the brain. If the ICP is markedly increased and is a result of obstruction of cerebrospinal fluid (CSF), a ventricular catheter may be inserted to drain CSF to decrease the ICP, temporarily relieving a life-threatening condition. See the *Clinical Skills Manual* SKILLS. See care specific to increased ICP and traumatic brain injury later in this chapter.

Nursing Management

For the Child With Altered Consciousness

Nursing Assessment and Diagnosis

General guidelines for assessing the child with a neurologic condition are provided in the accompanying *Assessment Guide: The Child With a Neurologic Condition*.

When consciousness is altered, initially assess the child's physiologic status, focusing on the child's responsiveness to the environment or stimuli, ability to maintain the airway, vital signs, and breathing patterns. When a cough or gag reflex is present, the child can protect the airway from aspiration. Assess the vital signs, respiratory effort, and color. Monitor pulse oximetry

TABLE 27–5 Glasgow Coma Scale for Assessment of Coma in Infants and Children

CATEGORY	SCORE*	PREVERBAL CHILD CRITERIA	OLDER CHILD AND ADULT CRITERIA
Eye opening	4	Spontaneous opening	Spontaneous
	3	To voice or sound	To verbal stimuli
	2	To pain	To pressure
	1	No response to painful stimuli	No response
Verbal response	5	Smiles, coos, cries to appropriate stimuli	Oriented; uses appropriate words and phrases
	4	Irritable; spontaneous crying	Confused
	3	Cries to pain	Words
	2	Moans to pain	Sounds
	1	No response	No response
Motor response	6	Spontaneous movement	Obeys commands
	5	Purposeful, localizes pain	Localizes pain
	4	Withdraws to pain	Normal flexion
	3	Flexion to pain	Abnormal flexion; flexor posturing
	2	Extension to pain	Extension; extensor posturing
	1	No response; flaccid	No response; flaccid

*Add the score from each category to get the total. The maximum score is 15, indicating the best level of neurologic functioning. The minimum is 3, indicating total neurologic unresponsiveness.

and arterial blood gas measurements. Adequate air exchange to keep oxygen and carbon dioxide levels within normal ranges and maintenance of acid–base balance are critical to reduce the risk of hypoxemia and increased ICP.

A baseline neurologic assessment should be performed, including pupils, eye movements, and motor function (Figure 27–3). Assess the cranial nerves; however, be aware that assessment and interpretation may be more challenging in the unconscious child (Table 27–6). Observe for other physiologic signs of increased ICP (Table 27–4). See Table 27–7 for a method to rapidly assess an infant's responsiveness, referred to by the acronym AVPU (alert, verbal, pain response, unresponsive).

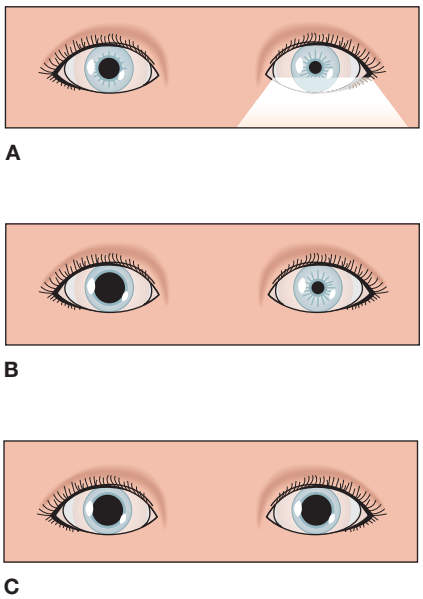

Figure 27–3 **Pupil findings in various neurologic conditions with altered consciousness. *A,* A unilateral dilated and reactive pupil is associated with an intracranial mass. *B,* A fixed and dilated pupil may be a sign of impending brainstem herniation. *C,* Bilateral fixed and dilated pupils are associated with brainstem herniation from increased intracranial pressure.**

TABLE 27–6 Assessment of Cranial Nerves in the Unconscious Child

CRANIAL NERVES	REFLEX	ASSESSMENT PROCEDURE AND NORMAL FINDINGS*
II, III	Pupillary	Shine a light source in eye. *Rapid, concentrically constricting pupils indicate intact cranial nerves II, III.*
II, IV, VI	Oculocephalic	Perform with eyes held open (doll's eyes) and head turned from side to side. *Eyes gazing straight up or lagging slightly behind head motion indicate intact cranial nerves II, IV, VI.* Precaution: Cervical spine injury must be ruled out before this assessment is performed.
III, VIII	Oculovestibular	Place the head in a midline and slightly elevated position. A physician injects ice water into ear canal. *Eyes deviating toward the irrigated ear indicate intact cranial nerves III, VIII.* Precaution: Ensure that the cervical spine is not injured and that the tympanic membranes are intact before this assessment.
V, VII	Corneal	Cornea is gently swabbed with sterile cotton swab. *A blink indicates intact cranial nerves V, VII.*
IX, X	Gag	Pharynx is irritated with tongue depressor or cotton swab. *Gagging response indicates intact cranial nerves IX, X.*

*Italics indicate normal findings.

TABLE 27–7 AVPU—Infant Responsiveness Assessment*

CRITERION	DESCRIPTION
Alert	Responsive to parents; cuddles, coos, or babbles; smiles
Verbal	Responsive to verbal stimulation
Pain response	Responsive to painful stimulation only
Unresponsive	No response to painful stimulation

*AVPU is the acronym formed from the first letter of each criterion.

A cry with a loud, energetic quality, a strong suck and suck–swallowing coordination, and appropriate common newborn reflex responses for age are other signs of an infant's intact mental status.

Among the nursing diagnoses that might be appropriate for the child with an altered level of consciousness are the following (NANDA-I © 2014):

- ***Breathing Pattern, Ineffective,*** related to neuromuscular dysfunction associated with increased intracranial pressure
- ***Aspiration, Risk for,*** related to poor control of secretions with decreased level of consciousness
- ***Skin Integrity, Risk for Impaired,*** related to agitation and skin rubbing against bedding
- ***Family Processes, Interrupted,*** related to care of a child with an acquired disability

Planning and Implementation

HOSPITAL-BASED NURSING CARE

Nursing care of the child with altered consciousness or increased ICP focuses on maintaining airway patency, monitoring neurologic status, performing routine care, providing adequate nutrition, providing sensory stimulation, and providing emotional support to parents. Nursing care for the child with increased ICP is described later in this chapter.

Make sure the child's airway is patent at all times. If the child has difficulty managing secretions or has no gag reflex, endotracheal intubation or a tracheostomy is performed. Frequent suctioning may be required (see the *Clinical Skills Manual* SKILLS). Keep suction apparatus with catheters, oxygen, resuscitation bag and mask, and extra endotracheal or tracheostomy tubes at the bedside. Pulse oximetry or arterial blood gas measurement is performed at regular intervals to ensure that gas exchange is adequate. Assisted ventilation may be required (see the *Clinical Skills Manual* SKILLS).

Anticipate that seizures may occur. Raise and pad the side rails to protect the child from injury.

Perform routine nursing care. If the corneal reflex is absent, place artificial tears in the eyes and keep them closed with gauze and tape. Perform routine mouth care by brushing the teeth and using swabs with water. Prevent complications associated with immobility (muscle atrophy, contractures, and skin breakdown). See Box 27–1.

Provide adequate nutrition. A nasogastric or transpyloric tube may be inserted if the child remains unconscious or is not alert enough to take food by mouth (see the *Clinical Skills Manual* SKILLS). A gastrostomy tube may be inserted for long-term enteral feeding.

Box 27–1 Care for the Child Who Is Immobile

- Massage child's skin gently using lotion.
- Change the child's position every 2 hours. Use splints or rolls made of towels or blankets to keep the body in proper alignment.
- Place child on a special mattress designed to relieve pressure points (airflow or foam), or use a sheepskin covering when a special mattress is not available.
- Place transparent dressing over skin surfaces exposed to rubbing or friction.
- Support physical therapy efforts with extra passive or gentle range-of-motion (ROM) exercises.
- Use sequential compression devices to prevent deep vein thrombosis.

Provide sensory stimulation. Because children with a severely altered level of consciousness may still be able to hear, talk to them. Listening to music or tapes of family members talking or reading can soothe the child when family members cannot be present. Encourage parents to stroke and touch the child in a soothing manner.

As the child becomes more alert, repeatedly orient the child to time, place, and person, depending on the child's age and level of understanding. Encourage parents to bring objects or toys from home to make the environment more familiar and promote a feeling of security.

Provide emotional support to the child and family. Explain the child's condition in simple terms. Encourage parents to take part in the child's care and therapy as much as possible. Give family members the opportunity to express their feelings. If the child's functioning has been permanently impaired, refer the family to the appropriate psychologic and social services. (See Chapter 13 for information about supporting families during a child's life-threatening illness.)

DISCHARGE PLANNING AND HOME CARE TEACHING

The child's transition from the hospital to home, a long-term care facility, or inpatient rehabilitation center must be planned well in advance of discharge. Identify a case manager or social worker to help plan the child's long-term care needs, including home health nursing and rehabilitation services, modifying the home, and purchasing special equipment.

COMMUNITY-BASED NURSING CARE

Home health nurses play a vital role in the care of the child with acquired neurologic dysfunction and prolonged altered consciousness. Teach the family how to care for the child with severe neurologic dysfunction and to perform routine procedures such as suctioning, maintaining the airway, skin care, feeding, positioning, ROM exercises, and stimulation. Regular follow-up visits are needed to assess the child's progress and to modify the treatment plan.

Link the child and family with community rehabilitation services through an early intervention program or school-based program. The home health nurse or case manager should help the family have an individual education plan (IEP) developed for the child (see Chapter 12).

Evaluation

Expected outcomes of nursing care include the following:

- The child's airway is maintained and the brain is adequately oxygenated.
- Complications of immobility are prevented.
- The family provides appropriate care to the child with prolonged altered consciousness to promote minimal long-term disabilities.

Seizure Disorders

Seizures are periods of abnormal electrical discharges in the brain that cause involuntary movement and behavior and sensory alterations. Epilepsy is a chronic disorder characterized by recurrent, unprovoked seizures, secondary to an underlying brain abnormality. Approximately 326,000 children under the age of 15 years live with epilepsy (Epilepsy Foundation, 2014a). The highest rate of onset occurs during the first 12 months of life (Kerr & Huether, 2014). See *Developing Cultural Competence: Seizures*.

Developing Cultural Competence Seizures

Some cultural groups have misperceptions of the cause of seizures, such as punishment for sins, a lack of spiritual faith, or possession by spirits (Institute of Medicine, 2012, p. 32). For example, the Hmong people of Asia believe the child is experiencing *quag dab peg*, or "the spirit catches you and you fall down." Traditional Hmong view the condition as serious but take pride in the child who has the condition, as they have a link to the spirit world. In 1997, Anne Fadiman wrote a compelling story about the cultural conflict between a Hmong family and healthcare providers over the treatment of their daughter's seizures: *The Spirit Catches You and You Fall Down*.

Etiology and Pathophysiology

When an excessive number of neurons in the brain become overexcited, they discharge abnormally, leading to seizures. An imbalance of exciting and inhibiting mechanisms caused by poor regulation of the gamma-aminobutyric acid ionotropic receptor family A ($GABA_A$) neurotransmitters may be a cause of early childhood seizures (Kerr & Huether, 2014). Rather than being one distinct disorder, epilepsy and seizures are associated with CNS structural defects, or from disorders that affect CNS functioning, such as brain injury, infection, electrolyte disturbance, toxins, and brain tumor. Genetic factors or familial predisposition may lead to seizures. Some seizures have no known cause.

Partial, or **focal**, seizures are caused by abnormal electrical activity in one brain hemisphere or a specific area of the cerebral cortex, most often the temporal, frontal, or parietal lobes. The symptoms depend on the region of the cortex affected.

Generalized seizures are the result of diffuse electrical activity that begins in both brain hemispheres simultaneously, spreading throughout the cortex into the brainstem. The child's movements and spasms are bilateral and symmetric, and consciousness is impaired.

Febrile seizures occur in susceptible infants and children in connection with a rise in temperature to 39.0°C (102.2°F) or higher during the first 24 hours of an associated acute illness. They occur in 3% to 5% of children (Ismail et al., 2012). No evidence of intracranial infection or systemic metabolic disorder is present. A genetic predisposition may be present. These seizures are usually seen in children between 9 months and 5 years of age (Kerr & Huether, 2014). Simple febrile seizures last less than 15 minutes and do not recur during the same illness. Some children have complex febrile seizures that last 15 minutes or longer and recur within 24 hours, and they may be at greater risk for developing epilepsy.

Status epilepticus is a prolonged continuous seizure of 15 minutes or evidence of intermittent seizures noted from clinical signs or EEG tracings lasting more than 15 minutes without full recovery of consciousness between seizures (Wilkes & Tasker, 2013). Low levels of antiepileptic medications, fever, infection, and a recent medical condition change are risk factors in children. Among children, the highest incidence is in the first 12 months of life (Varelas, Spanaki, & Mirski, 2013). The basal metabolic rate rises during peak seizure activity and increases the demand for oxygen and glucose.

Clinical Manifestations

The symptoms of a seizure depend on the type and duration of the seizure. The characteristics of the various partial and generalized seizures are presented in Table 27–8.

Partial seizures often start with an aura or an abrupt, unprovoked alteration in behavior. The child may have time to get to the floor and avoid injury once the aura pattern is recognized.

Generalized seizures often begin with the **tonic** phase, characterized by unconsciousness, continuous muscular contraction, and sustained stiffness. The **clonic** phase that follows is characterized by alternating muscular contraction and relaxation or repeated rhythmic jerking. During the **postictal period** following seizure activity, the level of consciousness is decreased. The length of the postictal period varies. Children may have a partial seizure that progresses to a generalized seizure.

Growth and Development

Neonatal seizures may be subtle with roving eye movements, repetitive blinking, sucking, lip smacking, tongue thrusting, swimming movements of the arms, leg pedaling movements, and apnea or tachycardia (Beaulieu, 2013).

Simple febrile seizures are generalized seizures with tonic-clonic movements and eye rolling, followed by a brief postictal period. Complex febrile seizures have additional focal signs.

Clinical Therapy

After the child's first seizure, a thorough history is taken from the parent, primary caretaker, or witnesses to the event. The description and length of the seizure, presence or absence of an aura, and whether the child lost consciousness are noted. This information helps to identify the type of seizure according to the International Classification of Epileptic Seizures in Table 27–8.

Based on the physical findings and history, diagnostic tests ordered may include a complete blood cell count, blood chemistry, and urine toxicology. A urine culture, blood culture, and lumbar puncture are performed if meningitis is suspected. A lead level and tests for inborn errors of metabolism may be considered. Radiologic tests such as CT scanning or MRI and angiography may be performed to identify a cerebral lesion or metabolic

TABLE 27–8 Clinical Manifestations of Seizures

TYPE OF SEIZURE AND CAUSE	CLINICAL MANIFESTATIONS
PARTIAL SEIZURES	
***Simple Partial Seizures* (focal seizures)**	
Focal damage (e.g., with cerebral palsy) Tumors or lesions Arteriovenous malformation Brain abscesses	Onset: any age No loss of consciousness; lasts less than 30 sec; no postseizure confusion No **aura** (a visual, auditory, taste, or motor sensation preceding a seizure or migraine headache) Signs depend on section of brain affected: motor activities such as twitching or lost muscle tone (may involve one extremity, part of an extremity, or ipsilateral extremities) or sensory sensations such as tingling, numbness, or a sensation involving sound, smell, or sight May progress to a generalized seizure
***Complex Partial Seizures* (psychomotor seizures)**	
Lesions, cysts, or tumors Perinatal trauma Focal sclerosis (e.g., scarring of the medio-temporal lobe from prolonged febrile seizures) Vascular anomalies (e.g., arteriovenous malformations) Brain trauma	Onset: 3 years of age to adolescence Consciousness is impaired immediately; lasts 30 sec to 5 min; postseizure amnesia or confusion Aura frequently present May have abnormal motor activity, twitching, loss of tone, or posturing; **automatisms** (unusual body movements without purpose, e.g., lip smacking, lip chewing, sucking) May have sensory changes such as tingling or numbness, feeling of anxiety, fear, or déjà vu (sensation that event occurred before) May progress to a generalized seizure Abdominal pain
GENERALIZED SEIZURES	
***Tonic-Clonic Seizures* (grand mal seizures)**	
Cerebral damage from perinatal trauma, brain trauma, tumors, structural lesions, metabolic and neuromuscular degenerative disorders Genetic, strong familial incidence Many are idiopathic	Onset: any age, rare before 6 months of age Abrupt onset seizure, 1- to 2-min loss of consciousness, postseizure confusion (few minutes to hours) May or may not have aura Body becomes stiff and rigid when all muscles contract (tonic phase), followed by rhythmic jerking motions (clonic phase) Drooling as secretions are not swallowed Pupils dilated; eyes roll upward or deviate to one side Abdominal or chest wall rigidity with leg, head, and neck extended, and arms flexed or contracted Cry or grunt as air is forced out when diaphragm and chest muscles contract Urinary or bowel incontinence as muscles become flaccid during clonic phase Sleepiness, difficulty in arousal; hypertension; diaphoresis; headache, nausea, vomiting; poor coordination, decreased muscle tone; confusion, amnesia; slurred speech; visual disturbances; combativeness
***Childhood Absence Epilepsy* (petit mal seizures)**	
Hyperventilation for 3 minutes Genetic (multifactorial) predisposition or mutations	Onset: ages 4–10 years with remission in adolescence More prevalent in females May develop other generalized seizures No aura; brief loss of consciousness, usually lasts 5–10 sec, rarely exceeds 30 sec, no postseizure confusion, lethargy, or sleepiness; amnesia regarding the seizure Frequent attacks (50–100 or more per day), may cluster, interfere with learning Eye blinking, eyelid fluttering, staring, glazed eye appearance, myoclonic jerks; interrupts voluntary activity, slight decrease or loss of muscle tone (head may droop, may drop objects) Verbal or touch stimulation does not interrupt seizure
Juvenile Myoclonic Epilepsy	
Genetic disorder	Onset often during puberty No loss of consciousness, child recovers in seconds, no postictal period Most often occur upon falling asleep or awakening Quick involuntary muscle jerks of the neck, shoulders, and arms Child usually has normal intelligence

TYPE OF SEIZURE AND CAUSE	CLINICAL MANIFESTATIONS
Infantile Spasms **(West syndrome, salaam seizures)**	
Tuberous sclerosis (genetic syndrome) Mutation of several genes Intrauterine stroke Inborn errors of metabolism CNS malformations	Onset: age 4 and 18 months with peak onset at 3–7 months; more common in males Severe form of epilepsy; may occur with altered consciousness as part of a complex partial seizure; seizures occur in clusters, 5–150 per day Spasms with abrupt flexion and extension of muscle groups in the neck, trunk, and extremities, involving head nods or jackknife body contractions; occur as infant awakens or falls asleep. Spasms stop by 5 years of age when other seizure types occur. Developmental delays occur
Lennox-Gastaut Syndrome **(akinetic or atonic seizure)**	
Gray matter degenerative diseases and subacute seizures Sclerosing panencephalitis Many are idiopathic	Onset: first seen between 1 and 8 years, predominantly in boys Combination of generalized seizures including tonic-clonic, absence, and myoclonic activity; drop attack (falls to ground with sudden loss of postural tone, inability to break fall, is limp for period of time) Associated intellectual disability, delayed psychomotor development, and severe behavior problems

disorder in the brain. An EEG is often performed at a follow-up visit between seizures. If the child is taking any anticonvulsants, a serum drug level is obtained.

Many seizures are self-limiting and require no emergency intervention. When the seizure is prolonged, emergency therapy includes airway management, supplemental oxygen, intravenous benzodiazepines, and careful monitoring of vital signs. Serum electrolytes, glucose, and blood gases may be monitored. The postictal period ranges from 30 minutes to 2 hours. When the child's seizure does not stop as expected with emergency intervention, treatment for status epilepticus is initiated (Table 27–9).

Children with simple febrile seizures are often not treated with an anticonvulsant at the time of the seizure because the seizure has stopped before arrival at the emergency department. Acetaminophen is given to lower the temperature. Long-term antiepileptic medications are not recommended for simple febrile seizures because of their adverse effects.

Most seizure disorders are treated with antiepileptic drugs (AEDs). A single (monotherapy) AED is preferred for seizure control to minimize the side effects such as sleepiness, decreased attention and memory, difficulty with speech, ataxia, and diplopia. A low dose is used initially and gradually increased until seizures are controlled. An alternate AED may be tried if seizure control is not achieved with a high therapeutic dose of the first medication or when unacceptable side effects occur. Some children have refractory or **intractable seizures**, requiring two or more AEDs. See *Medications Used to Treat: Seizures*. Medication dosage adjustments are often needed as the child grows. Blood tests to monitor for liver and hematologic problems and therapeutic drug levels are often performed.

SAFETY ALERT!

Because of the potential adverse effects of medications used to treat seizures, children are monitored for depression, suicidal thinking, and effects on learning. Medications should not be stopped abruptly, and dose is tapered when discontinuation is planned. When starting a new medication, adolescents should not engage in hazardous activities or drive a motorized vehicle until effects of the medication are known. Alcohol intake is contraindicated.

TABLE 27–9 Status Epilepticus Clinical Therapy and Nursing Management

TYPE OF CARE	CLINICAL THERAPY AND NURSING MANAGEMENT
Emergency assessment and management	• Maintain a patent airway. Muscle rigidity may compromise the airway. Keep suction equipment at the bedside in case secretions are excessive. • Give supplemental oxygen because increased metabolic demands deplete oxygen stores. • Monitor vital signs and circulation with pulse oximeter and cardiorespiratory monitor. • Perform neurologic assessments every 5–10 min.
Ongoing urgent management	• Establish an IV line for fluid or medication administration. • Assess blood glucose level; administer glucose if the child is hypoglycemic; the physical stress of the seizure may result in declining glucose levels. • Insert a nasogastric tube to reduce the risk for aspiration due to vomiting. • Protect the child from injury. • Manage thermoregulation.
Medications	• Administer benzodiazepines such as diazepam, lorazepam, or midazolam. If there is no response, the dose may be repeated. Fosphenytoin or phenobarbital may be necessary if seizure activity continues. Cumulative doses of drugs may produce apnea, so be prepared to assist with endotracheal intubation and ventilations.

A. (2013). Status epilepticus: An update. *Current Neurology and Neuroscience Reports, 13*(7), 357–365; McLauchlan, D. J., & Robertson, N. P. (2012). Management of status epilepticus. *Journal of Neurology, 259*, 2261–2263.

Medications Used to Treat: Seizures

MEDICATION AND ACTION	NURSING MANAGEMENT
Benzodiazepines (diazepam, lorazepam) CNS depressant, anticonvulsant properties, used for status epilepticus.	• Administer IV push medication very slowly into the IV entry site closest to the child's body. • Monitor for hypotension, tachycardia, and respiratory depression. • The rectal or nasal preparation may be prescribed for home administration to treat prolonged seizures.
Phenobarbital Enhances gamma-aminobutyric acid (GABA) neurotransmitter inhibition by prolonging the time that chloride channels are open in response to GABA.	• Administer IV push medication very slowly into the IV entry site closest to the child's body. • Monitor child's vital signs frequently when given IV. Monitor for excess sedation. • May crush tablets and mix with food or fluid. • Provide vitamin D and folic acid supplements when drug is used long term.
Phenytoin (Dilantin) **Fosphenytoin (Cerebyx)** Reduces voltage, frequency, and spread of electrical discharges within motor cortex to inhibit seizure activity.	• Monitor the child's vital signs frequently after IV dosage for respiratory depression. • Educate family to provide an adequate intake of vitamin D, folic acid, and calcium. • Promote frequent dental care for gingival hyperplasia. • Educate parents that urine may be pink, red, or brown color.
Carbamazepine (Tegretol) Inhibits sustained repetitive impulses and reduces synaptic transmission to the spinal cord, limiting the spread of seizure activity.	• Give with food to enhance absorption. Be aware that grapefruit may increase drug levels. • Educate parents about which tablets can be chewed and not chewed (sustained release). • Do not combine suspension with another liquid medication to prevent precipitation. • Causes photosensitivity reactions when skin is exposed to sunlight.
Valproic acid (Depacon, Depakote) Anticonvulsant; inhibits abnormal neuron discharges in the brain and decreases seizure activity.	• Do not use carbonated beverage to dilute syrup. Educate the child and parents that all tablets and capsules should be swallowed whole, not chewed. • Give with food to decrease gastrointestinal irritation. • Monitor platelet count and bleeding times. • Educate female adolescents about teratogenic effects of the medication, and the importance of contraception and planning pregnancy.
Ethosuximide (Zarontin) Suppresses spike and wave pattern in absence seizures; raises brain's seizure threshold.	• Monitor for weight loss or anorexia. • Give with food if gastrointestinal upset occurs. • Do not expose medication to light. Do not freeze.
Primidone (Mysoline) Raises the seizure threshold and changes seizure patterns.	• Give with food if gastrointestinal upset occurs. • Store medication away from light and moisture.
Felbamate (Felbatol) Blocks repetitive firing of neurons and increases seizure threshold.	• Monitor for weight gain or loss. • Monitor regularly for hematologic and liver problems as well as bruising or bleeding.
Gabapentin (Neurontin) Gamma-aminobutyric acid (GABA) neurotransmitter analog	• Monitor vision, concentration, and coordination as medication may cause impairments. • Do not take medication within 2 hr of an antacid.
Lamotrigine (Lamictal) Inhibits release of glutamate and aspartate in sodium channels to decrease seizure activity.	• Educate family about photosensitivity side effect. • Monitor for dizziness, lack of coordination, drowsiness, or depression if used with valproic acid. • Educate parents to notify the healthcare provider if a skin rash develops because of risk for Stevens–Johnson syndrome.

MEDICATION AND ACTION	NURSING MANAGEMENT
Tiagabine (Gabitril filmtabs) Enhances activity of GABA, making it more available for postsynaptic neurons.	• Give with food. Avoid using with over-the-counter medications that cause drowsiness. • Monitor for signs of dizziness, tremor, and sleepiness.
Topiramate (Topamax) Sodium channel blocker and enhances ability of GABA to move chloride ions into the neurons.	• Monitor for weight loss. • Increase fluid intake to reduce risk of kidney stones. • Monitor mental status and for impaired cognitive function. • Inform parents to report speech and language problems.
Levetiracetam (Keppra) Unknown mechanism of action; inhibits seizure activity.	• Ensure that parents know whether tablet must be swallowed whole or can be chewed or crushed. • Monitor for gait and coordination problems.
Oxcarbazepine (Trileptal) Similar mechanism of action to carbamazepine.	• Monitor for hyponatremia and CNS impairment. • Educate female adolescents that oral contraceptives may be ineffective.
Zonisamide Facilitates dopaminergic and serotonergic transmission between neurons.	• Increase fluid intake to reduce risk of kidney stones. • Capsules should not be broken or crushed.
Rufinamide (Banzel) Modulation of sodium channels inhibits firing of sodium-dependent neuron transmission.	• Tablet may be crushed or swallowed whole. • Give medication with a meal because food increases drug absorption.
Clobazam (Onfi) Binds at $GABA_A$ receptor site to inhibit seizures; used for Lennox-Gastaut syndrome.	• Tablet may be crushed or swallowed whole. • Inform female adolescents that oral contraceptives may be ineffective.

(2014). *Pediatric and neonatal dosage handbook* (21st ed.). Hudson, OH: Lexicomp; Zelleke, T. G., Depositario-Cabacar, D. F. T., & Gaillard, W. D. (2013). Epilepsy. In M. L. Batshaw, N. J. Roizen, & G. R. Lotrecchiano (Eds.), *Children with disabilities* (7th ed., pp. 487–506). Baltimore, MD: Paul H. Brookes Publishing Co.

Surgery may be performed to remove a tumor, lesion, or portion of the brain that has been identified as causing the seizures, particularly when seizures do not respond to multiple AEDs. A vagal nerve stimulator with leads wrapped around the left vagus nerve may be implanted in children who are not candidates for surgery and are unable to tolerate multiple medications. The child activates the vagal nerve stimulator after experiencing an aura to reduce the spread of the seizure.

A ketogenic diet may be used for children with seizures that do not respond to AEDs. The diet is customized for the child to have high fat (80% of calories), adequate protein for growth, and very low carbohydrates that will maintain an ideal body weight, maximize ketosis, and achieve optimal seizure control. Each meal typically has about 3 to 4 g of fat for every 1 g of protein and carbohydrate (Epilepsy Foundation, 2014b). Ketosis is believed to produce anticonvulsant effects. Family motivation must be high to maintain the rigid diet for 1 or more years because improved seizure control is directly related to diet compliance. Diet side effects include constipation, kidney stones, and slowed growth. Constipation is treated with medium-chain triglyceride (MCT) oil and increased fluids. Kidney stones are treated by increasing fluids and alkalinizing the urine. Approximately 10% to 15% of children become seizure-free, and nearly half of children have a 50% reduction in number of seizures (Epilepsy Foundation, 2014b).

A trial of medication withdrawal (slowly tapered over a few months) is often attempted for children who have been seizure-free for 2 years or longer. Approximately 25% to 36% of children have seizures recur after discontinuing medications (Zelleke, Depositario-Cabacar, & Gaillard, 2013). Children with epilepsy are more likely to have anxiety, depression, behavior problems, and disabilities (e.g., attention deficit hyperactivity disorder, developmental delay, or autism) than children who do not have epilepsy (Russ, Larson, & Halfon, 2012).

Nursing Management

For the Child With a Seizure Disorder

Nursing Assessment and Diagnosis

Assess and monitor the child's physiologic status. Observe the specific seizure activity, level of consciousness, vital signs, and signs of hypoxia. During the postictal period, monitor the child's vital signs, perform neurologic checks, and keep the environment safe. Once the child is stable, a more definitive assessment can be made. Level of consciousness is one of the most important indicators of neurologic function. Remember that the child's lack of response may be the result of the postictal state. Continuing

TABLE 27–10 Questions to Ask About Seizures

TIME PERIOD	QUESTIONS TO ASK
Just before the seizure	• What was the child doing? • Did the child complain of feeling unwell (headache, nausea, vomiting, muscle pain, fever) or feeling "funny"? • Did the child suffer any trauma? Did the child get into any medications or poisons?
During the seizure	• What movements of the arms and legs were seen? On one or both sides of the body or in one extremity only? • Did the child exhibit any chewing or other automatism? • Were the pupils dilated or the eyes deviated to one side? • Did the child's color change (pale, red, blue)? • Was the child incontinent of urine or stool? • Was the child aware of surroundings or able to respond to questions?
After the seizure	• How long did the episode last? • Was the child lethargic, weak, or uncoordinated when waking up? • Did the child have memory loss or confusion?

motor activity, which may be less intense after benzodiazepines are given, is a potential sign of status epilepticus.

Collect and analyze historical information about the seizure activity. See Table 27–10.

Assess the family's adaptation to the seizure disorder, including how well the family is coping with the uncertainty of when the next seizure will occur.

Common nursing diagnoses for the child with a seizure disorder include the following (NANDA-I © 2014):

- ***Breathing Pattern, Ineffective,*** related to neuromuscular dysfunction during the tonic phase of a seizure
- ***Airway Clearance, Ineffective,*** related to inability to control secretions during seizure
- ***Trauma, Risk for,*** related to falls with seizures
- ***Self-Esteem, Chronic Low,*** related to refractory seizures and loss of bowel and bladder control during seizure activity
- ***Anxiety*** related to unpredictable nature of seizure disorder
- ***Health Management, Family, Ineffective,*** related to poor adherence with medications

Planning and Implementation

Children with a seizure disorder may be hospitalized for another condition. Nursing care focuses on preventing and managing a potential seizure by maintaining airway patency, ensuring safety, administering medications, and providing emotional support. Both acute care and long-term management are involved.

MAINTAIN AIRWAY PATENCY

Place nothing in the child's mouth during a seizure; loose teeth may be knocked out and aspirated. The child is put in side-lying position for secretions to drain. Monitor the child to ensure adequate oxygenation: The child's color should be pink, the heart rate at a normal or slightly above normal rate for age, and the SpO_2 greater than 95%. Oxygen is usually given at SpO_2 levels below 95% (see the *Clinical Skills Manual* SKILLS).

ENSURE SAFETY

Protect the child from self-harm during seizures (Figure 27–4). If the child is in bed, pad the side rails to prevent injury. Children who have frequent, recurrent seizures should wear helmets to protect their heads in case they fall. All children with seizure disorders should wear some form of medical alert identification.

ADMINISTER MEDICATIONS

Take special precautions when administering IV medications (benzodiazepines) for urgent seizure management. Give these medications very slowly over several minutes to minimize the risk of respiratory or circulatory collapse, and carefully monitor the child's vital signs.

Medications for the daily management of seizures are given orally. Ensure that extended-release medications are not crushed or chewed. When a child is NPO because of illness or on the day of surgery, seizure medications are usually given with a swallow of water. Obtain medication orders in these cases.

PROVIDE EMOTIONAL SUPPORT

Seizures are frightening to the child and family because control of body movements and consciousness are often lost. Parents often feel guilty about the child's seizure disorder and need guidance to treat the child as normally as possible. They may perceive that the child is treated differently by family, friends, and peers because of lack of understanding about seizures. Parents need additional support when seizures do not respond to one or more antiepilieptic drugs (AEDs) and alternative therapies must be considered. Refer the child and family to support groups and counseling services if indicated. See *Evidence-Based Practice: Supporting Children With Epilepsy and Their Parents*.

Clinical Tip

When the child on a ketogenic diet is hospitalized, limit glucose and dextrose from all sources including IV fluids, elixirs, suspensions, and syrups. Use normal saline IV fluid. Obtain medications in pill form, crush them, and mix with an allowable food approved by the pharmacy.

Figure 27–4 Protect the child from injury during a seizure. The child who is standing should be gently assisted to the floor and placed in a side-lying position. Clear the area of any objects that might cause harm to the child.

EVIDENCE-BASED PRACTICE | Supporting Children With Epilepsy and Their Parents

Clinical Question

What factors are related to stress and health quality of life for children with epilepsy and their families?

The Evidence

Twenty children, aged 9 to 15 years, and their parents completed a voluntary survey while attending a summer camp for children with epilepsy. The survey asked about seizure control and management, age at diagnosis, the worst thing about having epilepsy, and one thing they could change about having epilepsy. Feeling different or being teased was the most frequent response campers (50%) and parents (27%) gave to the worst thing about epilepsy, followed by the physical act of the seizure (campers, 38%; parents, 40%). Reducing the number or having no seizures was desired by 63% of campers and parents as the one change about having epilepsy. An additional 13% of campers wanted no seizures in public (VanStraten & Ng, 2012). While responses were not statistically significant, they do reveal important information about the impact of the condition on quality of life.

The risk for development of clinical depression among mothers of children with epilepsy participating in a multisite Health-related Quality of Life in Children with Epilepsy Study was identified at time of diagnosis and every 6 months for 24 months. Data were collected using the 20-item Center for Epidemiologic Depression Scale to assess mood, somatic complaints, interactions with others, and motor functioning. Data from several other research instruments helped identify factors such as family functioning, family resources, and epilepsy severity. Of the 338 mothers who agreed to participate in the project, 128 (38%) had a risk for clinical depression at the time of the child's diagnosis and were excluded from further evaluation. Of the remaining 210 mothers, a total of 58 (28%) mothers developed depressive symptoms at some point during the subsequent 24 months. Statistically significant factors associated with risk for clinical depression included a younger mother, the child's prescribed number of antiepileptic drugs, worse family functioning, fewer family resources, and more family demands (Ferro & Speechley, 2011).

The same multisite Health-related Quality of Life in Children with Epilepsy Study also reported information on child health, well-being, and the impact of illness on life functions during the past 4 weeks for 374 children with a mean age of 7.4 years. The parent form of the Child Health Questionnaire was used at diagnosis and 24 months later for the study. Data from other research instruments helped identify factors such as parent depression, family functioning, family resources, and epilepsy severity. After controlling for physical and psychologic health at diagnosis, multiple regression analysis identified predictors at 24 months of better physical health (less severe cognitive problems and less parental depression) and better psychosocial health (less severe behavior problems, an older parent, better family functioning, and fewer demands) in participating children (Ferro, Landgraf, & Speechley, 2013). These studies further support the important role of the family environment on child health-related quality of life.

Best Practice

Epilepsy is a common neurologic condition that causes families and affected children to have social, psychologic, and physical challenges. Stressors can be related to the stigma associated with epilepsy, the unpredictable nature of when and where seizures may occur, loss of control, and even some of the disabilities associated with epilepsy. Research suggests that intervention programs to improve the family environment and to offer treatment for depression and anxiety may improve the family's healthy adaptation to epilepsy.

Clinical Reasoning

When caring for a child with epilepsy, what questions may help reveal the stressors that the parents and child are experiencing? Once stressors are identified, investigate resources with regard to parent mental health, improved epilepsy management, and support groups for children and their parents.

DISCHARGE PLANNING AND HOME CARE TEACHING

Encourage parents to express their fears and anxieties. Answer their questions honestly, and refer them to organizations such as the Epilepsy Foundation, where they can get more information about the child's disorder. Be sure parents know how to administer medications and keep the child safe. Provide information about whom to call with questions and when to return for follow-up.

COMMUNITY-BASED NURSING CARE

Educate the child and parents about medication regimens. Explain the purpose of each antiepileptic drug (AED), its administration schedule, and the importance of giving all doses. Provide information about the medication side effects, and alert parents to the signs of toxic reactions. Ensure that information is shared directly with older children so that they can begin taking more responsibility for self-care and gain a sense of self-control. A study explored nonadherence to AEDs in 124 newly diagnosed children ages 2 to 12 years. Researchers discovered that 58% of children had persistent nonadherence and 42% had near perfect adherence during the first 6 months of therapy. The pattern of adherence was established within the first month of therapy. Socioeconomic status was the only factor associated with adherence, and lower socioeconomic status was associated with higher nonadherence (Modi, Rausch, & Glauser, 2011).

Ensure that adolescents understand that alcohol intake is contraindicated and may result in medication toxicity. Ask questions at each visit that may reveal actual medication adherence, such as inquiring about the number of pills remaining or difficulties paying for medications. Monitor the child's growth because a weight change may require dosage adjustment to maintain seizure control. Encourage the family to obtain regular dental care for the child treated with phenytoin and similar AEDs because of their effects on the gingivae.

The parents of children with recurrent febrile seizures should be taught to give the proper dose of acetaminophen or ibuprofen with fever onset. Parents need to know that fever management may not prevent a febrile seizure. Reassure parents that complications from febrile seizures are rare.

Families Want to Know

Safety for the Child With a Seizure Disorder

Children with epilepsy have more injuries of all sorts, including burns and falls. Children are at increased risk for death due to drowning. Planning for safety includes the following:

- Do not leave the child alone in the bathtub.
- Children who bathe alone should use the shower.
- A buddy and lifeguard should always be present when the child swims.
- A life vest should always be worn when boating.
- A child with frequent seizures should wear a helmet to protect the head in case of a fall.
- The child should not play or stand around open flames or outdoor grills.
- The child should avoid areas where fall risks are increased.
- A form of medical identification should be worn, such as a medical alert bracelet.

Educate female adolescents about the potential teratogenicity of some antiepileptic drugs (AEDs). Valproic acid and carbamazepine are associated with neural tube defects. Contraception should be used when the adolescent is sexually active, but ensure that barrier methods are used correctly when AEDs interact with oral contraceptives. When pregnancy is desired, an alternate AED may be prescribed with a lower risk for birth defects.

Teach families about safety guidelines for the child. See *Families Want to Know: Safety for the Child With a Seizure Disorder*. Physical activity and exercise are important for all children. Encourage participation in sports when adequate supervision is provided. Children with well-controlled seizures may participate in most team sports, and activities such as bicycle riding. Activities such as rope climbing, rock or mountain climbing, tree climbing, snow skiing, scuba diving, and skydiving are more dangerous if seizures are not well controlled. Swimming and water sports require one-to-one supervision.

Assist the family to develop an individual health plan so the child can receive medications during school hours, if necessary. Provide information to teachers and school administrators about care of the child during a seizure and what information to report to the parents. Parents may want to provide a towel and clothing change for the child who has incontinence with a seizure.

The child may be afraid of having a seizure in front of friends. Reassure the child and family that taking medications regularly often controls seizures. Children need to be able to explain to peers what a seizure is and what to do if they are present when one occurs . Summer camps for children with seizures can be a safe and comfortable place for the child to enjoy outdoor activities. Teach parents to boost the child's self-image by emphasizing what the child can do, rather than focusing on contraindicated activities. Depending on state laws, most adolescents can drive after they have been seizure-free for at least 2 years.

Evaluation

Expected outcomes of nursing management include the following:

- The child achieves good seizure control with medication, ketogenic diet, or surgical intervention.
- The use of effective safety measures prevents injuries during seizures.
- The child gains enhanced self-esteem through participation in well-supervised sports and activities.

Infectious Diseases

Infections of the central nervous system need to be identified and treated rapidly because they can cause significant consequences in the developing child.

Bacterial Meningitis

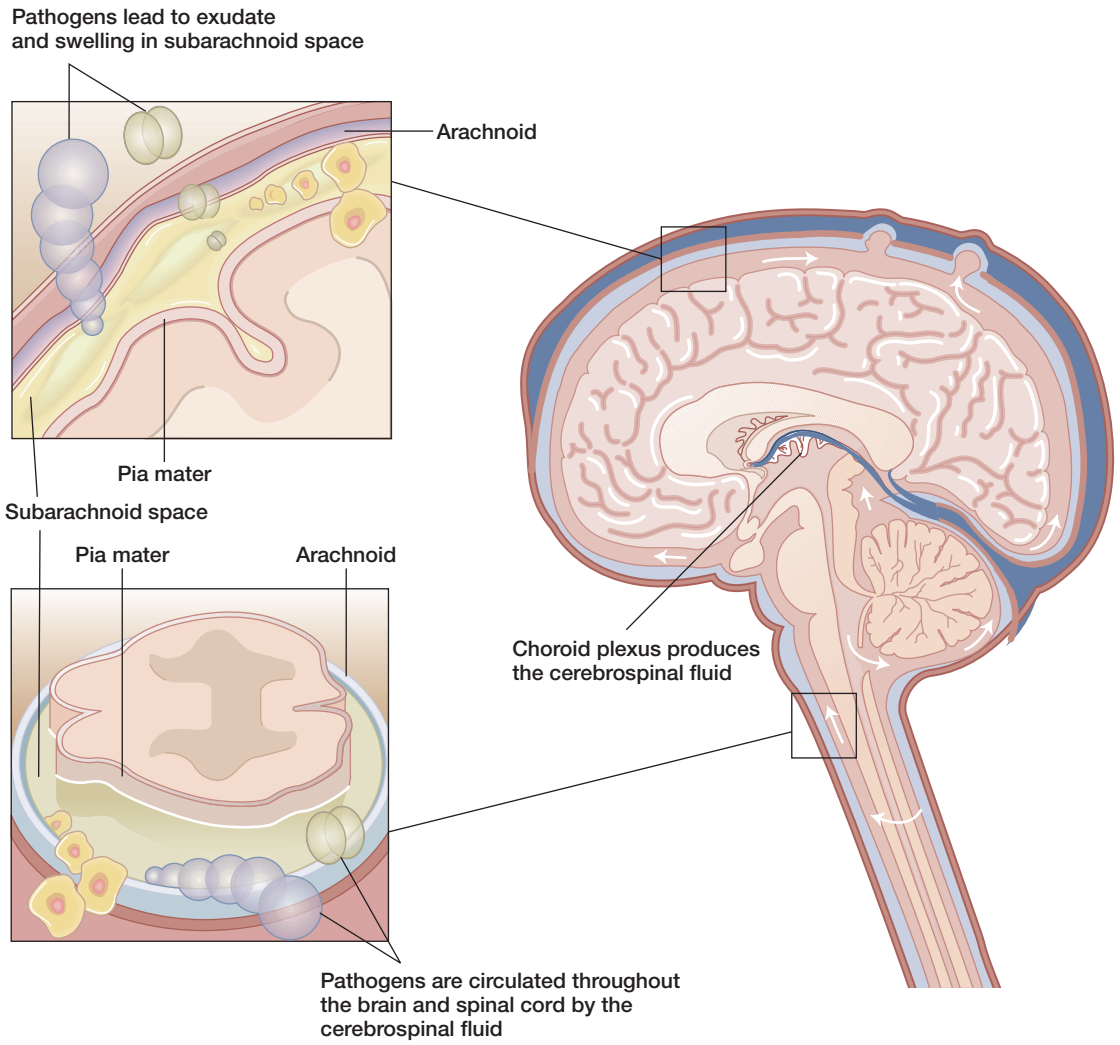
Meningitis, an inflammation of the meninges, can be caused by either bacterial or viral agents. Bacterial meningitis is more serious than viral meningitis and is sometimes fatal. Newborns and infants are at greatest risk for bacterial meningitis. Infants and children who develop meningitis may have acute complications and long-term morbidity.

ETIOLOGY AND PATHOPHYSIOLOGY

Meningitis may occur secondary to other infections such as otitis media, sinusitis, pharyngitis, cellulitis, pneumonia, or septic arthritis; brain trauma; or a neurosurgical procedure. *Streptococcus pneumonia, Neisseria meningitides*, and staphylococcal and gram-negative microorganisms cause most cases of meningitis in children in the United States. Group B streptococcus causes some cases of meningitis in newborns. Meningitis may also be caused by tuberculosis. Rates of meningitis have fallen for children because of increased protection from several vaccines (Castelblanco, Lee, & Hasbun, 2014). Risk factors for meningitis include immunosuppression, a ventriculoperitoneal shunt, cochlear implant, skull fracture, neurosurgery, or a recent sinus or ear infection (Kerr & Huether, 2014).

In many cases, the infectious organism spreads to the CNS from the bloodstream (see *Pathophysiology Illustrated: Central Nervous System Infection*), triggering an inflammatory response. The brain becomes inflamed and edematous, leading to **cerebral edema** (an increase in intracellular and extracellular fluid in the brain that results from anoxia, vasodilation, or vascular stasis) and increased ICP. If the infection spreads to the ventricles, they can become obstructed and impede the flow of cerebrospinal fluid (CSF), causing cerebral edema and hydrocephalus as acute complications. The infection may trigger the syndrome of inappropriate antidiuretic hormone (SIADH).

Pathophysiology Illustrated: **Central Nervous System Infection**



After bacteria reach the central nervous system, the pia mater, the arachnoid, and the cerebrospinal fluid-filled subarachnoid space become infected. The cerebrospinal fluid then circulates the pathogens throughout the brain and spinal cord.

CLINICAL MANIFESTATIONS

Symptoms vary by the child's age, the pathogen, and the length of the illness before diagnosis. Onset may be sudden or develop over 1 to 2 days. Symptoms in the young infant may include fever or hypothermia, change in feeding pattern, vomiting, or diarrhea. The anterior fontanelle may be bulging or flat. The infant may be alert, restless, lethargic, or irritable. Rocking or cuddling, which normally calms a fussy infant, irritates the infant with meningitis.

Older children are usually febrile, have altered consciousness (e.g., confusion, delirium, lethargy, irritability), and may have vomiting and complaints of muscle or joint pain. A hemorrhagic rash of petechiae that changes to purpura or large necrotic patches may be seen in meningococcal meningitis (see Chapter 16). Other symptoms consistent with meningeal irritation may include headache (most often frontal), photophobia, esotropia (inward eye deviation), and **nuchal rigidity** (resistance to neck flexion). The child is often comfortable only in an **opisthotonic position** (hyperextension of the head and neck) (Figure 27–5). The child may have a positive Kernig or Brudzinski sign, or both, on examination (Figure 27–6).

CLINICAL THERAPY

Diagnosis is based on the history, clinical presentation, and laboratory findings. Laboratory tests include a complete blood count, blood cultures, serum electrolytes, blood urea nitrogen, osmolality, and clotting factors. A lumbar puncture is performed to culture the CSF and evaluate it for white blood cells, protein, and glucose levels and also to determine CSF pressure. Real time polymerase chain reaction (PCR) assays of the CSF are also used for diagnosis. CT scanning may be performed when increased ICP or a brain abscess is suspected.

Antibiotics commonly used to treat bacterial meningitis include ampicillin, aminoglycosides, cefotaxime, ceftriaxone, penicillin G, and vancomycin. They are administered as soon

Figure 27–5 **The child with bacterial meningitis may assume an opisthotonic position, with the neck and the head hyperextended, to relieve discomfort.**

as diagnostic tests are obtained and often changed once culture and sensitivity results are known since many organisms have antibiotic resistance. IV antibiotics are administered for 7 to 21 days, depending on the organism and the child's clinical response. Dexamethasone is given to children in cases of suspected *Haemophilus influenzae* type b infection to reduce the severity of potential sensorineural hearing loss (Le Saux & Canadian Paediatric Society Infectious Diseases and Immunization Committee, 2014). Other treatments include fever and seizure control, increased ICP management, and fluids and electrolytes.

Infants and children receive nothing by mouth and are started on IV fluids to manage cerebral perfusion pressure. The child is carefully monitored for increased ICP and SIADH (see Chapter 30). IV fluid volume is carefully managed to treat cerebral edema.

Approximately 20% of child survivors have significant disabilities (Martin, Sadarangani, Pollard, et al., 2014). Examples of disabilities include hearing impairment, gross neurologic deficits, and behavioral and intellectual disorders.

Nursing Management

For the Child With Bacterial Meningitis

Nursing Assessment and Diagnosis

Assess the child's physiologic status, including vital signs and level of consciousness. Measure head circumference often in hospitalized infants because of the potential for hydrocephalus. Be alert for signs of a change in the child's condition and response to treatment. Monitor the child's ability to control secretions and to drink sufficient fluids. Monitor intake and output. Assess for any sensory deficits. Identify parents' concerns about this potentially life-threatening condition.

Several nursing diagnoses that may apply to the child with bacterial meningitis appear in the accompanying *Nursing Care Plan*. Additional nursing diagnoses might include the following (NANDA-I © 2014):

- ***Aspiration, Risk for,*** related to altered level of consciousness and poor secretion control
- ***Fluid Volume: Deficient, Risk for,*** related to poor oral fluid intake
- ***Spiritual Distress (Parent)*** related to the child's life-threatening condition
- ***Caregiver Role Strain*** related to a hospitalized child and other family responsibilities

A

B

Figure 27–6 **Testing for Kernig and Brudzinski signs, both common findings with meningitis. *A,* To test for Kernig sign, raise the child's leg with the knee flexed. Then extend the child's leg at the knee. If any resistance is noted or pain is felt, the result is a positive Kernig sign. *B,* To test for Brudzinski sign, flex the child's head while in a supine position. If this action makes the knees or hips flex involuntarily, a positive Brudzinski sign is present.**

Nursing Care Plan: The Child With Bacterial Meningitis

1. Nursing Diagnosis: *Injury, Risk for,* related to infection of cerebrospinal fluid and potential sequelae (NANDA-I © 2014)

GOAL: The child will suffer minimal CNS injury secondary to infection.

INTERVENTION	RATIONALE
• Administer antibiotics and corticosteroids as prescribed.	• Antibiotics help eradicate the pathogen and prevent cerebral edema. Corticosteroids reduce inflammation and the chance of neurologic sequelae.
• Note return of fever, nuchal rigidity, or irritability. Monitor vital signs, assess for signs of increased ICP. Measure head circumference once or twice daily. Note changes in responsiveness. Notify the health-care provider immediately if any signs are detected.	• Watching for common sequelae such as subdural effusions, hydrocephalus, or septic arthritis ensures prompt treatment.

EXPECTED OUTCOME: Child's condition will improve significantly within 48–72 hr (fever will decrease and no signs of neurologic sequelae will be detected).

GOAL: The child will not develop cerebral edema as a result of water retention.

INTERVENTION	RATIONALE
• Monitor for signs of increased ICP and SIADH.	• Early recognition is essential for management to be initiated quickly.
• Perform strict intake and output measurements. Determine urine specific gravity. Check electrolytes and osmolality of both serum and urine. Weigh the child daily. Restrict fluids and give sodium chloride as prescribed.	• Low urine output with a high specific gravity is a sign of fluid retention and SIADH. The child is maintained with lower fluids and is provided sodium supplements to reduce the possibility for cerebral edema.

EXPECTED OUTCOME: Cerebral edema will not develop. If SIADH or increased ICP occurs, the condition will be treated promptly so effects are minimized.

GOAL: The child will be free of injury resulting from disseminated intravascular coagulation (DIC).

INTERVENTION	RATIONALE
• Be aware of needlesticks and lesions that continue to bleed. Monitor clotting times.	• Prompt recognition leads to management of the coagulopathy.
• Administer blood products, vitamin K, or heparin as ordered.	• Prompt recognition allows for early initial treatment of DIC. The child may bleed to death if treatment is delayed.

EXPECTED OUTCOME: Child will not sustain injury from DIC.

GOAL: The child with any degree of hearing loss will be identified.

INTERVENTION	RATIONALE
• Arrange for hearing assessment prior to discharge.	• Hearing loss is a common complication. Early intervention is needed to promote growth and development.

EXPECTED OUTCOME: Child with identified hearing loss will be referred to an appropriate specialist or program for intervention.

2. Nursing Diagnosis: *Pain, Acute,* related to meningeal irritation (NANDA-I © 2014)

GOAL: The child will be as comfortable as possible.

INTERVENTION	RATIONALE
• Assess pain with age-appropriate pain scale.	• Pain scales provide ability to quantify pain for future comparison.
• Minimize tactile stimulation.	• Sensory stimulation increases discomfort.

(*continued*)

Nursing Care Plan: The Child With Bacterial Meningitis (*continued*)

GOAL: The child will be as comfortable as possible. (*continued*)

INTERVENTION	RATIONALE
• Allow the child to assume a comfortable position.	• The child determines the most comfortable position. The opisthotonic position may be the most comfortable.
• Keep the lights dim and maintain a quiet environment.	• Dim lights reduce the discomfort from photophobia. Noise can disturb the child.
• Provide pain medication as prescribed.	• Pain medication is appropriate for acute discomfort associated with illness.

EXPECTED OUTCOME: Child will be calm, and behaviors will indicate increased comfort.

3. Nursing Diagnosis: *Infection, Risk for (Family and Close Contacts)*, related to exposure to child with meningitis (NANDA-I © 2014)

GOAL: Caretakers or family members will have no apparent evidence of infection.

INTERVENTION	RATIONALE
• Explain rationale and dose schedule for taking rifampin or ciprofloxacin.	• Rifampin and ciprofloxacin provide prophylaxis for many bacterial pathogens responsible for meningitis.

EXPECTED OUTCOME: Family members and other close contacts will verbalize the schedule for rifampin or ciprofloxacin therapy.

Planning and Implementation

The accompanying *Nursing Care Plan* summarizes care for the child with bacterial meningitis. Nursing care begins with emergency treatment and continues as the child's condition stabilizes. Monitor respiratory and neurologic status, maintain hydration, administer medications, and prevent complications. Promote the child's comfort with reduced stimulation (dim lights, quiet room) and by placing in a side-lying position. Isolate the child according to hospital protocol until the causative organism is identified and effective treatment has been administered for 24 hours.

SAFETY ALERT!

Monitor the serum sodium concentration and urine specific gravity since the child is at risk for SIADH (see Chapter 30). Maintenance and replacement fluids are usually given to children with bacterial meningitis. If SIADH occurs, moderate fluid restriction with an isotonic solution is ordered until serum sodium levels return to normal.

Monitor the child's response to antibiotic therapy. Observe for signs of gastrointestinal bleeding, which is a potential complication of corticosteroid use.

Respond to parents' concerns about their child's condition, explaining all measures to reduce the child's discomfort and treat the illness. Identify ways parents can help meet the child's comfort needs.

Prevention is a major role for nurses. Encourage parents to get their infants and children fully immunized with the *Haemophilus influenzae*, pneumococcal, and meningococcal vaccines (see Chapter 16).

DISCHARGE PLANNING AND HOME CARE TEACHING

Identify and address home care needs well in advance of discharge. Follow-up visits are important to monitor for complications and sequelae. Help parents deal with any physical requirements resulting from the child's illness and any emotional, social, and financial repercussions of the child's condition. Teach parents what to do if the child has a seizure.

Infants and toddlers with neurologic sequelae should be referred to an early intervention program. Refer the child with a hearing loss to an otolaryngologist and speech and language specialist. Encourage early identification of other neurologic sequelae, such as learning problems. Children with neurologic sequelae need to have an individual education plan (IEP) developed (see Chapter 12), and parents may need help planning for the child's special educational needs. Refer parents to the appropriate social service agencies for support and assistance.

Evaluation

Expected outcomes of nursing care are provided in the accompanying *Nursing Care Plan*.

Viral (Aseptic) Meningitis

Viral meningitis is an inflammatory response of the meninges characterized by an increased number of blood cells and protein in the CSF. In the United States, an enterovirus is the most common cause of viral meningitis in children (Kelesidis, Mastoris, Metsini, et al., 2014).

Generally, the child with aseptic meningitis does not appear as ill as the child with bacterial meningitis. The child may have an abrupt onset of fever of 38.0°C to 40.0°C (100.4°F to 104°F) and have meningeal signs (headache, photophobia, stiff neck, and back pain), myalgia, irritability, and lethargy. Other symptoms include malaise, vomiting and diarrhea, upper respiratory symptoms, and a maculopapular rash. The infant may have a tense anterior fontanelle. Seizures are rare. Symptoms usually resolve spontaneously within 3 to 10 days.

The child with fever and meningeal signs is hospitalized. Blood, urine, and CSF analyses are performed. PCR and DNA testing of the CSF help detect viral meningitis, often within 24 hours. Until the diagnosis of aseptic meningitis is confirmed, the child is treated aggressively for bacterial meningitis. Other treatment is supportive of symptoms. Children usually make a full recovery.

Nursing Management

Initial nursing care focuses on providing supportive care as described for the child with bacterial meningitis. Give acetaminophen or ibuprofen as ordered to reduce fever, headache, and muscle or joint pain. Keep the room dark and quiet (to decrease stimuli and meningeal irritation), give IV or oral fluids, and promote comfort with proper positioning.

The child and family need information about the disease. Explain medical and nursing procedures in terms that the child and family can understand. Keep parents informed about the child's progress. Once the diagnosis of viral meningitis is made, immediately begin discharge planning and teaching for home care. Explain that recovery may take several weeks but that complete recovery is expected.

Encephalitis

Encephalitis is an acute inflammation of the brain often caused by an arbovirus that is transmitted by a mosquito, such as the West Nile, Eastern equine, Western equine, St. Louis, and La Crosse viruses. Other causes of encephalitis include Colorado tick fever, enteroviruses, and Epstein-Barr virus. Inflammation of the meninges is also common. Epidemics occur most often in warm weather seasons.

Encephalitis may occur as a direct or primary infection by an organism (virus, bacteria, fungi, or parasite) that successfully passes through the blood–brain barrier. Some children only have symptoms of a flulike illness after being infected and never develop encephalitis. Signs and symptoms include fever, irritability, severe headache, and bulging fontanelle, followed by altered mental status. The child may have flaccid or spastic paralysis. Meningeal irritation signs such as nuchal rigidity, photophobia, and positive Kernig or Brudzinski signs are common. Focal or generalized seizures may occur. Altered mental status may progress to coma over hours or days.

Diagnosis is based on history and laboratory findings. Information about recent immunizations, insect bites, or residence in or travel to areas where cases of encephalitis are present should be obtained (e.g., West Nile virus or Eastern equine encephalitis). CSF culture and analysis, blood serologic tests, and nasopharyngeal and stool specimens are evaluated to identify viral pathogens. Testing for virus-specific immunoglobulin M antibodies using the enzyme-linked immunosorbent assay (ELISA) test is performed after 5 days of acute illness. The PCR test is used to assay for herpes DNA in the CSF. A CT scan, MRI, and EEG may also be performed. An EEG may help assess seizure activity and help localize the area of the brain affected.

The child with encephalitis is at risk for seizures, respiratory failure, and increased ICP and receives supportive treatment in the intensive care unit (ICU). Physical therapy, occupational therapy, and speech therapy may be prescribed for these children. Children admitted to the ICU with serious symptoms are more likely to have persistent symptoms that last up to 6 months. Some fatalities occur, and significant neurologic sequelae may result.

Nursing Management

Nursing care focuses on monitoring cardiorespiratory function, preventing complications resulting from immobility, reorienting the child, and teaching the parents about the child's condition.

Monitor the child's cardiorespiratory function. Check the child's airway and ability to handle secretions. Assess the child's color, respiratory rate and effort, SpO_2, and arterial blood gases. Monitor the heart rate, blood pressure, capillary refill time, and urine output.

Provide seizure precautions. Prevent complications resulting from immobility (see Box 27–1). Maintain skin integrity. Proper positioning with frequent turning is important. When prescribed by the healthcare provider, perform chest physiotherapy to prevent pneumonia.

Give the parents information about their child's condition and prognosis. Provide support to parents as they cope with the serious nature of this condition.

As the level of consciousness begins to improve, the child may at first be confused and disoriented and may have residual effects of the disease. Orient the child to the hospital environment. Have the family take an active role in the child's physical and emotional recovery, such as by bringing favorite stuffed animals or music from home. Engage in therapeutic play (refer to Chapter 11 for techniques). Give the child age-appropriate toys to encourage a return to normal behavior.

Provide parents with instructions for home care. Plan follow-up visits so the child can be evaluated for neurologic sequelae. Ensure that children are referred for physical or speech therapy as needed. Refer parents to home care, social services, family counseling, and support groups as needed.

Reye Syndrome

Reye syndrome is an acute **encephalopathy**, which is a cerebral dysfunction caused by a toxic, inflammatory, or anoxic insult or injury that may result in permanent tissue damage, although the dysfunction may improve over time. In 1980, an association was identified between the use of aspirin for influenza or varicella and Reye syndrome. The condition is now rare in the United States (approximately 35 cases a year) since most parents give children acetaminophen or ibuprofen rather than aspirin for flulike symptoms and varicella (Ibrahim & Balistreri, 2016). The mortality rate associated with Reye syndrome is high.

Reye syndrome is classified as a secondary mitochondrial hepatopathy. It is caused by a drug toxic to the liver or other toxin, metal, or metabolite and results in a poorly functioning organ. In the case of Reye syndrome, an interaction between a viral illness and aspirin occurs in a susceptible individual (Ibrahim & Balistreri, 2016). The disorder is characterized by cerebral edema, hypoglycemia, and an enlarged, fatty, poorly functioning liver (due to an elevation of short-chain fatty acid levels and hyperammonemia).

Reye syndrome begins with a preceding viral illness that seems to be resolving, followed by an acute onset of vomiting, mental status changes, seizures, and progressive unresponsiveness. The condition progresses to cerebral edema and neurologic dysfunction, leading to a final stage with coma, seizures, flaccidity, loss of deep tendon reflexes, and respiratory arrest.

The diagnosis of Reye syndrome is based on an abrupt change in the child's level of consciousness and diagnostic laboratory tests that reveal liver dysfunction and no other identifiable cause. CSF analysis usually reveals white blood cells. Radiographic imaging reveals cerebral edema. Liver enzyme and ammonia levels are elevated, blood glucose levels are below

normal, and prothrombin time is prolonged. Serum bilirubin levels are normal. A liver biopsy is sometimes performed to confirm the diagnosis.

The child with Reye syndrome receives supportive care in a pediatric ICU. Efforts are made to prevent the secondary effects of cerebral edema and metabolic injury associated with the elevated short-chain fatty acid and ammonia levels. Mechanical ventilation is often needed once the child is comatose. Arterial and venous blood pressure monitoring is performed. The child is monitored for signs of increased ICP secondary to cerebral edema (see the *Clinical Skills Manual* SKILLS). Hypoglycemia is treated with IV glucose. Electrolytes, blood chemistry, and blood pH are monitored.

Clinical Tip

Make sure all parents know that they should use acetaminophen or ibuprofen rather than aspirin when the child has a viral illness such as influenza to prevent the development of Reye syndrome. Most over-the-counter medications for children are now made with acetaminophen or ibuprofen, but parents should be encouraged to verify this.

Nursing Management

Nursing care focuses on monitoring the child's physical status, providing emotional support, and teaching parents about disease prevention.

Check the child's respiratory and neurologic status frequently, and note any signs of improvement or deterioration. Refer to the discussion of nursing management of altered states of consciousness earlier in this chapter for specific nursing interventions.

Monitor laboratory tests for acidosis, elevation of ammonia levels, or hypoglycemia. Monitor the child's intake and output. Correct imbalances by administering fluids, electrolytes, or medications as ordered. Prevent complications associated with immobility. Support the family faced with the child's life-threatening illness (see Chapter 13).

The child who survives and is discharged is monitored for sequelae. Developmental and neurologic deficits may occur and are more severe in children under 2 years of age. Arrange for home nursing or frequent clinic visits during the recovery period for monitoring. Inform the parents about community resources that can assist them in promoting the child's recovery.

Guillain-Barré Syndrome (Postinfectious Polyneuritis)

Guillain-Barré syndrome is an acute inflammatory peripheral neuropathy with an acute onset of rapidly developing symmetric motor weakness that progresses in an ascending pattern. It is rare in children compared to adults.

Guillain-Barré syndrome is thought to be a postinfectious disorder that affects motor neurons, but may also affect sensory and autonomic neurons. The damaged neurons experience demyelinization. Onset occurs within 6 weeks after an influenza-like or gastrointestinal illness (*Campylobacter jejuni* was the most common organism) in 60% of cases (Shui et al., 2012). An association between immunizations such as for influenza and the disorder has not been confirmed.

Infants have an onset of rapidly progressive severe hypotonia, possible respiratory distress, irritability, and feeding difficulties. Older children initially have pain, numbness, paresthesia, or weakness in all limbs. Weakness progresses bilaterally over days for up to 4 weeks. Maximum weakness is often reached in 2 to 4 weeks. Deep tendon reflexes may be diminished or absent. The child may develop acute ataxia or an inability to walk. Respiratory muscles and cranial nerves may not be affected, but difficulty swallowing and bilateral facial nerve weakness are signs of impending respiratory failure. If the autonomic nervous system is affected, blood pressure fluctuations and episodes of bradycardia and asystole may occur.

Diagnostic criteria of Guillain-Barré syndrome include varying degrees of progressive motor weakness (up to total paralysis of all extremities) and **areflexia** (no reflex response to stimulation). CSF protein levels rise to twice the upper limit of normal, and a few white blood cells are seen in the CSF. Bacterial and viral cultures are usually negative. Electroconduction tests such as electromyography show acute muscle denervation. An MRI of the spinal cord may be requested.

Clinical therapy for Guillain-Barré syndrome is intravenous immune globulin (IVIG) at a dose of 0.4 g/kg/day for 2 to 5 days when ascending paralysis is progressing rapidly. Guidelines for administration of IVIG can be found in Chapter 22. Responses to IVIG are dramatic, often within days. Plasma exchange to remove autoantibodies or immunosuppressive medications are alternate therapies. Corticosteroids are not effective. Pain management is important. Physical therapy and supportive care are initiated early to promote ambulation. The condition is rarely fatal; however, some disability may result.

Nursing Management

Nursing care focuses on monitoring respiratory status, meeting nutritional needs, managing autonomic nervous system dysfunction, preventing complications associated with weakness and immobility, providing emotional support, and teaching the parents how to care for the child after discharge.

Place the child on a cardiorespiratory monitor for continuous assessment in the early phase of the illness. Monitor the child for dyspnea, inability to handle secretions, inadequate respiratory effort, and mucous membrane color changes that may indicate the need for endotracheal intubation and mechanical ventilation.

Monitor the child's vital signs closely for episodes of tachycardia, bradycardia, blood pressure fluctuations, sweating, and bowel and bladder dysfunction. Observe frequently for decreased responsiveness. Promptly report the occurrence of these signs to the child's healthcare provider.

Assess the child's ability to swallow. If the child has no gag reflex, nutrition is provided with IV supplements or nasogastric tube feedings.

Prevent complications associated with immobility (see Box 27–1). Ensure good postural alignment, and turn the child every 2 hours. Maintaining skin integrity is also important.

Evaluate the child's muscle tone, strength, and symmetry. When the child's condition begins to improve, recovery of lost strength is the priority. Active exercise is emphasized in physical therapy. Encourage family members to participate in the child's care, especially during the recovery phase. They can help with the activities of daily living and reinforce what the child has learned in physical therapy.

Explain the progression of Guillain-Barré syndrome to the parents during the initial stages. Witnessing a rapid deterioration in their child's physical status can be frightening; therefore, inform parents that deterioration may continue until the treatment becomes effective. Be honest when discussing recovery and

prognosis for the child. Have parents bring in favorite toys, dolls, or books to make the child feel more secure. Playing with or reading to the child can be comforting.

DISCHARGE PLANNING AND HOME CARE TEACHING

Identify and address home care needs well in advance of discharge. Support the parents as they prepare for the child's return home, especially when return to full strength is expected to be slow. Outpatient physical therapy sessions may be needed several times a week in the early recovery stages. Frequent follow-up visits to the health center are essential to monitor the child's recovery. Refer the parents to home health services that can provide guidance for financial assistance.

COMMUNITY-BASED NURSING CARE

Help the child to adjust to any residual effects of Guillain-Barré syndrome. Help the child practice exercises learned in physical therapy sessions, and encourage the child to perform activities of daily living, such as brushing the teeth or combing the hair.

To promote a positive self-image, praise any effort the child makes to be self-sufficient. The child may be frustrated and angry. Allow the child to express these feelings in an appropriate way, either during play or in conversation. Home schooling may be needed until the child has strength to walk and participate in a full school day.

Headaches

An estimated 75% of children experience a headache by age 15 years, and headaches are a major reason for school absence (Antonaci et al., 2014). Up to 20% of children and adolescents experience migraine headaches (Sun et al., 2013). The incidence of headaches increases as children age. Headaches interfere with physical, social, and mental health aspects of daily life.

Etiology and Pathophysiology

Headaches have both benign (migraine, inflammatory, and tension) and structural causes, such as a tumor. See Table 27–11 for headache classifications and clinical manifestations.

- Migraine headaches may be triggered by stress; foods containing nitrates, glutamate, caffeine, tyramine, and salt; menses; fatigue; and hunger. Genetic predisposition may be a factor. Some children may also have abdominal migraine episodes (Catala-Beauchamp & Gleason, 2012).
- Tension headaches may be associated with stress related to school, anxiety, demanding schedules, fasting, and inadequate sleep.
- Medication overuse (rebound) headaches are associated with the frequent use (2 to 3 times a week) of medications for headaches (e.g., acetaminophen, nonsteroidal anti-inflammatory drugs [NSAIDs], decongestants, triptans, opioids, benzodiazepines, and ergotamines).

Clinical Manifestations

Table 27–11 shows the signs and symptoms associated with specific types of headaches.

Clinical Therapy

Diagnosis involves a detailed history of the headache characteristics (onset, duration, pain severity, quality, and location; aura; treatment or medications used) and associated symptoms (abdominal pain, nausea, vomiting). Assessment for neurologic signs such as altered consciousness, abnormal cranial nerves, papilledema, and motor or sensory deficits is performed. Radiologic studies (CT scan or MRI) are used only in cases of abnormal neurologic signs or a suspected structural problem. A lumbar puncture is performed if an infection or inflammatory process is suspected.

Treatment includes relaxation techniques, analgesics, and anti-inflammatory medications. A behavior management program may help reduce common headache triggers (inadequate sleep, stress, missed meals, caffeine, chocolate, or excessive extracurricular activities). Medications to abort migraines (e.g., almotriptan malate and rizatriptan benzoate by mouth) are approved by the U.S. Food and Drug Administration (FDA) for adolescents who can identify an aura or signs of an impending headache. Topiramate was recently approved by the FDA as a prophylactic medication for migraine headaches in adolescents. Medication overuse headaches are treated by withdrawal of all medications used for headaches for a 2- to 4-week period. Limited use of medications may be permitted after that period.

Nursing Management

Assess the child for potential neurologic signs associated with headaches. Encourage the child to keep a headache diary, either written or electronic, that tracks the events and stresses at the time of a headache to help identify patterns and potential triggers. Assist the child and family to see patterns in the headache diary and discuss potential strategies for relieving the headaches. Behavior changes that may reduce headaches include a consistent bedtime and wake-up time 7 days a week, a regular eating schedule, regular physical activity for 30 to 45 minutes at least 5 days a week, and avoidance of hunger, identified food triggers, and smoke and other strong odors.

Teach the child to take the prescribed medications at the first sign of a headache, but no more often than 2 to 3 days a week. See Chapter 24 for care of the child with a brain tumor.

Structural Defects

Common structural defects include microcephaly, hydrocephalus, neural tube defects, craniosynostosis, positional plagiocephaly, and neurofibromatosis.

Microcephaly

Microcephaly is a small brain with a head circumference below the third percentile on growth curves. Causes may include a genetic disorder or destructive insult during infancy, such as an infection, metabolic disorder, or hypoxia-ischemia. Intellectual disability is common (see Chapter 28 for more information).

Hydrocephalus

Hydrocephalus is the body's response to an imbalance between the volume of cerebrospinal fluid (CSF) produced and absorbed. The condition may be congenital or acquired as a result of intraventricular hemorrhage, meningitis, traumatic brain injury, or brain tumor. An estimated 1 to 2 infants per 1000 are born with hydrocephalus (National Institute of Neurological Disorders and Stroke [NINDS], 2014). It is commonly associated with myelomeningocele (described later in this chapter).

TABLE 27–11 Clinical Manifestations of Headaches by Classification

CLASSIFICATION OF HEADACHES	CLINICAL MANIFESTATIONS
MIGRAINE	
Vascular, acute recurrent	• Unilateral or bilateral pulsatile throbbing pain lasting for hours or days, moderate to severe pain intensity, aggravated by routine activity • Lasts 2–3 hr; may be relieved by sleep, but may last 48–72 hr if untreated • Nausea and vomiting • Photophobia and phonophobia • Visual or motor aura several minutes before headache starts; if no aura may have mood changes, food cravings, or anorexia hours before the attack • Preschool-age children may have irritability, restlessness, malaise, head banging, head holding, and sensitivity to light and sound • Recurrent abdominal pain
TENSION	
Muscular contraction Acute recurrent (less than 15 days a month)	• Intermittent or constant pain of mild to moderate intensity (may fluctuate), pressure or tightening (nonpulsatile) sensation • May last 30 min to 7 days • Unlikely to have nausea, vomiting, abdominal pain, or visual disturbances • Sensitive to light or sound
REBOUND OR MEDICATION OVERUSE	
Chronic nonprogressive (more than 15 days a month)	• Pain many be bandlike, over entire head, or crushing; may be bad enough to interfere with academic performance • Occurs at least 2–4 times a week or daily • Usually increases in frequency and severity over time, paralleling the increase in medication use • Recurs when medication wears off
INFLAMMATORY	
Sinusitis or dental abscess Acute localized	• Facial pain or tenderness over affected sinus, gum, or periorbital area; may be associated with nasal congestion • Dull, constant pressure; severity varies with head position • Fever may be present • No nausea, visual changes, light or sound sensitivity
STRUCTURAL	
Space-occupying lesion, hemorrhage, increased ICP Chronic progressive	• Severe pain, increases in frequency and severity, often in occipital or frontal location • Pain awakens child or is present in the morning; increases with coughing, sneezing, or straining • Vomiting that is persistent or preceded by recurrent headache • Abnormal neurologic signs (e.g., double vision, papilledema, strabismus, weakness, ataxia)

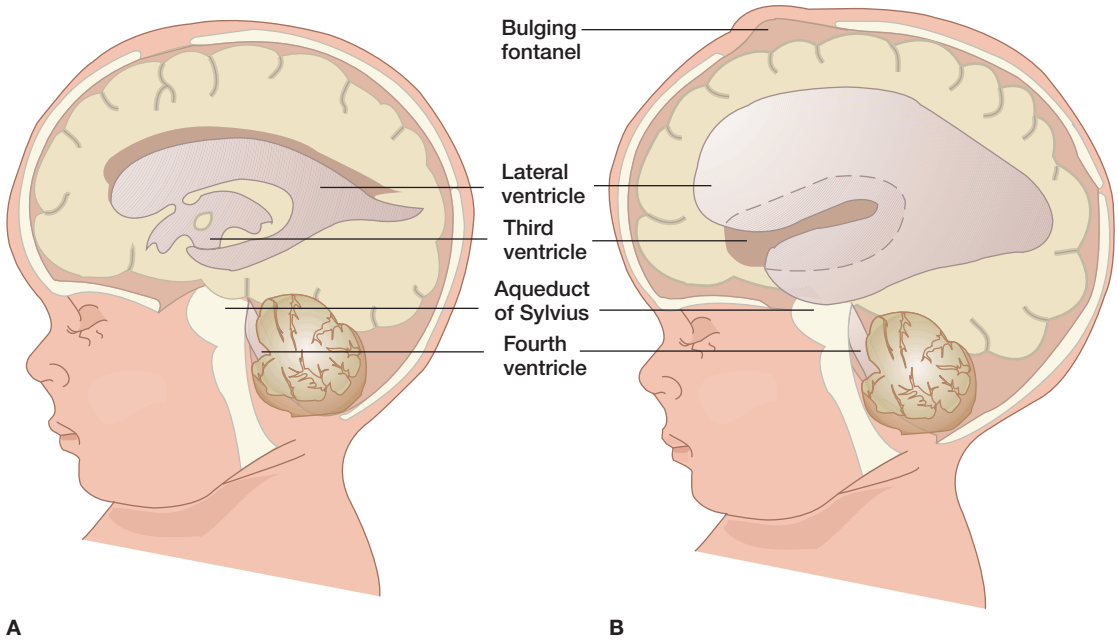
Clinical update: Recognising brain tumours early in children. *Community Practitioner, 86*(4), 42–45.

ETIOLOGY AND PATHOPHYSIOLOGY

Hydrocephalus may be either communicating or noncommunicating. In communicating hydrocephalus, the CSF flows freely among normal channels and pathways, but CSF absorption in the subarachnoid space and the arachnoid villi is impaired. It may be acquired or caused by a congenital malformation in the subarachnoid spaces.

Noncommunicating hydrocephalus accounts for most cases in children. It results from a blockage in the ventricular system that prevents CSF from entering the subarachnoid space, resulting in enlargement of one or more ventricles (see *Pathophysiology Illustrated: Hydrocephalus*). This obstruction can be caused by infection, hemorrhage, tumor, surgery, or structural deformity. Congenital structural defects include the Chiari type II malformation (found in children with myelomeningocele), aqueduct of Sylvius stenosis, and the Dandy-Walker syndrome (includes hydrocephalus, a posterior fossa cyst, and hypoplasia of the cerebellum).

Pathophysiology Illustrated: **Hydrocephalus**



A, Normal size of ventricles. *B*, Enlarged ventricles, characteristic of hydrocephalus.

The Arnold-Chiari malformation (Chiari type II) involves a downward placement of the medulla and lower cerebellum through the foramen magnum of the skull into the cervical vertebrae. This displacement can cause sudden death, respiratory difficulty, swallowing difficulties, and the need for assisted ventilation. Symptoms during infancy may include stridor, a weak cry, and apnea. An older child may have an extremity weakness, difficulty swallowing, choking, hoarseness, vocal cord paralysis, and breath-holding episodes. This defect is also associated with intellectual disability and epilepsy.

CLINICAL MANIFESTATIONS

The signs and symptoms of hydrocephalus vary with the age of the child (Table 27–12). Infants have a rapidly increasing head circumference (Figure 27–7). Older children show signs of increased ICP. Signs of shunt malfunction in infants are nonspecific and include irritability, vomiting, poor appetite, disordered sleep, and fever. Older children with shunt malformation may have a headache, nausea, vomiting, and decreased level of consciousness.

CLINICAL THERAPY

The diagnosis of hydrocephalus may be made prenatally by ultrasound or based on physical findings and neuroimaging studies after birth. Daily head circumference measurements are essential for any infant at risk of developing hydrocephalus. CT and MRI imaging diagnose hydrocephalus, and in some cases reveal the anatomic cause. When the infant's fontanelle is still open, ultrasonography or echoencephalography may be used to confirm the diagnosis. CT and MRI imaging are also used to evaluate shunt failure.

Clinical therapy for hydrocephalus involves surgery to remove the obstruction (e.g., surgical removal of a tumor or endoscopic third ventriculostomy) or to create a pathway to divert excess CSF. A catheter or shunt is placed in the ventricle and passes the CSF to the peritoneal cavity, right atrium of the heart, the pleural spaces of the lungs, or the subgaleal space (space between the skull and scalp used for preterm infants with intraventricular hemorrhage) (Figure 27–8). Initial shunt placement is usually performed early in infancy with adequate tubing length for the child's future growth. Shunt revisions are often needed during childhood. Children with ventriculoatrial shunts receive perioperative IV antibiotics to reduce the risk for reinfection.

Figure 27–7 **In communicating hydrocephalus, an excessive amount of cerebrospinal fluid accumulates in the subarachnoid space, producing the characteristic head enlargement seen here. Note the large forehead and facial features that seem small for the size of the head. When observing the child with hydrocephalus, look for a downward deviation of the eyes in which the lower half of the iris is hidden by the lower eyelid (sunsetting eyes). This finding occurs in severe hydrocephalus, but is not present in this child.**

TABLE 27–12 Clinical Manifestations of Hydrocephalus

CAUSE	CLINICAL MANIFESTATIONS
CONGENITAL STRUCTURAL DEFECT	
Dandy-Walker syndrome	***Early signs***
Arnold-Chiari type II malformation	Rapidly increasing head circumference; tense, bulging fontanelle, split sutures
ACQUIRED DEFECT IN INFANCY	*Bossing* (protrusion) of frontal area, face is disproportionate for skull size
Intraventricular hemorrhage	Difficulty holding head up
	Macewen's or "cracked-pot" sign with percussion
	Prominent, distended scalp veins, translucent scalp skin
	Increased tone or hyperreflexia, Babinski sign
	Irritability or lethargy, poor feeding
	Decline in level of consciousness
	Late signs
	Sunsetting eyes (sclera visible above iris), sixth cranial nerve palsy
	Apnea spells
	Shrill, high-pitched cry
	Difficulty swallowing or feeding; vomiting
	Cardiopulmonary depression (severe cases)
ACQUIRED HYDROCEPHALUS IN OLDER CHILD AFTER CLOSURE OF SUTURES	
Postinfectious	Signs of increased ICP, no head enlargement
Tumor	Headache upon arising with vomiting
Hemorrhage	Irritability, sleepiness, confusion, lethargy, apathy, altered consciousness
	Personality change, loss of interest in daily activities
	Poor judgment or verbal incoherence, worsening school performance, memory loss
	Ataxia, spasticity, or other motor problems
	Visual defects secondary to pressure on second, third, and sixth cranial nerves

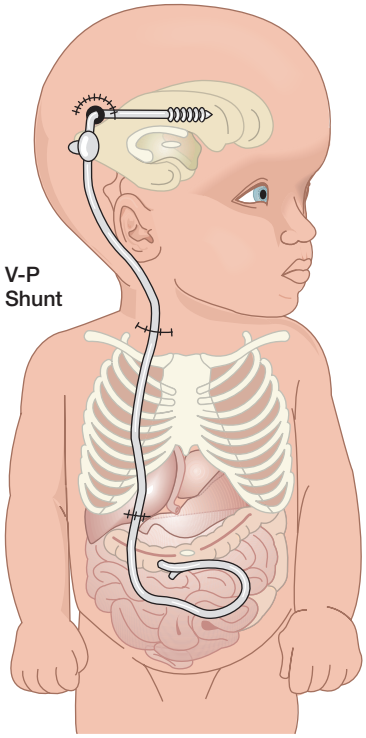


Figure 27–8 **A ventriculoperitoneal shunt system consists of four parts: a ventricular catheter, a pumping chamber or reservoir, a one-way pressure valve, and a distal catheter. A shunt, commonly used to treat children with hydrocephalus, is often placed at 3 to 4 months of age.**

SAFETY ALERT!
Technologic advances have led to the development of shunts with adjustable pressure valves that can be programmed with magnets. If the child receives an MRI, schedule time for the child to have the shunt pressure checked and adjusted as needed because the magnet from the MRI could affect the pressure setting.

Shunt mechanical complications may include a blocked catheter, kinked tube, or valve breakdown. Shunt materials and systems continue to be refined in an attempt to reduce mechanical problems.

Shunt infection is the most serious complication. To confirm the infection, a CSF culture is obtained from the shunt reservoir located in a burr hole placed in the skull. The shunt is surgically removed, and an external drainage device is placed. IV antibiotics are usually prescribed. A new shunt is inserted when the CSF cultures are sterile.

An upper cervical laminectomy may be performed in infants and children with the Arnold-Chiari malformation to prevent an emergency. Alternative treatment includes symptomatic care while maintaining the airway and preventing aspiration. Rapid surgical decompression may be needed to reduce brainstem compression and to prevent death.

Nursing Management

For the Child With Hydrocephalus

Nursing Assessment and Diagnosis

Nurses should assess all infants to promptly identify children with hydrocephalus. Measure the head circumference of all

infants at each well-child visit and compare to prior measurements plotted on the growth curve (see the *Clinical Skills Manual* SKILLS). Note any signs of increased ICP, such as irritability, poor appetite, sunsetting eyes, or a shrill cry.

Monitor the child following placement of a ventriculoperitoneal shunt for signs of shunt failure and infection. Signs of infection in infants may include changes in responsiveness, unusual irritability, low-grade fever, diminished appetite, and sleep pattern disturbance. Measure the infant's head circumference daily and compare to prior measurements when shunt failure is suspected. Report any abnormalities to the healthcare provider immediately. Older children will have signs of increased ICP (Table 27–4).

Nursing diagnoses that might be appropriate for the child with hydrocephalus include the following (NANDA-I © 2014):

- ***Infection, Risk for,*** related to surgical procedure
- ***Mobility: Physical, Impaired,*** related to insufficient muscle strength to lift the increased weight of head
- ***Caregiver Role Strain, Risk for,*** related to care of a child with a chronic condition or life-threatening illness
- ***Development: Delayed, Risk for,*** related to repeated shunt infections and hospitalizations
- ***Injury, Risk for,*** related to potential shunt failure

Planning and Implementation

HOSPITAL-BASED NURSING CARE

Nursing care focuses on providing preoperative and postoperative care and providing emotional support.

Before surgery, position the infant carefully; do not stretch or strain the neck muscles since they must support the large head. Holding the infant may be difficult because of the additional weight of the head. Reduce the risk for skin breakdown with an airflow mattress or by placing sheepskin under the head. Prevent any other complications associated with immobility (see Box 27–1). Attend to the child's special nutritional needs. Because the infant is prone to vomiting, frequent small feedings and frequent burping are beneficial.

After surgery, the child is usually placed in a flat position to prevent rapid CSF drainage as the shunt begins working. The head of the bed is elevated gradually over a day or 2. Take vital signs, including the assessment of neurologic signs (such as pupil size and response to light, extraocular movements, and change in muscle tone) every 2 to 4 hours. Care for the child's surgical site as directed by healthcare provider order or agency guidelines. Monitor the child carefully for any signs of shunt malfunction, increased ICP, or infection. See Chapter 11 for other postoperative nursing care.

Support the parents and explain the child's condition and all procedures to be performed. Encourage parents and family to help with the child's care in the hospital when appropriate. Be sympathetic and understanding, and allow parents to express their concerns. If hydrocephalus occurs during early infancy, the parents will be anxious about the impact of the chronic condition and subsequent surgical procedures. If hydrocephalus is secondary to neoplasm or other acquired condition, however, the parents' anxieties are compounded by their child's life-threatening illness. Assure parents that most children with shunts lead normal lives, attending school and interacting with others no differently from their peers.

DISCHARGE PLANNING AND HOME CARE TEACHING

Identify and address home care needs well in advance of discharge. Parents must learn how to care for the surgical site until healed. Educate parents and other family members about important signs and symptoms of shunt failure (signs of increased ICP) and infection (changes in responsiveness, irritability, malaise, headache, nausea, and low-grade fever). Provide the telephone numbers of healthcare providers, and reinforce the need to contact a healthcare provider immediately if a problem with the shunt is suspected. Some children experience a seizure after shunt placement. Teach parents how to care for the child if a seizure occurs. Refer families to the appropriate home care, social services, and support groups such as the Hydrocephalus Association.

COMMUNITY-BASED NURSING CARE

Infants and children need frequent monitoring to ensure proper shunt functioning. Head circumference is measured at each visit to monitor growth. After shunt placement in an infant, head circumference may decrease 1 to 2 cm (0.39 to 0.79 in.) as the pressure is relieved. Head growth as a result of brain development may then be noted in 2 to 4 months. Alert the healthcare provider if head growth resumes sooner than 2 to 4 months, as the shunt may have malfunctioned or need a pressure setting change. Assess the child for visual problems and cognitive, speech, and motor developmental delays. Refer the child and family to an early intervention program to promote developmental progress. School-age children may need an IEP (see Chapter 12).

Encourage parents to provide good nutrition and reduce exposure to infections. Teach parents alternate positions for burping infants with an enlarged head and to use an infant seat after feeding to reduce regurgitation. Provide foods with fiber to promote regular bowel movements. Constipation increases abdominal pressure that may interfere with CSF drainage through the ventriculoperitoneal shunt.

Using a childcare setting with a small number of children, such as family or home-based child care, helps decrease exposure to infection. Encourage good hand hygiene by all caregivers.

Teach parents to protect the infant with an enlarged head from injury by using a rear-facing car safety seat regardless of age. This position decreases their risk of cervical spine injury and death in a car crash. Discourage participation in sports with a high potential for head and abdominal impact, but encourage other sports.

Evaluation

Expected outcomes of nursing care include the following:

- The infant develops adequate neck muscle control to interact with the environment.
- Shunt infections and malfunctions are rapidly identified by the parents, and medical attention is sought quickly.
- The child's potential for growth and development is maximized by care and a stimulating environment.

Neural Tube Defects

The neural tube is the tissue that ultimately develops into the CNS, including the brain and spinal cord. **Neural tube defects** occur in about 3000 pregnancies each year in the United States (Kerr & Huether, 2014). Neural tube defects include the following:

- *Anencephaly*—no development of the brain above the brainstem, which is ultimately fatal
- *Encephalocele*—protrusion of meningeal tissue or meninges-covered brain through a defect in the skull

- *Spina bifida occulta*—a vertebral defect in which the posterior vertebral arches fail to fuse (usually the fifth lumbar or first sacral vertebrae), but the spinal cord and meninges are contained in the vertebral canal
- *Spina bifida cystica*—a posterior vertebral arch defect with protrusion of meninges through the bony spine
- *Meningocele*—protrusion of a meningeal sac filled with CSF through a vertebral defect, associated with no abnormalities of the spinal cord
- *Myelodysplasia (spina bifida or meningomyelocele)*—protrusion of a meningeal sac that contains CSF, a portion of the spinal cord, and nerves through a vertebral defect

MYELODYSPLASIA OR SPINA BIFIDA

Myelodysplasia (sometimes called *meningomyelocele*) refers to a malformation of the spinal cord and spinal canal. *Spina bifida* refers to a defect in one or more vertebrae that allows spinal cord contents to protrude. The malformation can occur anywhere along the vertebral column, but is most common at the lumbar or sacral portion of the spine. Each year in the United States, approximately 1500 infants are born with spina bifida (Centers for Disease Control and Prevention [CDC], 2014b). The incidence is higher among newborns of Hispanic women and lowest among non-Hispanic Black women (CDC, 2015).

Developing Cultural Competence Folate Deficiency

Mandatory fortification of all enriched grain products with folate was initiated in 1998. This public health initiative has prevented an estimated 1326 cases of spina bifida and anencephaly annually, a 28% reduction. Hispanic women have a lower intake of folic acid and a higher rate of folate deficiency, potentially because of a genetic susceptibility to folate deficiency or to the greater use of corn masa flour, which is not fortified like other cereal grains (CDC, 2015).

Etiology and Pathophysiology. The cause of spina bifida is unknown, although environmental factors have been implicated, such as chemicals (excessive use of alcohol), medications (e.g., valproic acid and carbamazepine used for seizures, isotretinoin for acne), genetic factors, and maternal health conditions (diabetes mellitus, gestational diabetes, folic acid deficiency, and maternal obesity). The increased incidence of the condition in families points to a possible genetic influence.

Healthy People 2020

(MICH-28) Reduce occurrence of neural tube defects

Clinical Manifestations. A saclike protrusion on the infant's back indicates meningocele or myelodysplasia (Figure 27–9). The clinical manifestations (paralysis, weakness, and sensory loss) depend on the location of the defect. The higher the defect on the spinal cord, the greater the neurologic dysfunction:

- *Thoracic level*—paralysis of the legs, weakness and sensory loss in the trunk and lower body region
- *Lumbar 1–2 level*—some hip flexion and adduction, cannot extend knees
- *Lumbar 3 level*—can flex hips and extend the knees; paralyzed ankles and toes
- *Lumbar 4–5 level*—can flex hips and extend the knees; weak or absent ankle extension, toe flexion, and hip extension
- *Sacral level*—mild weakness in ankles and toes

Sensory loss is more pronounced on the back of the legs, and the loss of lower extremity motor and sensory functioning may not be symmetric.

Bowel and bladder incontinence occurs with all but the sacral level lesions, but bowel and bladder function may still be affected at the sacral level. Renal damage may result from neurologic impairment and urinary retention (neurogenic bladder). Hydrocephalus is usually present in children with a myelomeningocele defect above the sacral level, along with the Arnold-Chiari type II malformation (see hydrocephalus earlier in this chapter). The range of problems associated with spina bifida is listed in Table 27–13.

Children with myelodysplasia have mobility problems, intellectual disability, and visual impairment. Additional complications include spinal curvatures, musculoskeletal and joint abnormalities, skin sores, precocious puberty, and sexual dysfunction.

Clinical Therapy. A high-resolution fetal ultrasound leads to the diagnosis, and an elevated maternal serum alpha-fetoprotein level is present. Fetal surgery prior to 26 weeks' gestation improved cognitive and motor function of infants at 30 months of age. It also reduces the need for a shunt for hydrocephalus; however, the surgery increases the risk for preterm birth (Scully, Mallon, Kerr, et al., 2012). Fetal surgery is becoming more common as maternal-fetal surgery centers are developed.

If fetal surgery is not performed, the lesion is examined after birth and the neurologic status is evaluated. Radiologic imaging by ultrasonography, CT scan, MRI, and flat films of the spinal column can pinpoint the bony defect and nerve

Figure 27–9 Lumbosacral myelomeningocele is caused by a neural tube defect in which the vertebral column is incompletely closed. The meninges (and sometimes the spinal cord) protrude as a saclike structure. Observe for leakage of cerebrospinal fluid.

TABLE 27–13 Clinical Manifestations of Myelodysplasia

CAUSE	CLINICAL MANIFESTATIONS
Interruption of the spinal cord at site of the spinal defect	Loss of motor and sensory function of the abdomen and lower extremities, dependent on defect level Scoliosis or kyphosis Incontinence of urine or urinary retention Incontinence of feces or constipation Sensory loss around genitalia
Muscle imbalance	Hip abnormalities, hip dysplasia Foot deformities (e.g., clubfoot)
Tethered spinal cord (the cord is abnormally attached to tissues around the spine that keeps it from moving freely within the spinal column)	Walking ability deteriorates Back pain, increasing scoliosis Leg pain, spasticity, progressive foot deformity Bladder and bowel function deteriorates
Brain abnormalities	Hydrocephalus, generalized seizures Learning problems, attention deficit disorder Problems with perceptual motor skills Memory and organization problems Problems with numeric reasoning

involvement. Subsequent testing is performed to evaluate bowel and bladder function, neurologic and motor function, and cognitive function.

Surgery to close and repair the lesion usually occurs within 24 to 48 hours of the infant's birth to reduce infection risk. As the child grows, braces are used to support joint position and mobility. Assistive devices such as walkers, crutches, and wheelchairs are used to enhance mobility. To minimize the risk for osteoporosis, the diet should ensure adequate calcium and vitamin D, and weight-bearing activities should be encouraged. Surgery to release a tethered spinal cord may be needed. An orthotic jacket may be prescribed to correct spinal deformities that affect lung capacity and interfere with mobility and sitting.

Interventions for a neurogenic bladder are initiated early to prevent kidney damage, to maintain bladder function, and to promote urinary continence. Clean intermittent catheterization is performed on a regular schedule (every 3 to 4 hours) (see Chapter 26). A Mitrofanoff procedure that creates a reservoir for urine and a stoma for catheterization in the umbilicus may be performed.

Dietary fiber, stool softeners, and glycerin or bisacodyl suppositories are prescribed for bowel evacuation and to promote bowel continence. Surgery to create a channel between the skin and bowel using the appendix (Malone antegrade continence enema) is often performed in children with fecal incontinence or severe constipation at the same time as the Mitranoff procedure. This procedure enables a child or adolescent to infuse an enema into the ascending and transverse colon to promote bowel evacuation to eliminate fecal soiling and incontinence.

Prognosis depends on the type of defect, the level of the lesion, and other complicating factors, such as renal dysfunction. In the United States, 90% survive to adulthood, and about 80% have normal intelligence (Spina Bifida Association, 2014). Children need multiple surgeries and invasive procedures. A team of healthcare providers, nurses, and therapists from the neurosurgery, orthopedic, urology, and physical medicine departments works with the child and family to form a comprehensive care plan.

Nursing Management

For the Child With Myelodysplasia or Spina Bifida

Hospital-Based Nursing Care

The newborn is often transferred to a specialty center or neonatal intensive care unit until surgery is performed. Place the newborn in a prone position with hips slightly flexed and legs abducted to minimize tension on the sac. Monitor the sac for leakage of cerebrospinal fluid (CSF). Assess the extremities for deformities. Frequently assess the vital signs and stay alert for signs of infection, especially meningitis. Encourage the parents to interact with and soothe the newborn while waiting for surgery. Depending on when surgery will be performed, the newborn may be given small frequent feedings in the prone position.

Following surgery, inspect the surgical site for signs of infection and CSF leakage. Manage the infant's postoperative pain. Assess intake and output. Measure the head circumference daily to detect hydrocephalus. If a shunt was placed, provide care as described in the section on hydrocephalus.

Place the infant in a prone or side-lying position for sleep until healing has occurred, after which the supine sleep position may be used. Keep the diaper away from the incision site. Provide incision care according to agency guidelines. Assess the neonate regularly for signs of infection, motor deficits, and bladder and bowel involvement. Perform urinary catheterization on a regular schedule if needed.

Begin gentle range-of-motion (ROM) exercises as soon as possible to prevent muscle contractures and atrophy. Use caution because these children have brittle bones that fracture easily. Splints may be used to maintain extremity alignment.

Support the parents by keeping them informed about their child's status. Allow them to express their frustrations and anger. As soon as parents are able to cope with the child's condition, encourage them to become involved in the infant's care in the hospital.

The child with myelodysplasia may be hospitalized for surgery numerous times to correct deformities. Assess the child's vital signs, responsiveness, and level of pain. Because the child may have decreased pain sensation in the lower extremities, careful assessment is needed. Assess dressing sites for bleeding and drainage. Monitor the distal extremities for swelling and circulation.

SAFETY ALERT!

Children and adolescents with spina bifida are at high risk for latex allergy, thought to be related to frequent and cumulative numbers of exposure over time. See Table 22–10 for a list of products containing latex commonly found in the home.

DISCHARGE PLANNING AND HOME CARE TEACHING

Address home care needs well in advance of discharge. Help parents obtain special devices such as splints, wedges, and rolls, if needed, to prevent complications. Instruct parents how to

position, handle, and feed the infant, and to perform ROM exercises. Teach parents to perform intermittent clean catheterization and establish a schedule for catheterization every 3 to 4 hours. See the *Clinical Skills Manual* SKILLS.

Teach parents the symptoms of increased ICP, hydrocephalus, shunt infection or malfunction, and urinary tract infection. Arrange for home care nursing to reinforce skills learned in the hospital as needed. Refer parents to resource groups such as the Spina Bifida Association.

COMMUNITY-BASED NURSING CARE

Because of multiple system involvement and to promote optimal development, children with myelodysplasia need comprehensive care planned and coordinated by a knowledgeable team of healthcare providers (e.g., orthopedics, neurosurgery, urology, developmental pediatrics, rehabilitation medicine, nursing, physical therapy, nutrition, and family support services). This care may be provided in partnership with the primary healthcare provider. A case manager may be helpful to coordinate the health plan coverage and the child's care with numerous healthcare providers. Parents have many financial issues related to the child's need for medical supplies and new adaptive equipment to match growth.

At an appropriate age, teach the child to perform intermittent self-catheterization. When the child begins school, an individualized health plan should be developed so the child has access to the restroom, assistance as needed for toileting, and accommodations for mobility challenges.

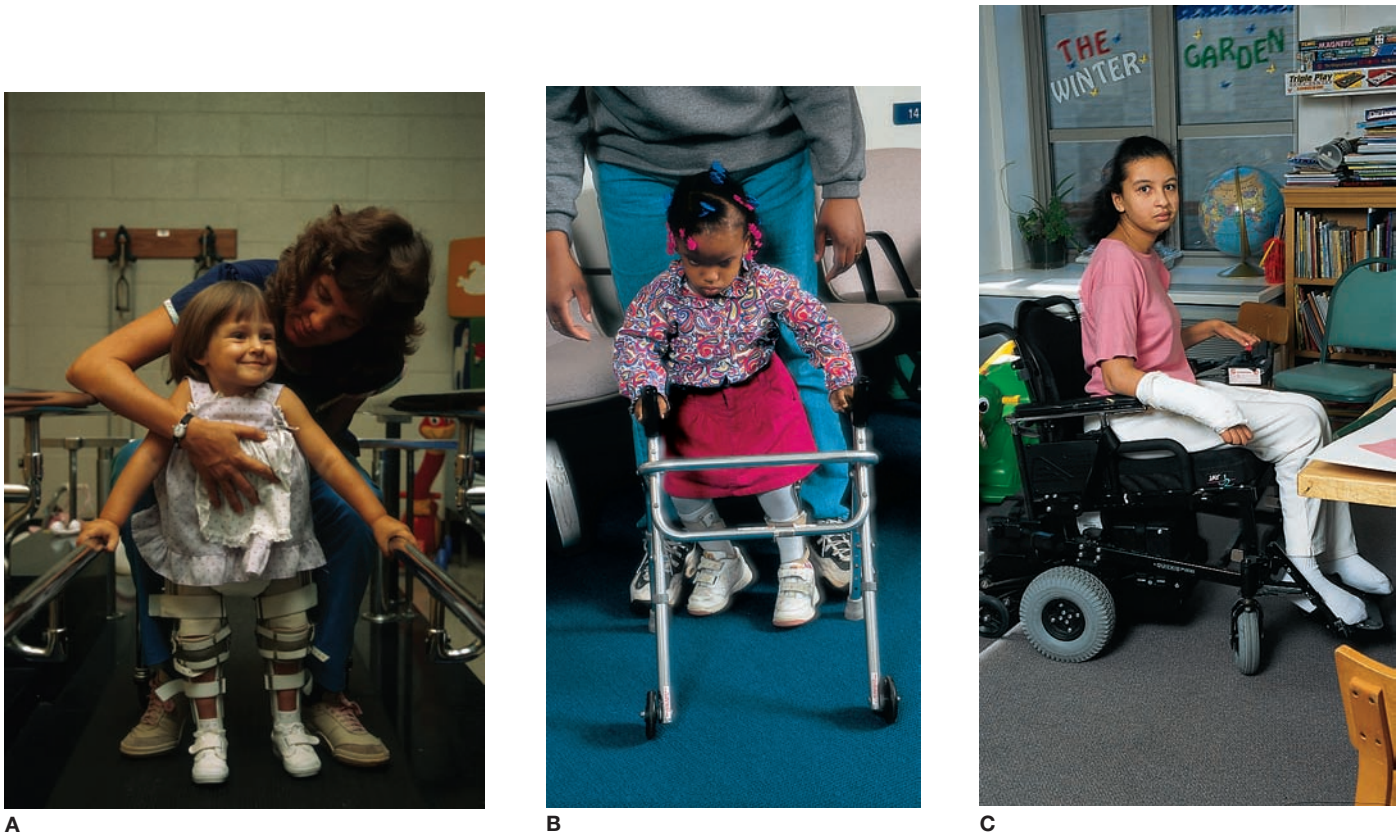
Clinical Tip

The child who has clean intermittent catheterization performed usually has some bacteria in the urine. Symptoms indicating a urinary tract infection that should be treated include fever, dysuria, or new-onset incontinence.

Good nutrition planning is important to prevent obesity and to reduce constipation and fecal impaction. Bowel training is initiated to control bowel evacuation. A diet high in fiber helps ensure adequate stool. The child should have a bowel movement at least every 1 to 2 days to avoid impaction. Consistency in time of day for bowel evacuation is important to promote continence. A glycerin or bisacodyl suppository can be given to promote bowel evacuation at the appropriate time.

Promote safety and independent mobility with proper use of braces, walkers, crutches, canes, and in some cases custom-designed wheelchairs and car safety seats (Figure 27–10). For other safety guidelines, see *Families Want to Know: Safety for the Child With Spina Bifida*.

Treat older children according to their intellectual level, not their motor development. Encourage them to take responsibility for self-care, and recognize their need to control their body functions. Monitor adolescents for mental health problems, especially as differences from peers and challenges in lifestyle become of greater concern. Refer for counseling as needed. See *Health Promotion: The Child With Myelodysplasia*.



A B C

Figure 27–10 **Help determine the best assistive device for the child to gain the most mobility independence and to promote development. The child may vary the devices used in different settings to promote optimal independence. *A* and *B*, Braces and walkers may be best for young children to promote an upright posture that encourages a normal interaction with the environment. *C*, A motorized wheelchair can assist the child with a significant neurologic impairment to achieve independence and mobility.**

Families Want to Know

Safety for the Child With Spina Bifida

Because of the loss of sensation in the lower extremities, injuries to the skin may not be immediately noticed by the child. Several routine actions will help reduce the risk for injury:

- Perform a daily check of all skin surfaces and pressure points associated with sitting, braces, and shoes to identify abrasions, scrapes, reddened areas, and other lesions. Stop using the braces or shoes until the skin heals or redness disappears.
- Keep all skin surfaces clean and dry. Wear socks under braces.
- Use a gel-filled cushion in the wheelchair, and teach the child to shift positions hourly to prevent pressure sores.
- Avoid burns to the lower extremities by checking the temperature of bath water and car safety seats in a hot car.
- Teach parents how to avoid the use of latex products and to inform all healthcare providers about the child's latex allergy or risk.
- Use safe ambulation techniques with walkers, canes, and crutches.

Health Promotion The Child With Myelodysplasia

Preventive Health Care

- Provide all recommended immunizations. If the child has a seizure disorder, alert parents that seizures may occur following immunizations.
- Perform all recommended routine screening procedures (vision, hearing, hematocrit, blood pressure).
- Obtain a urinalysis with culture in the newborn period and when signs of infection are noted.
- Screen for scoliosis annually beginning at birth.

Growth and Development Surveillance

- Monitor the growth of the child (length or height, weight, head circumference) and plot on growth curves. Monitor head circumference growth carefully because of hydrocephalus risk.
- Assess developmental status regularly. Motor skills are often delayed.
- Enroll the infant in an early intervention program to assist the parents to promote the child's development.
- Promote gradual independence in mobility and self-care.

Nutrition

- Teach families appropriate caloric intake and portion control for the child at each age to reduce the risk for obesity.
- Provide guidance about increased fluids and fiber in the diet to reduce the risk for constipation and urinary tract infections.
- Alert parents that allergies to foods such as bananas, avocados, papaya, kiwi, and other foods may occur because of the risk of latex allergy.

Elimination

- Teach families the importance of performing intermittent catheterization on a regular schedule. Teach the child to perform self-catheterization and care for the catheter in preparation for school entry.
- Teach families to initiate bowel training so that a bowel regimen is established.

Sleep and Rest

- Position the child to prevent contractures. Change the child's position during the night to reduce pressure over skin surfaces.
- Teach parents to be alert for apnea spells or snoring that could be related to a Chiari type II malformation.

Relationships

- Encourage interaction with peers.
- Be alert for psychosocial adjustment problems, especially during the adolescent years.

Craniosynostosis

Craniosynostosis is the premature closure of cranial sutures in utero or during the first 18 months of life. This condition occurs in 1 per 1800 to 2200 live births, and boys are affected twice as often as girls (Kerr & Huether, 2014). Craniosynostosis may occur in association with chromosomal abnormality syndromes such as Apert and Crouzon syndromes, but most cases are not related to a syndrome (McCarthy et al., 2012).

When one or more sutures closes too early, bone growth continues in a direction parallel to the suture line. This leads to overgrowth at normal suture lines and classic skull deformities (Figure 27–11). Sagittal synostosis (scaphocephaly) occurs more commonly in males and is the most common form of craniosynostosis (Brown & Proctor, 2011). Bicoronal synostosis is associated with Alpert or Crouzon syndromes.

Diagnosis of craniosynostosis is made by clinical appearance and palpation of a bony ridge along a skull suture line. Detection may occur during fetal ultrasound. Skull measurements, radiographs, and CT imaging confirm the diagnosis. Surgery is performed for cosmetic reasons and when increased ICP occurs. A custom orthotic helmet may be used for several months to promote optimal skull reshaping. Follow-up care is coordinated to manage potential associated problems, such as hypoplasia of the midface, orthodontic or ophthalmologic issues, and obstructive sleep apnea.

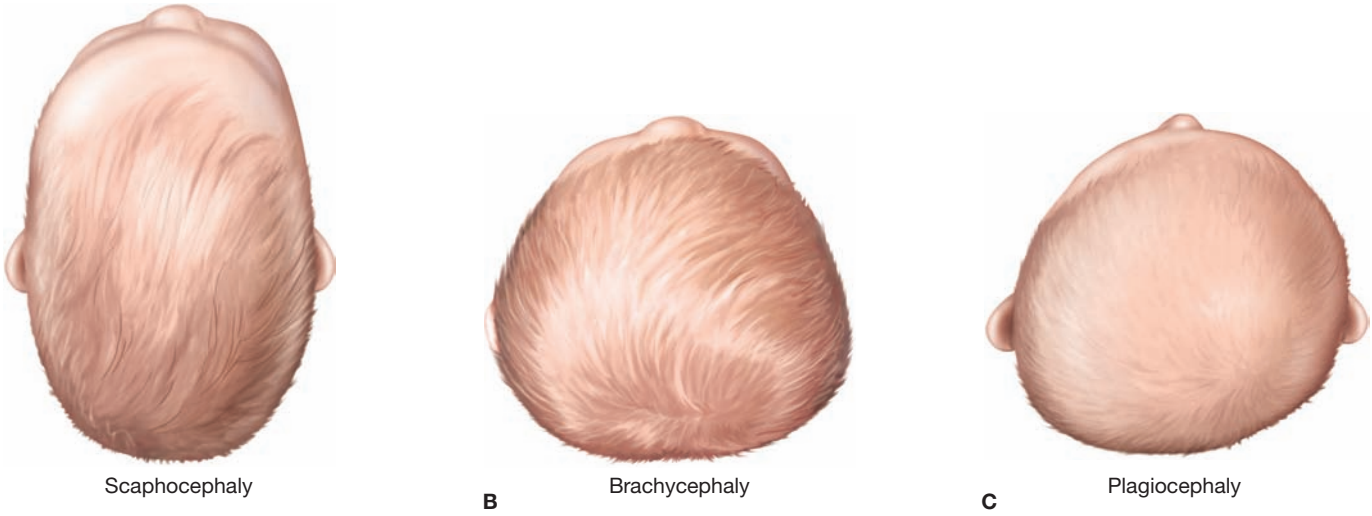

Figure 27–11 **In craniosynostosis, the head shape is dependent on which sutures are involved. *A,* Scaphocephaly, premature closure of the sagittal suture causes a long, narrow skull, flattened parietal bones with a prominent occiput, a broad forehead, and a small or absent anterior fontanelle. *B,* Brachycephaly, premature closure of the bicoronal suture causes a head shape shortened anterior to posterior, and the occiput is flattened. *C,* Positional plagiocephaly is often asymmetric flattening of the occiput due to preferred sleep position when supine or due to torticollis.**

After surgery, nursing care involves keeping the incision dry and intact. Observe the child for symptoms of increased ICP (see Table 27–4). The nurse should monitor intake and output, manage patient positioning, protect skin integrity, and monitor for infection. Explain to parents that surgery will improve the child's appearance. Assure them that most children with craniosynostosis are healthy, and that their brains develop normally.

Positional Plagiocephaly

Positional plagiocephaly (an asymmetric flattening of the skull) is associated with sleep position to prevent sudden infant death syndrome or in infants with neck problems such as congenital torticollis. Some infants have variable tone and developmental delay that reduces development of neck muscles strength (Looman & Flannery, 2012). The sutures do not close prematurely. If the infant's sleep position does not change, the weight of the head flattens the skull (see Figure 27–11C).

If torticollis is a factor in plagiocephaly, a physical therapy referral is important. In cases of severe positional plagiocephaly, a helmet device is used to correct the condition, especially when facial asymmetry is present. The helmet is most effective when treatment is initiated at 6 months of age when the skull bones are most malleable. The helmet is worn for 23 hours a day for 2 to 4 months. Remolding of the head shape continues naturally after that treatment period because the infant spends more time awake and upright.

Clinical Tip

To help prevent positional plagiocephaly, encourage parents to try to reduce the infant's preference for lying supine in one position. Rotate the side of the crib where an interesting toy is placed each day. Alternate the infant between the top and bottom of the crib each day, so the infant must turn the head in a different direction to look at who comes into the room. Put the infant in a bouncy seat while awake. Rotate the arm used for formula feeding the infant. When the child is alert and continuously supervised, place the infant in the prone position on the floor for short periods (tummy time) to promote neck muscle strength and interaction with nearby objects.

Neonatal Abstinence Syndrome

Illicit substances that may cause neonatal abstinence syndrome (NAS) when used by the mother during pregnancy include opioids (heroin, meperidine, methadone), CNS stimulants (cocaine, propoxyphene, amphetamines), CNS depressants (barbiturates, alcohol, and marijuana), as well as antidepressants and benzodiazepines. The overuse of prescription opioids is contributing to an increase in incidence of NAS. It is estimated that 5.4% of women 15 to 44 years of age use illicit drugs during pregnancy, but the rates vary by age: women 15 to 17 years (14.6%), women 18 to 25 years (8.6%), and women 26 to 44 years (3.2%) (Substance Abuse and Mental Health Services Administration, 2014). Among pregnant women 15 to 44 years of age, 8.5% report current alcohol use, and 2.7% report binge drinking (Substance Abuse and Mental Health Services Administration, 2013). See Chapter 28 for information about fetal alcohol syndrome.

Illicit substances readily cross the placenta, enter the fetal circulation, and have the same effects on the fetus that they do on the mother. For example, cocaine decreases placental blood flow, depriving the fetus of essential oxygen and nutrients while elevating the fetal blood pressure and heart rate. The mother's repeated use of opioids and other illicit substances leads to fetal tolerance and physical dependence. Abrupt withdrawal of the illicit substance after birth leads to signs of NAS. See Chapter 15 for information about opioid withdrawal. Withdrawal symptoms for illicit substances usually appear 24 to 72 hours after birth, depending on timing of last exposure prior to birth.

Initial signs of NAS often include irritability, jitteriness, tremors, and excessive crying. Other signs include yawning, diarrhea, vomiting, seizures, inconsolable high-pitched crying, difficulty sleeping, hypertonia, and autonomic nervous system signs (e.g., temperature instability, tachycardia, hypertension, sweating, and sneezing). The skin may become excoriated from continuous movement against bed linens. Severity of signs is associated with number of substances, duration, and total accumulation of exposure. Depending on substances to which the fetus was exposed, signs of NAS may persist for 10 to 30 days after birth (Kocherlakota, 2014).

Diagnosis is based on the history of maternal substance abuse and physical signs in the newborn. Maternal and neonatal urine drug screening identifies substances to which the fetus was exposed a few days before birth. Meconium screening provides information of drug use by the mother for the last half of the pregnancy. Hair and umbilical cord testing may be performed. Neonatal EEG abnormalities may be noted.

Treatment is often supportive when signs and symptoms are mild, minimizing stimulation, swaddling, and gentle handling. Medications are used when supportive treatments do not control signs and symptoms. Medications commonly used include morphine, methadone, phenobarbital, and clonidine to alleviate symptoms of drug withdrawal. The newborn often needs an extended hospital stay. Breastfeeding is encouraged as minimal amounts of most drugs used by the mother cross over into milk. Mothers who breastfeed and misuse prescription opioids should be informed about the sedative effect of these medications. The long-term effects of this condition on cognitive function continue to be studied.

Nursing Management

Prevention and early identification of the newborn with NAS is an important nursing role. Providing information for all parents about the risks and effects of various illicit substances increases the chance that they will avoid these substances in future pregnancies.

High-pitched crying, irritability, tremors, and poor feeding should increase the nurse's suspicion of NAS. Observe the newborn carefully for increased muscle tone, sweating, seizures, vomiting, diarrhea, and tachycardia. Observe the neonate carefully for signs of severe NAS in which diarrhea and vomiting may lead to dehydration and electrolyte disturbances. Monitor the condition of the skin to identify abrasions associated with rubbing against sheets.

Provide frequent, small, high-calorie feedings on demand, which are more readily tolerated by these newborns. Monitor the neonate's weight gain or loss to determine if a change in nutritional approach is needed, such as a formula with 24 calories per ounce or nasogastric feeding (MacMullen, Dulski, & Blobaum, 2014). Support breastfeeding if this is the mother's preference. Patience is needed when feeding these newborns because their sucking and swallowing may be poorly coordinated, and regurgitation is common. Teach parents to use a calm approach and soothing voice when feeding. Newborns may initially feed better in a side-lying position while swaddled. Hold the baby with the spine flexed to decrease extensor tone.

Administer medications, if prescribed, for drug withdrawal and monitor the newborn's response. Keep in mind that many babies are managed without medications, using supportive care. Several techniques are used to calm and soothe the newborn with neonatal abstinence syndrome:

- Keep the newborn in a quiet environment, away from monitors that beep and paging speakers.
- Keep the lighting subdued and minimize stimulation to promote rest and sleep. Cluster nursing care interventions to reduce sleep disruptions.
- Comfort and pacify the newborn with swaddling and a pacifier for sucking needs. Rocking and soothing music may also be calming. Infant massage may be beneficial for some neonates.

Protect the newborn's skin with barrier shields as jitteriness may lead to greater skin surface rubbing against sheets, and apply topical ointments to scratches and abrasions. When diarrhea is present, use a barrier ointment to prevent skin breakdown. Support neonatal rooming-in practices to promote mother–newborn bonding.

Assess the strengths, safety, and competence of the mother and other potential caregivers in preparation for discharge. Determine if the mother is still using illicit drugs and identify other family supports that may help provide the care and safety needed by the newborn. Begin working with the mother and other family members to demonstrate strategies to promote parent–newborn interaction, minimize stimulation, and promote feeding until neonatal withdrawal is completed. Make plans for careful follow-up by healthcare professionals (social services, physicians, and nurses) so that the baby's safety is ensured and growth and development are monitored and promoted.

Long-term follow-up care of the child should be planned to ensure regular developmental testing and assessment for neurobehavioral problems.

Neurofibromatosis

Neurofibromatosis 1 (NF1), or von Recklinghausen disease, is an autosomal dominant genetic disorder in which tumors grow along nerves. One in 3500 individuals develops the disorder, and 50% of new cases result from a mutation (Julian, Edwards, DeCrane, et al., 2014).

The *NF1* gene is located on chromosome 17. Individuals with NF1 do not have adequate neurofibromin to control cell growth, and neurofibromas form from nerve sheath cells along peripheral nerves or at nerve endings. The neurofibroma may be an isolated growth, or extend along the length of a nerve and include nerve branches (plexiform neurofibroma). Dermal neurofibromas, which usually begin to appear around the time of puberty, may reside in the skin or project above the skin surface. Up to 5% of tumors become malignant in the brain or along nerves, and children may be at risk for leukemia, rhabdomyosarcoma, and pheochromocytoma (Julian et al., 2014). A higher prevalence of autism spectrum disorder may also occur in children with NF1 (Garg et al., 2013).

The disorder is characterized by six or more café au lait spots (darker than surrounding skin) 5 mm (0.20 in.) in diameter or larger seen at birth or by 2 years of age. The spots grow to 15 mm (0.6 in.) or larger by adulthood. Freckling in the axillary and inguinal areas is common. Multiple neurofibromas or benign tumors grow on or under the skin beginning during puberty. Pain may occur when a tumor compresses a nerve or grows in the spinal cord. Lisch nodules, tan or brown benign tumors on the iris of the eye, are characteristic. Vision deficits or blindness is found in some children because of a tumor along the optic pathway. Precocious puberty or delayed puberty and menarche may occur when the optic tumor invades the hypothalamus. The child often has a larger than expected head circumference. Other manifestations include thinning or bowing of the tibia, fractures that do not heal properly, and scoliosis. See Figure 27–12.

Diagnosis is made in early childhood by the presence of two or more characteristic physical findings listed in the previous paragraph and a positive family history. Radiologic imaging (MRI of brain and radiographs of the spine and other bones) is performed when problems are detected. Ophthalmologic examinations are performed at least annually. Clinical therapy focuses on monitoring the child for signs of problems associated with the condition. The severity of the condition ranges from mild to severe with disabilities. Surgery may be performed to remove the tumor when neurofibromas become malignant, are painful or disfiguring, cause paralysis, or when life-threatening problems develop.

Figure 27–12 **Physical signs of neurofibromatosis become more apparent during adolescence. Café au lait spots enlarge, axillary freckling appears, and multiple neurofibromas develop. Some children develop plexiform neurofibromas.**

Nursing Management

Nurses assess the child for signs of neurofibromatosis. Assess the child's growth, pubertal development, vital signs, and vision on a regular basis to detect any problems associated with the disorder. School performance should be monitored as learning disabilities and hyperactivity may occur. Pay attention to any mass that is rapidly enlarging or causing new pain.

Provide psychologic support to the child and family. As tumor development increases during adolescence, problems with self-image and self-esteem are common. Adolescents may fear the response of peers to the tumors and isolate themselves. Identify potential peers or refer the adolescent to a support group.

Cerebral Palsy

Cerebral palsy (CP), a common syndrome of movement and posture development disorders, is caused by a nonprogressive lesion abnormality in the fetal or infant brain that results in activity limitations. The condition may also have associated hearing, vision, communication, perceptual, cognitive, and behavioral problems. An estimated prevalence of CP is 3.9 children per 1000 (Burkhard, 2013). Four types of motor dysfunction seen—spastic, dyskinetic, ataxic, and mixed—are related to the location of brain insult. Dystonia and athetosis are sometimes categorized together as dyskinesia.

Etiology and Pathophysiology

The majority of cases occur during the prenatal and perinatal periods. Risk factors include low birth weight, placental abnormalities, birth defects, meconium aspiration, birth asphyxia, neonatal seizures, respiratory distress syndrome, hypoglycaemia, and neonatal infections. Postnatal cases are related to meningitis, encephalitis, and traumatic brain injury (Colver, Fairhurst, & Pharoah, 2014).

Healthy People 2020

(MICH-27) Reduce the proportion of children with cerebral palsy born as low-birth-weight infants (less than 2500 grams)

Muscle growth is usually coordinated with bone growth, but muscle spasticity interferes. Contractures can develop that limit joint movement or cause deformities such as scoliosis. Because of more limited weight-bearing activity and potential nutritional problems with swallowing and independent feeding, children with CP are at greater risk for osteoporosis and fractures (Aronson & Stevenson, 2012).

Clinical Manifestations

Cerebral palsy is characterized by abnormal muscle tone and lack of coordination. Children have a variety of symptoms depending on their ages, and the pattern or extremities involved may vary:

- *Diplegia*—both legs are affected
- *Hemiplegia*—one side of the body is involved, the arm is usually more severely affected than the leg
- *Quadriplegia*—all four extremities are affected

All children with CP have motor impairment, with spasticity present more commonly than ataxia or athetosis and dystonia. Even if both sides of the body are affected, the impairment is usually more severe on one side. Spasticity is also associated with muscle weakness that interferes with gross motor activities.

See Table 27–14 for clinical manifestations of CP by type of brain injury. Symptoms are variable for this lifelong disability and depend on the area of the brain involved and the extent of brain injury. Behavioral and emotional problems may result from disruption of nerve pathways that reduce the adaptation of the brain.

Children with CP usually have delayed developmental milestones. The functional consequences of motor deficits become more obvious as the child grows even though the brain injury is nonprogressive. Other complications include intellectual disabilities, vision impairments, hearing loss, speech and language impairments, and seizures. Feeding may be difficult because of oral motor involvement, including hypotonia, with poor sucking and swallowing coordination that may result in aspiration or poor nutrition.

Clinical Therapy

Diagnosis is usually based on clinical findings of delayed development and increased or decreased muscle tone. CP is difficult to diagnose in the early months of life because it must be distinguished from other neurologic conditions and signs may be subtle. Suspicious historical findings include risk factors described in the *Etiology and Pathophysiology* section.

Ultrasonography can be used to detect fetal and neonatal abnormalities of the brain, such as intraventricular hemorrhage. Neuromotor tests are used to evaluate the presence of normal movement patterns, absence of common newborn reflexes, and abnormal tone. Once CP is suspected, CT and MRI imaging provide information about anatomic structures and help identify the cause of CP. Genetic and metabolic tests are performed if congenital anomalies are present. Hearing and vision should be evaluated. Standardized tools, such as the Functional Mobility Scale and Manual Ability Classification System, are used to describe the child's capabilities.

Clinical therapy focuses on helping the child develop to a maximum level of independence and to perform activities of daily living. This involves promoting mobility, an optimal range of motion, muscle control, balance, and communication with braces and splints, serial casting, and positioning devices (prone wedges, standers, and side-lyers). Referrals are made for physical, occupational, and speech therapy, as well as special education to improve motor function and ability.

Orthopedic surgery may be required to improve function by balancing muscle power and stabilizing uncontrollable joints. Surgical interventions may include Achilles tendon lengthening to increase the ankle range of motion, hamstring release to correct knee flexion contractures, procedures to improve hip adduction

TABLE 27–14 Clinical Manifestations of Cerebral Palsy by Type of Insult

CLASSIFICATION AND TYPE OF INSULT	CLINICAL MANIFESTATIONS
SPASTIC	
Cerebral cortex or pyramidal tract injury 75% of cases	Increased muscle tone through a joint's range of motion Leads to contractures and abnormal curvature of the spine Exaggerated deep tendon reflexes, clonus Persistent common newborn reflexes, positive Babinski sign
DYSKINETIC—ATHETOSIS	
Extrapyramidal, basal ganglia injury 10%–15% of cases	Muscle tone abnormalities affecting the entire body Difficulty with fine and purposeful movements or coordinating the timing of movement; tremors Slow involuntary writhing motions that interfere with ability to maintain a stable posture
DYSKINETIC—DYSTONIA	
Basal ganglia, extrapyramidal injury	Involuntary sustained muscle contractions that lead to sustained or intermittent exaggerated and distorted posturing, twisting, or repetitive movements Rigid muscles when awake; normal or decreased muscle tone when asleep
ATAXIC	
Cerebellar (extrapyramidal) injury 5%–10% of cases	Abnormalities of voluntary movement (muscle instability) involving balance and position of the trunk and limbs, difficulty maintaining posture, wide-based unsteady gait Difficulty controlling hand and arm movements during reaching Increased or decreased muscle tone, hypotonia in first couple of years
MIXED	
Multiple areas of brain are injured	No dominant motor pattern; may have mild spasticity, dystonia, and/or athetoid movement

Figure 27–13 **Baclofen may be administered by an intrathecal pump. This child is having the reservoir of the baclofen pump filled.**

or correct spinal deformities, or dorsal rhizotomy (cutting the afferent fibers that contribute to spasticity).

Medications are given to control seizures, to control spasms (skeletal muscle relaxants, baclofen, and benzodiazepines), and to minimize gastrointestinal side effects (cimetidine or ranitidine). Benzodiazepines affect brain control of muscle tone to help control spasticity. Dantrolene is a calcium channel blocker that is a muscle relaxant. Baclofen is administered orally or by intrathecal pump to decrease spasticity. See Figure 27–13. Botulinum toxin injection into specific muscles is a therapy that helps to temporarily control spasticity.

The prognosis for infants and children with CP depends on the level of motor disability and on the presence of intellectual, visual, or hearing deficits. Early intervention programs can help improve performance. Many children with hemiplegia or ataxia show some improvement with maturation and are able to ambulate. Others need assistance with mobility and activities of daily living. Many of these children have difficulty with swallowing and aspiration, making feeding a challenge for families. A gastrostomy tube may ultimately be needed to ensure that the child has adequate nutrition and to prevent aspiration.

Nursing Management

For the Child With Cerebral Palsy

Nursing Assessment and Diagnosis

Be alert for children whose histories indicate an increased risk for CP. Assess all children at each healthcare visit for developmental delays. Note any orthopedic, visual, auditory, or intellectual deficits. When the common newborn reflexes persist beyond the normal age, refer for further evaluation (see Chapter 5). Identify infants who appear to have an abnormal muscle tone or abnormal posture (head lag beyond 6 months of age, arched back, poor trunk control and balance, toe walking or scissoring). Asymmetric or abnormal crawling by using two or three extremities and hand dominance prior to 18 months of age indicates a motor problem. Perform a simple screening test by placing a clean cloth on the infant's face. Infants normally use two hands to remove it. Be concerned if the infant over 6 months of age uses one hand or does not remove the cloth at all. Record dietary intake as well as height and weight percentiles for children suspected to have or diagnosed with the condition.

The child has many potential sources of pain. Pain could be associated with constipation, muscle spasms, physical therapy, bladder spasms, decubitus ulcers, headaches, and dental caries. Anticipate and take a careful history to identify potential causes of pain and pain patterns.

Nursing diagnoses for the child with CP often vary by the type of CP, the child's symptoms and age, and the family situation. *Nursing Care Plan: The Child With Cerebral Palsy* includes several nursing diagnoses. Additional nursing diagnoses might include the following (NANDA-I © 2014):

- ***Constipation, Risk for,*** related to low intake of fiber and fluids and insufficient physical activity
- ***Tissue Integrity, Impaired,*** related to decreased physical mobility and limited self-care ability
- ***Communication: Verbal, Impaired,*** related to hearing and/or motor speech impairment
- ***Pain, Chronic,*** related to spasticity and stretching exercises to prevent contractures
- ***Development: Delayed, Risk for,*** related to lack of muscle strength or limited social interaction

Planning and Implementation

The accompanying *Nursing Care Plan* summarizes care for the child with CP. Since the condition varies in severity and manifestations, interventions need to be customized to the child and family. Nursing care focuses on providing adequate nutrition, maintaining skin integrity, promoting physical mobility, promoting safety, promoting growth and development, teaching parents how to care for the child, and providing emotional support.

PROVIDE ADEQUATE NUTRITION

Children with CP require high-calorie diets because of feeding difficulties associated with spasticity or hypotonia. Many children have difficulty chewing and swallowing, and therefore are at risk for aspiration. Give the child small amounts of soft foods at a time. Utensils with large, padded handles may be easier for the child to hold. Make sure the child gets adequate fluids as the child may not be able to communicate thirst. Children with severe CP may need a gastrostomy tube to obtain adequate nutrition and fluids. Adequate fiber is needed to prevent constipation, and some children need a bowel management program to treat chronic constipation.

MAINTAIN SKIN INTEGRITY

Protect bony prominences from skin breakdown. Monitor splints and braces for proper fit and the skin under them for redness. If the skin is red or broken, the braces or splints should be removed and not worn until the skin is healed.

PROMOTE PHYSICAL MOBILITY

Proper body alignment should be maintained at all times. Support the child with pillows, towels, and bolsters whether the child is in bed or in a chair. Use splints and braces to help support joints in extension or a functional position and to reduce the risk for contractures. Support the head and body of a floppy infant. A spastic child with scissored, extended legs or a child with athetosis who writhes constantly is difficult to carry and transport.

Range-of-motion exercises are essential to maintain joint flexibility and to prevent contractures. Consult with the physical therapists who work with the child and assist with recommended exercises. Massage may be helpful when performing stretching exercises. Horseback riding is a therapeutic activity as adjustment to the horse's gait helps improve balance and posture control.

Nursing Care Plan: The Child With Cerebral Palsy

1. Nursing Diagnosis: *Mobility: Physical, Impaired,* related to decreased muscle strength and control (NANDA-I © 2014)

GOAL: The child will attain the maximum physical abilities possible.

INTERVENTION	RATIONALE
• Perform development assessment and record age at which milestones are achieved (e.g., reaching for objects, sitting).	• Delayed development milestones are common with CP. As one milestone is achieved, interventions are revised to focus on the next skill.
• Plan activities to use gross and fine motor skills (e.g., holding eating utensils, toys positioned to encourage reaching). Allow time for the child to complete activities.	• Many activities of daily living and play activities promote physical development. The child may perform tasks more slowly than most children.
• Perform range-of-motion exercises every 4 hours for the child unable to move body parts. Position the child to promote tendon stretching (e.g., foot plantar flexion, legs extended at the knees and hips).	• Exercises and positioning promote mobility and increased circulation, and decrease the risk of contractures.
• Arrange for and encourage parents to keep appointments with a rehabilitation therapist.	• A regular and frequently reevaluated rehabilitation program assists in promoting development.
• Teach the family to use braces and other positioning devices.	• Adaptive devices are often necessary to maximize physical mobility.

EXPECTED OUTCOME: Child will reach maximum physical mobility and achieve developmental milestones.

2. Nursing Diagnosis: *Nutrition, Imbalanced: Less than Body Requirements,* related to difficulty chewing and swallowing and high metabolic needs (NANDA-I © 2014)

GOAL: The child will receive nutrients needed for normal growth.

INTERVENTION	RATIONALE
• Monitor height and weight and plot on a growth grid. Perform hydration status assessment.	• Insufficient intake can lead to impaired growth and dehydration.

• Teach the family techniques to promote caloric and nutrient intake:
  • Position the child upright for feedings.
  • Place foods far back in the mouth to overcome tongue thrust.
  • Use soft and blended foods. Allow extra time for chewing and swallowing.
  • Obtain adaptive handles for utensils and encourage self-feeding skills.
	• Special techniques can facilitate food intake. Adaptive handles may help the child better manage feeding self.

• Perform frequent respiratory assessment. Teach the family the preceding techniques to prevent aspiration. Teach care of the gastrostomy and tube-feeding technique as appropriate.	• Aspiration pneumonia is a risk for the child with poor swallowing coordination. Special feeding techniques or tube feeding may be needed.

EXPECTED OUTCOME: Child will show normal growth patterns for height, weight, and other physical parameters.

3. Nursing Diagnosis: *Health Management, Family, Ineffective,* related to excessive demands made on the family for the child's complex care needs (NANDA-I © 2014)

GOAL: The family will adapt to the growth and development needs of the child with CP.

INTERVENTION	RATIONALE
• Allow chances for parents to verbalize the impact of CP on the family. Provide referral to other parents and support groups.	• The family needs to explore the emotional and social impact of the child's care so they can integrate and grow from the experience.

(*continued*)

Nursing Care Plan: The Child With Cerebral Palsy (*continued*)

GOAL: The family will adapt to the growth and development needs of the child with CP. (*continued*)

INTERVENTION	RATIONALE
• Explore community services for rehabilitation, respite care, child care, early intervention program, and refer family as appropriate.	• Diverse services are available and will be needed because of the multiple impacts of CP on the child.
• During home and office visits, review the child's achievements and praise the family for care provided.	• The child's achievements are positive reinforcement of the family's efforts.
• Teach the family skills needed to manage the child's care (e.g., medication administration, muscle stretching, seizure management).	• Complex skills must be learned before they can be performed efficiently.
• Teach case management techniques.	• The child requires care by many specialists, and many parents become case managers to coordinate care.
• Involve siblings in the care of the child with CP. Review with parents the needs of all children in the family.	• Siblings of the child with CP may feel left out because of the care provided. Special efforts help to meet the developmental needs of all family members.

EXPECTED OUTCOME: Child will demonstrate appropriate growth and developmental progress. Family will successfully support all of its members.

4. Nursing Diagnosis: *Activity, Deficient Diversional (Child),* related to poor social skills (NANDA-I © 2014)

GOAL: The child will engage in activities that maximize growth and development.

INTERVENTION	RATIONALE
• Refer the family to an early intervention program. Encourage contact with other children.	• The child needs a variety of activities and contact with other children and adults to maximize development.
• Work with the school to develop an individualized education plan that encourages interaction with peers and a variety of activities that support development.	• The education system is obligated to work with families to provide methods to enhance learning, including social interactions.
• Investigate recreational programs for children with disabilities and share information with the parents.	• Recreational programs for children with disabilities may promote social experiences and physical activity.

EXPECTED OUTCOME: Child will engage in activities to maximize development.

Refer parents to the appropriate resources for help getting adaptive devices (Figure 27–14). To enhance interaction with the environment, teach the parents to position the child to foster flexion rather than extension (e.g., the child can bring objects closer to the face). Encourage parents to bring in the child's *adaptive appliances* (braces, positioning devices) for use during a hospitalization; however, secure them as the family may have difficulty replacing them if lost.

PROMOTE SAFETY

Safety belts should be used for children in strollers and wheelchairs (see the *Clinical Skills Manual* SKILLS). Determine if an adaptive car safety seat is needed so the child can be safely transported. A child with chronic seizures should wear a helmet to protect against further injury.

PROMOTE GROWTH AND DEVELOPMENT

Remember that many children with CP are physically but not intellectually disabled. Use terminology appropriate for the child's developmental level. Help the child develop a positive self-image to ensure emotional health and social growth. Children with a hearing impairment may need referral to learn American Sign Language or other communication methods. Provide audio and visual activities for the child who is quadriplegic.

Figure 27–14 **This child has cerebral palsy and wears glasses because of vision impairment. She uses a wheelchair for transport to the health center. Notice the planned placement and level of toys to promote her interaction.**

SOURCE: Will & Deni McIntyre/Science Source.

Adaptive and assistive technology may be needed to promote mobility and communication. **Assistive technology** is any item, equipment, or product customized for use to promote the functional capabilities and independence of an individual with disabilities. Examples include computers, communication devices, adaptive utensils, and customized wheelchairs.

FOSTER PARENTAL KNOWLEDGE

Teach parents about the disorder and arrange sessions to teach them about all of the child's special needs. Teach administration, desired effects, and side effects of medications prescribed for seizures. Make sure parents are aware of the need for dental care for children because of the enamel defects and malocclusion that commonly occur in children with CP, and the gingival hyperplasia that occurs when taking some antiepileptic medications.

PROVIDE EMOTIONAL SUPPORT

Listen to the parents' concerns and encourage them to express their feelings and ask questions. Explain what they can expect from future treatment. Work with other healthcare providers to help families adjust to this chronic disease. Refer parents to individual and family counseling if appropriate.

COMMUNITY-BASED NURSING CARE

Children with CP need continuous support in the community. A case manager such as the parent or nurse is often needed to coordinate care. Parents may need financial assistance to provide the care that the child needs and to obtain appliances such as braces, wheelchairs, or adaptive utensils. Children need new adaptive devices, ongoing developmental assessment and care planning, and possibly surgery as they grow. Although the brain lesion does not change, it manifests differently as the child grows. For example, once the child begins to walk, the extensor tone may cause Achilles cord tightening. Braces may decrease deformities, but surgery may eventually be needed. Technology offers many new strategies to promote communication and self-care by these children.

Monitor the child's growth. If the child is unable to ambulate, use a scale that accommodates a wheelchair when weighing. Standing height measurements may be inaccurate. Other possible measures for stature include recumbent length, arm span, tibia length, and knee height. Schedule regular vision and hearing screening during health promotion visits. Give immunizations according to the recommended schedule, even though the pertussis, measles, mumps, and rubella vaccines may increase the risk of seizures in children with a seizure disorder. Educate parents about the possible risk for a seizure associated with the vaccines.

Early intervention programs can help parents learn to meet their child's special needs and obtain physical, occupational, and speech therapy. The child often needs an IEP to maximize learning potential (see Chapter 12). The nurse can help parents meet the needs of the child with CP in preschool, school, and healthcare settings. The nurse also makes referrals as appropriate to support groups and organizations such as the United Cerebral Palsy Association and Shriners Hospitals. Recreational activities may be identified through the National Association of Sports for Cerebral Palsy.

An individualized transition plan should be developed during adolescence to assist the family and adolescent with CP with plans for adult living. Vocational training options can be explored. Both the special mobility needs and educational support needed by the child must be addressed. See Chapter 12.

Evaluation

Expected outcomes of nursing care for the child with CP are provided in the *Nursing Care Plan.*

Injuries of the Neurologic System

Injuries to the brain and spinal cord are major causes of disability in previously healthy children. Drowning is another cause of brain injury in children.

Traumatic Brain Injury

A traumatic brain injury (TBI) is a blunt force or penetrating injury to the head that disrupts normal brain functioning, such as a loss of consciousness. More than 2600 children, ages 0 to 14 years, are estimated to die each year as a result of TBI (Brain Injury Association of America, 2014). Adolescents, 15 to 19 years, have the highest rate of death, followed by children less than age 5 years. The highest rate of hospitalization occurs in adolescents 15 to 19 years old, followed by children less than 5 years old (CDC, 2014a). TBI is a leading cause of death and disability in children and adolescents (Geyer, Meller, Kulpan, et al., 2013).

Growth and Development

Leading TBI mechanisms of injury resulting in emergency department visits or hospitalization vary by age (Quayle, Holmes, & Kuppermann, 2014):

- *Children 0 to 2 years old*—falls, usually from elevation or down stairs
- *Children 2 to 12 years old*—falls from elevation or associated with standing, running, or walking at ground level, or struck by or against an object
- *Adolescents 13 to 17 years old*—assault, sports, and motor vehicle related

ETIOLOGY AND PATHOPHYSIOLOGY

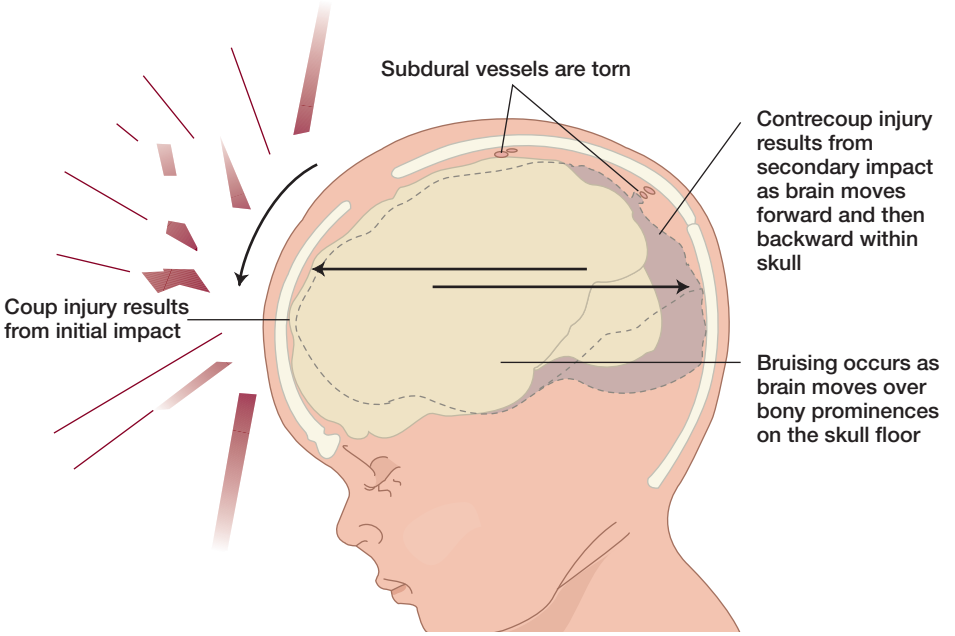
With a blunt injury the impact transfers energy through the skull and meninges to the brain. Primary injury occurs at the time of the impact when the initial cellular damage takes place, such as skull fracture, bruising, or hemorrhage. See *Pathophysiology Illustrated: Brain Injury* for an explanation of the primary injury. With a penetrating injury, additional brain damage occurs along the track of penetration. The secondary injury for both blunt and penetrating TBI is a biochemical and cellular response to the primary injury. Brain swelling begins immediately, leading to cerebral edema, inflammation, ischemia, and increased ICP. Decreased cerebral perfusion pressure limits the circulation, oxygen and nutrient delivery, and removal of toxins resulting from cell death. Brain cells are further damaged by the release of amino acids and an inflammatory response that increase the permeability of the blood–brain barrier.

CLINICAL MANIFESTATIONS

Traumatic brain injury signs and symptoms in children depend on the pathologic features and severity of the injury. The child with a mild TBI (concussion) may remain conscious or have brief loss of consciousness (seconds to a few minutes). The child with a moderate TBI loses consciousness for 5 to 10 minutes. Following mild or moderate TBI, children may have amnesia about the event, headache, nausea, and vomiting. See Table 27–15 for clinical manifestations of TBI by severity.

Unconsciousness may result from increased ICP, cerebral edema, intracranial hemorrhage, or extensive damage to the cerebral cortex or brainstem. Posttraumatic seizures are common. The presence of retinal hemorrhages, frenulum injuries,

Pathophysiology Illustrated: **Brain Injury**



Brain injury can result from a direct blow to the head (coup injury) or the acceleration–deceleration movement of the brain (contrecoup injury) such as occurs from a motor vehicle crash. Movement of the brain in the skull tears nerves, fibers, and blood vessels, causing altered level of consciousness (LOC). Scalp injuries, skull fractures, contusions, and hematomas of brain tissue may also occur if the head experiences a direct blow.

and fractures in an infant should raise the suspicion of child abuse (Fingarson & Pierce, 2012).

SAFETY ALERT!

Any infant who arrives in the emergency department with seizures, failure to thrive, respiratory irregularities, or coma should be evaluated for child abuse (shaken child syndrome). An infant has a large head and relatively weak neck muscles. Shaking an infant causes inertial injuries (acceleration and deceleration) that tear nerve fibers as the brain moves back and forth in the skull. Throwing the infant down onto a mattress further increases the forces with which the brain hits the back of the skull (Dubowitz & Lane, 2016).

Changes in respiratory effort or periods of apnea can occur secondary to shock, injury to the spinal cord above C4, or damage to or pressure on the medulla. Heart rate and blood pressure provide information about brainstem function. Tachycardia can be a sign of blood loss, shock, hypoxia, anxiety, or pain. The Cushing triad (increased systolic blood pressure with a wide pulse pressure, bradycardia, and irregular respirations) is associated with significantly increased ICP, impending herniation, or compromised blood flow to the brainstem. Reflexes may be hyporesponsive, hyperresponsive, or nonexistent. The child may assume a flexor, extensor, areflexic, or flaccid posture (see Figure 27–2). Refer to Table 27–4 for signs of increased ICP. See Table 27–16 for clinical manifestations of specific brain injuries.

TABLE 27–15 Clinical Manifestations of Traumatic Brain Injury by Severity

TYPE OF BRAIN INJURY	CLINICAL MANIFESTATIONS
Concussion or mild brain injury	Low-grade headache that will not go away Slowness in thinking, acting, speaking, reading Memory problems Loss of balance, unsteady walking Poor concentration, change in performance at school, lack of motivation or interest in favorite toys Feeling tired all the time, change in sleeping pattern Change in eating patterns Increased sensitivity to lights, sounds, distractions; easily irritated
Moderate brain injury	Glasgow Coma Scale score of 9–12 Posttraumatic amnesia for 1–24 hr Loss of consciousness
Severe brain injury	Glasgow Coma Scale score of 8 or less Posttraumatic amnesia lasting longer than 24 hr Coma or unconsciousness Increased intracranial pressure Posttraumatic seizures

TABLE 27–16 Clinical Manifestations of Intracranial Hematomas

TYPE OF HEMATOMA	CLINICAL MANIFESTATIONS
SUBDURAL HEMATOMA	
Results from severe brain trauma, including shaken child syndrome. Is more common in infants less than age 1 year. Inertial forces tear veins bridging the subdural space; a venous hematoma forms beneath the dura and presses directly on the brain.	Symptoms that may occur 48–72 hr after the injury: • Gradual change in LOC (confusion, agitation, or lethargy) • Hemiparesis or eye deviation • Nausea or vomiting • Headache • Retinal hemorrhages in both eyes • Pupil on side of injury may be fixed and dilated • Seizures
EPIDURAL HEMATOMA	
Is rare in children, especially those less than 4 years of age. Results from blunt trauma such as falls, assaults, or baseball to temporal area. Arterial or venous bleeding occurs between the skull and the dura; associated with skull fracture.	• Minimal or absent symptoms at time of injury, followed by rapid deterioration in mental status and signs of increased ICP • Headache or full fontanelle • Paresis of cranial nerves III and VI • Papilledema • Fixed and dilated pupil
CEREBRAL CONTUSION	
Bruising on surface of brain is associated with coup and contre-coup injuries, including the base of the brain as it moves across the bony prominences in the base of the skull. Commonly occurs on frontal and temporal lobes. Is the most common TBI.	• Altered levels of consciousness ranging from confusion and disorientation to being obtunded • Focal symptoms depending on the area of injury
DIFFUSE AXONAL INJURY	
Results from rapid acceleration-deceleration injuries, such as with motor vehicle crash or shaken child syndrome. Nerve fibers are torn in both cerebral hemispheres and other brain areas. Other organ systems may also be injured.	• Immediate loss of consciousness • Unconsciousness lasting longer than 6 hr • Abnormal movements or posturing • Seizures • Increased ICP • Difficulty regulating blood pressure and breathing
SUBARACHNOID HEMORRHAGE	
Associated with severe head injuries such as intracranial hematomas or contusions; results from tearing of arteries or veins in the subarachnoid space.	• Progressive decrease in LOC • Severe headache, nausea, and vomiting • Ipsilateral pupil dilation • Diplopia • Hemiparesis • Nuchal rigidity
INTRACEREBRAL HEMATOMA	
Often results from acceleration-deceleration injury or penetrating injury; hemorrhage to frontal or temporal lobe.	• Focal symptoms depend on size and location of hematoma, such as epilepsy

CLINICAL THERAPY

The severity of a brain injury is diagnosed from the history, physical examination, Glasgow Coma Scale (see Table 27–5), and diagnostic tests. Information about the events associated with and mechanism of injury, the child's initial and current responses, any loss of consciousness, and the child's memory of the event are obtained. The cranial nerves, pupillary response, palpation of the skull for depressions, deep tendon reflexes, and muscle strength are all evaluated.

Laboratory tests include a complete blood cell count, blood chemistry, coagulation tests, toxicology screening, and urinalysis. Radiographs detect fractures of the skull and cervical vertebrae. A CT scan detects fractures, intracranial bleeding, swelling, and diffuse axonal injury. An MRI scan is used during recovery to determine the extent of brain damage. PET scans measure the blood flow in the brain. A fracture indicates a more serious injury. Many children with brain injuries have multiple other injuries. Children with a moderate to severe TBI should be evaluated for a potential cervical spine injury.

The initial management of a child with a severe brain injury is based on the child's physiologic status (see *Concussion* section later in this chapter for management of a mild TBI). The airway must be clear and stable, and hypoxia must be prevented. The child is continuously monitored for hypercapnia, which causes vasodilation and increased ICP. The child may be intubated and mechanically ventilated with 100% oxygen at a slightly

increased respiratory rate in the first 24 hours after injury to maintain oxygenation levels and reduce ischemia (see the *Clinical Skills Manual* SKILLS).

Clinical Tip

In the child with moderate head injury, the oxygen saturation should remain over 95%. For the severely injured child who is intubated, monitor arterial blood gas results. A PaO_2 greater than 60 mmHg and a $PaCO_2$ between 35 to 38 mmHg are recommended (Geyer et al., 2013).

An intraventricular catheter (ventriculostomy) may be inserted and attached to a monitor to measure intracranial pressure. Efforts are made to maintain the cerebral perfusion pressure (difference between the mean arterial pressure minus the ICP or central venous pressure) so that the brain circulation is adequate to deliver oxygen and nutrients and to remove neurotoxins. Hypotension is avoided. Hypovolemic shock is treated if present and inotropic medications may be used to maintain the blood pressure. Keep the head of the bed flat until adequate cerebral perfusion pressure is ensured and maintained.

Increased Intracranial Pressure. Treatment is required when the ICP value is greater than 20 mmHg; it becomes life threatening at 40 mmHg (Geyer et al., 2013). If increased ICP is not relieved, brain shifting begins in the cranium, a precursor of herniation. Invasive procedures may be used to reduce ICP. Burr holes or more extensive surgery may be performed to evacuate a lesion or hematoma. An external ventricular drainage system may be placed to monitor ICP, to drain CSF when brain swelling reaches dangerous heights, and to help maintain CPP (see the *Clinical Skills Manual* SKILLS). Decompressive craniectomy may be considered as a last resort when ICP cannot be otherwise controlled.

Mannitol or IV hypertonic saline (3%) may be administered to decrease the ICP by shifting water out of the brain tissues. When prescribed, serum osmolality and electrolytes should be monitored. Sedation, analgesia, and paralytic agents may be administered to eliminate the child's resistance to mechanical ventilation, relieve pain, and lower the ICP. Medications to prevent seizures may be prescribed. Therapeutic hypothermia may be used. Sometimes despite all efforts, the child dies as a result of the consequences of the TBI.

If there is no cervical spine injury, the head of the bed is elevated up to 30 degrees. The child's head is kept in the midline to promote venous (jugular) drainage. Hip flexion is avoided. Normothermia is maintained. The environment is kept as quiet as possible. A urinary catheter is inserted to monitor output. Enteral nutrition support is started, using a postpyloric feeding tube to reduce the risk for aspiration.

Rehabilitation. Initial stages of rehabilitation are made during the acute phase of management to prevent complications from immobilization, disuse, and neurologic dysfunction. Physical therapists, occupational therapists, speech-language specialists, and social workers all play vital roles. Moderate and severe TBI may result in a permanent disability, such as epilepsy, motor and cognitive impairments, learning problems, hearing and vision impairment, communication problems, and behavioral or emotional problems. Difficulties with learning skills are common. Reliable predictions of outcome in the child who has experienced a severe brain injury cannot be made until 6 to 12 months postinjury. One study reported that 61.6% of children with moderate and severe injuries were reported to receive services such as special education, 504 accommodations (see Chapter 12), tutoring, and occupational, physical, and speech therapy for disabilities 12 months after injury (Rivara et al., 2012).

Nursing Management

For the Child With Traumatic Brain Injury

Nursing Assessment and Diagnosis

Frequently assess the child's neurologic status using guidelines in *Assessment Guide: The Child With a Neurologic Condition* at the beginning of this chapter and the Glasgow Coma Scale (see Table 27–5). Compare findings to prior evaluations, and note improvement, stability, or deterioration. Assess the cranial nerves and pupils for size and reactivity. Monitor vital signs, responsiveness, and behavior carefully. Note any irritability or signs that might indicate increased ICP (see Table 27–4). Changes in these signs may indicate hypoxia, decreased perfusion, shock, or increased ICP. When the child has a decreased level of consciousness shortly after a brain injury, consider if a posttraumatic seizure occurred and if the child could still be in the postictal state. The cause of any deterioration must be quickly determined and appropriate interventions taken.

Observe for physiologic and behavioral signs of pain. Assume that the child with increased ICP is in pain, even when unresponsive. Assess the family's coping with the child's life-threatening injury and any support systems available to them (see Chapter 13).

Examples of nursing diagnoses appropriate for the child with TBI include the following (NANDA-I © 2014):

- ***Tissue Perfusion: Cerebral, Risk for Ineffective,*** related to hypoventilation, hypovolemia, and/or reduction of arterial blood flow to the brain due to increased ICP
- ***Aspiration, Risk for,*** related to decreased LOC and loss of protective reflexes
- ***Fluid Volume: Imbalanced, Risk for,*** related to therapies for reducing ICP
- ***Coping: Family, Compromised,*** related to life-threatening injury to child

Planning and Implementation

HOSPITAL-BASED NURSING CARE

The child with a severe TBI is initially cared for in the pediatric ICU. Nursing care focuses on maintaining cerebral perfusion pressure, minimizing increased ICP, reducing stimulation, preventing complications, and providing emotional support.

Once the child is on the general pediatric unit, maintain cardiopulmonary function. In the moderately injured child, observe breathing patterns and check color, neurologic signs, and LOC. The oxygen saturation should remain over 95%. Report any sign of decreased oxygenation or signs and symptoms of increased ICP to the healthcare provider immediately (see Table 27–4). Keep suction equipment at the bedside in case aspiration occurs.

Reduce physiologic stresses on the body that could increase ICP. Minimize unpleasant stimuli when possible, keep the environment quiet, and avoid jarring the bed. Pain management and temperature control are important. Position the child with the bed flat or elevated 15 to 30 degrees to avoid excessive flexion of the hips, and maintain the head and neck in neutral alignment

to encourage venous return to the heart. The child may also be placed in a side-lying position with the head neither flexed nor extended. Monitor the effect of nursing procedures on ICP. Determine if clustering procedures is better than spreading procedures over time. Encourage parents to talk to the child and provide comforting touch.

Administer medications as prescribed. When the child is unresponsive, provide oral care to keep mucous membranes moist and intact and to reduce the risk for infection, especially if the child is being ventilated (see the *Clinical Skills Manual* SKILLS). Pad and cushion bony prominences, provide skin care, and change the child's position frequently. Protect the eyes from corneal irritation with ophthalmic ointment and patching.

Enteral feeding may be used initially, slowly progressing to oral foods as tolerated. Fluids are given to meet daily fluid requirements, or to maintain the child's blood pressure within normal ranges for age. Stool softeners and suppositories should be used as needed to prevent constipation. The side rails of the bed should be padded to protect the child if a seizure occurs.

Promote recovery and prevent physical deformities. Perform passive range-of-motion (ROM) exercises to prevent contractures. Splints may be used to position extremities in functional positions. Work with physical, occupational, and speech therapists to reinforce exercises and help teach parents the techniques so they can work with the child in the hospital and at home.

Provide stimulation and promote general awareness when the child is ready, based on the child's age and ability, by using toys, books, music, or games. Assist the family to provide stimulation but also to provide quiet time when the child displays agitation.

Provide emotional support to the family in collaboration with the social workers, healthcare providers, psychologists, rehabilitation therapists, and members of the clergy caring for the child and family. All can help the family adjust to having a child with a new disability.

Sometimes despite all efforts, the child dies as a result of the consequences of the brain injury. Provide support for the family while brain death testing is performed. See Chapter 13 for brain death criteria and methods for supporting the family when termination of life support and organ donation are discussed.

DISCHARGE PLANNING AND HOME CARE TEACHING

Children with serious traumatic brain injuries may be transferred to an inpatient rehabilitation center to promote optimal achievement of function. Other children may have outpatient rehabilitation prescribed, and thus home care needs should be identified and addressed well in advance of discharge. A case manager is often needed to coordinate services and resources during rehabilitation. Social services intervention may be needed when brain injury results from child abuse.

Give parents information about caring for children with mild or moderate TBIs at home and possible behaviors to expect from the child. For children with disabilities, determine what adaptations and assistive technology are needed in the home to care for the child, such as a wheelchair, a walker, braces, or a special bed.

COMMUNITY-BASED NURSING CARE

Home care nursing may be important for the child with an acquired neurologic dysfunction and prolonged altered consciousness. The nurse can teach the family to meet the child's needs, monitor the intake of fluids and foods, position the child, and provide skin care. In-home physical therapists may teach parents to perform ROM exercises and other strategies to prevent contractures. Regular follow-up visits are needed to assess the child's recovery and to modify the treatment plan.

Clinical Reasoning **The Child With Severe Brain Injury**

Marcus, 7 years old, was struck by a car and thrown several feet. He was unconscious on admission to the emergency department and showed some signs of increased ICP (dilated and fixed pupils). He was treated for shock, and his neurologic status and vital signs were frequently assessed. Marcus was found to have sustained several contusions of the brain, but no skull fracture. He was intubated and medicated to manage the increased ICP.
